In 2001, Van den Berghe and colleagues demonstrated that tight glycemic control by insulin infusion is associated with a 50% reduction in mortality in the critical care setting.¹¹³ This prospective, randomized, controlled trial of 1500 patients had two study arms: the intensive-control arm, where the serum glucose was maintained between 80 and 110 mg/dL with insulin infusion; and the control arm, where patients received an insulin infusion only if blood glucose was greater than 215 mg/dL, but serum glucose was then maintained at 180 to 200 mg/dL.

The tight glycemic control group had an average serum glucose level of 103 mg/dL, and the average glucose level in the control group was 153 mg/dL. Hypoglycemic episodes (glucose <40 mg/dL) occurred in 39 patients in the tightly controlled group, while the control group had episodes in 6 patients. The overall mortality was reduced from 8% to 4.6%, but the mortality of those patients whose ICU stay lasted longer than 5 days was reduced from 20% to 10%. Secondary findings included an improvement in overall morbidity, a decreased percentage of ventilator days, less renal impairment, and a lower incidence of bloodstream infections. These findings have been corroborated by subsequent similar studies, and the principal benefit appears to be a greatly reduced incidence of nosocomial infections and sepsis. It is not known whether the benefits are due to strict euglycemia, to the anabolic properties of insulin, or both, but the maintenance of strict euglycemia appears to be a powerful therapeutic strategy.^{113–115}

METABOLISM-RELATED COMPLICATIONS

"Stress dose steroids" have been advocated for the perioperative treatment of patients on corticosteroid therapy, but recent studies strongly discourage the use of supraphysiologic doses of steroids when patients are on low or maintenance doses (e.g., 5 to 15 mg) of prednisone daily. Parenteral glucocorticoid treatment need only replicate physiologic replacement steroids in the perioperative period. When patients are on steroid replacement doses equal to or greater than 20 mg per day of prednisone, it may be appropriate to administer additional glucocorticoid doses for no more than two perioperative days.^{116–118}

Adrenal insufficiency may be present in patients with a baseline serum cortisol less than 20 µg/dL. A rapid provocative test with synthetic adrenocorticotrophic hormone may confirm the diagnosis. After a baseline serum cortisol level is drawn, 250 µg of cosyntropin is administered. At exactly 30 and 60 minutes following the dose of cosyntropin, serum cortisol levels are obtained. There should be an incremental increase in the cortisol level of between 7 and 10 µg/dL for each half hour. If the patient is below these levels, a diagnosis of adrenal insufficiency is made, and glucocorticoid and mineralocorticoid administration is then warranted. Mixed results are common, but the complication of performing major surgery on an adrenally insufficient patient is sudden or profound hypotension.¹⁰⁸

Thyroid hormone abnormalities usually consist of previously undiagnosed thyroid abnormalities. Hypothyroidism and the so-

called *sick-euthyroid syndrome* are more commonly recognized in the critical care setting. When surgical patients are not progressing satisfactorily in the perioperative period, screening for thyroid abnormalities should be performed. If the results show mild to moderate hypothyroidism, then thyroid replacement should begin immediately and thyroid function studies monitored closely. All patients should be reassessed after the acute illness has subsided regarding the need for chronic thyroid replacement therapy.

Problems with Thermoregulation

HYPOTHERMIA

Hypothermia is defined as a core temperature less than 35°C (95°F), and is divided into subsets of mild [35 to 32°C, (95 to 89.6°F)], moderate [32 to 28°C (89.6 to 82.4°F)], and severe [<28°C, (<82.4°F)] hypothermia. Shivering, the body's attempt to reverse the effects of hypothermia, occurs between 37 and 31°C (98.6 and 87.8°F), but ceases at temperatures below 31°C (87.8°F). Patients who are moderately hypothermic are at higher risk for complications than are those who are more profoundly hypothermic.

Hypothermia creates a coagulopathy that is related to platelet and clotting cascade enzyme dysfunction. This triad of metabolic acidosis, coagulopathy, and hypothermia is commonly found in long operative cases, and in patients with blood dyscrasias. The enzymes that contribute to the clotting cascade and platelet activity are most efficient at normal body temperatures; therefore all measures must be used to reduce heat loss intraoperatively.¹¹⁹

The most common cardiac abnormality is the development of arrhythmias when body temperature drops below 35°C (95°F). Bradycardia occurs with temperatures below 30°C (86°F). It is well known that hypothermia may induce CO₂ retention resulting in respiratory acidosis. Renal dysfunction of hypothermia manifests itself as a paradoxical polyuria, and is related to an increased glomerular filtration rate, as peripheral vascular constriction creates central shunting of blood. This is potentially perplexing in patients that are undergoing resuscitation for hemodynamic instability, because the brisk urine output provides a false sense of an adequate intravascular fluid volume.

Neurologic dysfunction is inconsistent in hypothermia, but a deterioration in reasoning and decision-making skills progresses as body temperature falls, and profound coma (and a flat electroencephalogram) occurs as the temperature drops below 30°C (86°F). The diagnosis of hypothermia is important, so accurate measurement techniques are required to get a true core temperature.

Methods used to warm patients include warm air circulation over the patient, and heated IV fluids, and more aggressive measures such as bilateral chest tubes with warm solution lavage, intraperitoneal rewarming lavage, and extracorporeal membrane oxygenation. A rate of temperature rise of 2 to 4°C/h (3.6 to 7.2°F/h) is considered adequate, but the most common complication for nonbypass rewarming is arrhythmia with ventricular arrest.

HYPERTHERMIA

Hyperthermia is a core temperature greater than 38.6°C (101.5°F), and has a host of etiologies (Table 12-21).¹²⁰ Hyperthermia can be environmentally induced (e.g., summer heat with inability to dissipate heat or control exposure), iatrogenically induced (e.g., heat lamps and medications), endocrine in origin (e.g., thyrotoxicosis), or neurologically induced (i.e., hypothalamic).

Table 12-21 Common Causes of Elevated Temperature in Surgical Patients

Hyperthermia	Hyperpyrexia
Environmental	Sepsis
Malignant hyperthermia	Infection
Neuroleptic malignant syndrome	Drug reaction
Thyrotoxicosis	Transfusion reaction
Pheochromocytoma	Collagen disorders
Carcinoid syndrome	Factitious syndrome
Iatrogenic	Neoplastic disorders
Central/hypothalamic responses	
Pulmonary embolism	
Adrenal insufficiency	

Malignant hyperthermia occurs after exposure to agents such as succinylcholine and some halothane-based inhalational anesthetics. The presentation is dramatic, with rapid onset of increased temperature, rigors, and myoglobinuria related to myonecrosis. Medications must be discontinued immediately and dantrolene administered (2.5 mg/kg every 5 minutes) until symptoms subside. Aggressive cooling methods are also implemented, such as an alcohol bath, or packing in ice. In cases of severe malignant hyperthermia, the mortality rate is nearly 30%.

Thyrotoxicosis can occur after surgery, due to undiagnosed Graves' disease. Hyperthermia [$>40^{\circ}\text{C}$, (104°F)], anxiety, copious diaphoresis, congestive heart failure (present in about one fourth of episodes), tachycardia (most commonly atrial fibrillation), and hypokalemia (up to 50% of patients) are hallmarks of the disease. The treatment of thyrotoxicosis includes glucocorticoids, propylthiouracil, beta blockade, and iodide (Lugol's solution) delivered in an emergent fashion. As the name suggests, these patients are usually toxic and require supportive measures as well. Acetaminophen, cooling modalities noted in the paragraph above, and vasoactive agents often are indicated.

ISSUES IN CARING FOR OBESE PATIENTS AND PATIENTS AT THE EXTREMES OF AGE

Surgery in the obese patient has multiple risks, and it is important to optimize these patients before surgery to minimize these risks. Optimization begins preoperatively with teaching about dietary modifications, exercise, and pulmonary toilet issues. Obese patients often have eccentric left ventricular hypertrophy, right ventricular hypertrophy, and congestive heart failure. Sleep studies and patient history may also reveal significant sleep apnea and gastroesophageal reflux disease. Glycemic control is often poor and contributes significantly to infection and diabetes. The obese patient has a decrease in antithrombin III levels, and a higher risk of DVT and PE. Measures to optimize physiologic function in obese patients include keeping the head of the bed elevated at all times. This can improve the FRC of the lungs by almost a liter, thereby decreasing complications associated with atelectasis and pneumonia. Proper glycemic control via a tight insulin sliding scale is also recommended. Finally, the risk of DVT may be attenuated by immediate use of prophylactic doses of low molecular weight heparin and early ambulation.

Issues for surgery in the very young and the very old have many similarities when it comes to potential errors and complications. Perhaps the most notable similarity is the lack of physiologic reserve. The elderly may have end-organ insufficiency, while the young can have underdeveloped or anomalous organ function that may not yet have become manifest. Similarly, the immune responses at the extremes of age are often compromised. This makes diagnosing an

infection difficult; elderly adults may not be capable of mounting a febrile response, and young children can often resolve fevers overnight, and the cause may remain undiagnosed.

Other alterations in these groups include the amount and distribution of total body water and total body fat. This is important to consider because some medications are predominantly distributed to fat stores, and this deposition may lead to altered drug clearance. Similarly, total body water is decreased and serum concentrations of medications may be higher than anticipated. In both groups there is a lower lean body mass, which may potentiate the adverse effects of some anesthetic agents. Metabolism of various analgesic and anesthetic agents can be protracted, leading to postoperative problems such as prolonged intubation and the need for the administration of reversal agents.

Other issues that can lead to complex decision making include those related to communication. Whether due to neurologic impairments, agitation, confusion, or an inability to comprehend a language, these factors associated with the extremes of age increase the potential for medical errors. Open and direct communication with the supporting family members is critical for optimal outcomes in these patient groups.

Schwartz's Principles of Surgery > Part I. Basic Considerations > Chapter 13. Physiologic Monitoring of the Surgical Patient >

KEY POINTS

1. The delivery of modern critical care is predicated on the ability to monitor a large number of physiologic variables and formulate evidenced-based therapeutic strategies to manage these variables.
2. Technologic advances in monitoring have at least a theoretical risk of exceeding our ability to understand the clinical implications of the derived information. This could result in the use of monitoring data to make inappropriate clinical decisions. Therefore, the implementation of any new monitoring technology must take into account the relevance and accuracy of the data obtained, the risks to the patient, as well as the evidence supporting any intervention directed at correcting the detected abnormality.
3. The routine use of invasive monitoring devices, specifically the pulmonary artery catheter, must be questioned in light of the available evidence that does not demonstrate a clear benefit to its widespread use in various populations of critically ill patients.
4. The future of physiologic monitoring will be dominated by the application of noninvasive and highly accurate devices that guide evidenced-based therapy.

BACKGROUND

The Latin verb *monere*, which means "to warn, or advise" is the origin for the English word *monitor*. In contemporary medical practice, patients undergo monitoring to detect pathologic variations in physiologic parameters, providing advanced warning of impending deterioration in the status of one or more organ systems. The intended goal of this endeavor is that by using this knowledge, the clinician takes appropriate actions in a timely fashion to prevent or ameliorate the physiologic derangement. Furthermore, physiologic monitoring is used not only to warn, but also to titrate therapeutic interventions, such as fluid resuscitation or the infusion of vasoactive or inotropic drugs. Monitoring tools also can be valuable for diagnostic evaluation and assessment of prognosis. The intensive care unit (ICU) and operating room are the two locations where the most advanced monitoring capabilities are routinely used in the care of critically ill patients.

In the broadest sense, physiologic monitoring encompasses a spectrum of endeavors, ranging in complexity from the routine and intermittent measurement of the classic vital signs (i.e., temperature, pulse, arterial blood pressure, and respiratory rate) to the continuous recording of the oxidation state of cytochrome oxidase, the terminal element in the mitochondrial electron transport chain. The ability to assess clinically relevant parameters of tissue and organ status and use this knowledge to improve patient outcomes represents the "holy grail" of critical care medicine. Unfortunately, consensus is often lacking regarding the most appropriate parameters to monitor to achieve this goal. Furthermore, making an inappropriate therapeutic decision due to inaccurate physiologic data or misinterpretation of good data can lead to a worse outcome than having no data at all. Of the highest importance is the integration of physiologic data obtained from monitoring

into a coherent and evidenced-based treatment plan. Current technologies available to assist the clinician in this endeavor are summarized in this chapter, as well as a brief look at emerging techniques that may soon enter into clinical practice.

In essence, the goal of hemodynamic monitoring is to ensure that the flow of oxygenated blood through the microcirculation is sufficient to support aerobic metabolism at the cellular level. Mammalian cells cannot store oxygen (O_2) for subsequent use in oxidative metabolism, although a relatively tiny amount is stored in muscle tissue as oxidized myoglobin. Thus aerobic synthesis of adenosine triphosphate, the energy "currency" of cells, requires the continuous delivery of O_2 by diffusion from hemoglobin (Hgb) in red blood cells to the oxidative machinery within mitochondria. Delivery of O_2 to mitochondria may be insufficient for several reasons.

For example, cardiac output, Hgb, or the O_2 content of arterial blood can each be inadequate for independent reasons. Alternatively, despite adequate cardiac output, perfusion of capillary networks can be impaired as a consequence of dysregulation of arteriolar tone, microvascular thrombosis, or obstruction of nutritive vessels by sequestered leukocytes or platelets. Hemodynamic monitoring that does not take into account all of these factors will portray an incomplete and perhaps misleading picture of cellular physiology.

Under normal conditions when the supply of O_2 is plentiful, aerobic metabolism is determined by factors other than the availability of O_2 . These factors include the hormonal milieu and mechanical workload of contractile tissue. However, in pathologic circumstances when O_2 availability is inadequate, O_2 utilization ($\dot{V}O_2$) becomes dependent upon O_2 delivery ($\dot{D}O_2$). The relationship of $\dot{V}O_2$ to $\dot{D}O_2$ over a broad range of $\dot{D}O_2$ values is commonly represented as two intersecting straight lines. In the region of higher $\dot{D}O_2$ values, the slope of the line is approximately equal to zero, indicating that $\dot{V}O_2$ is largely independent of $\dot{D}O_2$. In contrast, in the region of low $\dot{D}O_2$ values, the slope of the line is nonzero and positive, indicating that $\dot{V}O_2$ is supply dependent. The region where the two lines intersect is called the point of critical O_2 delivery ($\dot{D}O_{2crit}$), and represents the transition from supply-independent to supply-dependent O_2 uptake. Below this critical threshold of O_2 delivery (approximately 4.5 mL/kg per minute), increased O_2 extraction cannot compensate for the delivery deficit; hence, O_2 consumption begins to decrease.¹ The slope of the supply-dependent region of the plot reflects the maximal O_2 extraction capability of the vascular bed being evaluated.

The dual-line representation for depicting $\dot{D}O_2$ - $\dot{V}O_2$ relationships has proven useful and informative. Nevertheless, other approaches for depicting $\dot{D}O_2$ - $\dot{V}O_2$ relationships may be equally or even more relevant. For example, some investigators believe that experimentally derived $\dot{D}O_2$ - $\dot{V}O_2$ data are optimally characterized by using the classic Michaelis-Menten relationship for describing the kinetics of an enzymatic reaction, a view that is prompted by the recognition that the oxygen-consuming reaction in mitochondria is catalyzed by an enzyme, cytochrome oxidase.²

ARTERIAL BLOOD PRESSURE

The pressure exerted by blood in the systemic arterial system, commonly referred to as *blood pressure*, is a cardinal parameter measured as part of the hemodynamic monitoring of patients. Extremes in blood pressure are either intrinsically deleterious or are indicative of a serious perturbation in normal physiology. In the past, blood pressure served as a proxy for cardiac output; the term *shock* was used more or less as a synonym for arterial hypotension. Although it is now known that arterial blood pressure is a complex function of both cardiac output and vascular input impedance, clinicians, especially inexperienced ones, tend to assume that the presence of a normal blood pressure is evidence that cardiac output and tissue perfusion are adequate. This assumption is frequently incorrect and is the reason why some critically ill patients may benefit from forms of hemodynamic monitoring in addition to measurement of arterial pressure.

Blood pressure can be determined directly by measuring the pressure within the arterial lumen or indirectly using a cuff around an extremity. When the equipment is properly set up and calibrated, direct intra-arterial monitoring of blood pressure provides accurate and continuous data. Additionally, intra-arterial catheters provide a convenient way to obtain samples of blood for measurements of arterial blood gases and other laboratory studies. Despite these advantages, intra-arterial catheters are invasive devices and occasionally are associated with serious complications. Noninvasive monitoring of blood pressure is desirable in many circumstances.

Noninvasive Measurement of Arterial Blood Pressure

Both manual and automated means for the noninvasive determination of blood pressure use an inflatable cuff to increase pressure around an extremity. If the cuff is too narrow (relative to the extremity), the measured pressure will be artifactually elevated. Therefore, the width of the cuff should be approximately 40% of its circumference.

In addition to using a cuff to cause vascular compression and thereby cessation of blood flow, noninvasive means for measuring blood pressure also require some means for detecting the presence or absence of arterial pulsations. Several methods exist for this purpose. The time-honored approach is the auscultation of the Korotkoff sounds, which are heard over an artery distal to the cuff as the cuff is deflated from a pressure higher than systolic pressure to one less than diastolic pressure. *Systolic pressure* is defined as the pressure in the cuff when tapping sounds are first audible. *Diastolic pressure* is the pressure in the cuff when audible pulsations first disappear.

Another means for pulse detection when measuring blood pressure noninvasively depends upon the detection of oscillations in the pressure within the bladder of the cuff. This approach is simple, and unlike auscultation, can be performed even in a noisy environment (e.g., a busy emergency room). Unfortunately, this approach is neither accurate nor reliable. Other methods, however, can be used to reliably detect the reappearance of a pulse distal to the cuff and thereby estimate systolic blood pressure. Two excellent and widely available approaches for pulse detection are use of a Doppler stethoscope (reappearance of the pulse produces an audible amplified signal) or a pulse oximeter (reappearance of the pulse is indicated by flashing of a light-emitting diode).

A number of automated devices are capable of repetitively measuring blood pressure noninvasively. Some of these devices measure pressure oscillations in the inflatable bladder encircling the extremity to detect arterial pulsations as pressure in the cuff is gradually lowered from greater than systolic to less than diastolic pressure.³ Another automated noninvasive device uses a piezoelectric crystal positioned over the brachial artery as a pulse detector.³ According to one clinical study of these approaches, the most accurate is oscillometry combined with stepped deflation of the sphygmomanometric cuff. Using this approach and comparing the results of oscillometry to those obtained by invasive intra-arterial monitoring, errors in the measurement of mean blood pressure greater than 10 or 20 mmHg occur in 0% and 8.5% of readings, respectively.³

Another noninvasive approach for measuring blood pressure relies on a technique called *photoplethysmography*. This method is capable of providing continuous information because systolic and diastolic blood pressures are recorded on a beat-to-beat basis. Photoplethysmography uses the transmission of infrared light to estimate the amount of Hgb (directly related to the volume of blood) in a finger placed under a servo-controlled inflatable cuff. A feedback loop controlled by a microprocessor continually adjusts the pressure in the cuff to maintain the blood volume of the finger constant. Under these conditions, the pressure in the cuff reflects the pressure in the digital artery. Although results obtained using photoplethysmography generally agree closely with those obtained by invasive monitoring of blood pressure, the difference between the two methods occasionally can be large (20 to 40 mmHg) in some patients.⁴ This problem limits the usefulness of

photoplethysmography as a stand-alone method for monitoring arterial blood pressure, particularly in high-risk situations. However, if initial photoplethysmographic readings are corrected by comparison with measurements obtained noninvasively by an oscillometric device, then photoplethysmography is sufficiently accurate to be used for continuous monitoring in most situations.⁴

Invasive Monitoring of Arterial Blood Pressure

Direct monitoring of arterial pressure in critically ill patients may be performed by using fluid-filled tubing to connect an intra-arterial catheter to an external strain-gauge transducer. The signal generated by the transducer is electronically amplified and displayed as a continuous waveform by an oscilloscope. Digital values for systolic and diastolic pressure also are displayed. Mean pressure, calculated by electronically averaging the amplitude of the pressure waveform, also can be displayed.

The fidelity of the catheter-tubing-transducer system is determined by numerous factors, including the compliance of the tubing, the surface area of the transducer diaphragm, and the compliance of the diaphragm. If the system is underdamped, then the inertia of the system, which is a function of the mass of the fluid in the tubing and the mass of the diaphragm, causes overshoot of the points of maximum positive and negative displacement of the diaphragm during systole and diastole, respectively. Thus in an underdamped system, systolic pressure will be overestimated and diastolic pressure will be underestimated. In an overdamped system, displacement of the diaphragm fails to track the rapidly changing pressure waveform, and systolic pressure will be underestimated and diastolic pressure will be overestimated. It is important to note that even in an underdamped or overdamped system, mean pressure will be accurately recorded, provided the system has been properly calibrated. For these reasons, when using direct measurement of intra-arterial pressure to monitor patients, clinicians should make clinical decisions based on the measured mean arterial blood pressure.

The degree of ringing (i.e., overshoot and undershoot) in a minimally damped system is determined by its resonant frequency. Ideally, the resonant frequency of the system should be at least five times greater than the highest frequency component of the pressure waveform. The resonant frequency can be too low for optimal performance if the connector tubing is too compliant or there are air bubbles in the fluid column between the arterial pressure source and the diaphragm of the transducer. For arterial pressure monitoring, the optimal resonance frequency is higher than is practically obtainable. Therefore, to prevent excessive ringing, some degree of damping is essential. To determine if the combination of resonance frequency and damping is adequate, one can pressurize the system to approximately 300 mmHg by pulling the tab that controls the valve between the monitoring system and the high-pressure bag of flush solution. When the valve is abruptly closed by allowing the tab to snap back into its normal position, a sharp pressure transient will be introduced into the system. The resulting pressure tracing can be observed on a strip chart recording. Damping is optimal if at least two oscillations are observed, and there is at least a threefold decrease in the amplitude of successive oscillations.

The radial artery at the wrist is the site most commonly used for intra-arterial pressure monitoring. It is important to recognize, however, that measured arterial pressure is determined in part by the site where the pressure is monitored. Central (i.e., aortic) and peripheral (e.g., radial artery) pressures typically are different as a result of the impedance and inductance of the arterial tree. Systolic pressures typically are higher and diastolic pressures are lower in the periphery, whereas mean pressure is approximately the same in the aorta and more distal sites.

Distal ischemia is an uncommon complication of intra-arterial catheterization. The incidence of thrombosis is increased when larger-caliber catheters are used and when catheters are left in place for an extended period of time. The incidence of

thrombosis can be minimized by using a 20-gauge (or smaller) catheter in the radial artery and removing the catheter as soon as feasible. The risk of distal ischemic injury can be reduced by ensuring that adequate collateral flow is present before catheter insertion. At the wrist, adequate collateral flow can be documented by performing a modified version of the Allen test, wherein the artery to be cannulated is digitally compressed while using a Doppler stethoscope to listen for perfusion in the palmar arch vessels.

Another potential complication of intra-arterial monitoring is retrograde embolization of air bubbles or thrombi into the intracranial circulation. In order to minimize the risk of this rare but potentially devastating complication, great care should be taken to avoid flushing arterial lines when air is present in the system, and only small volumes of fluid (less than 5 mL) should be used for this purpose. Catheter-related infections can occur with any intravascular monitoring device. However, catheter-related bloodstream infection is a relatively uncommon complication of intra-arterial lines used for monitoring, occurring in 0.4 to 0.7% of catheterizations.⁵ The incidence increases with longer duration of arterial catheterization.

ELECTROCARDIOGRAPHIC MONITORING

The electrocardiogram (ECG) records the electrical activity associated with cardiac contraction by detecting voltages on the body surface. A standard 3-lead ECG is obtained by placing electrodes that correspond to the left arm (LA), right arm (RA), and left leg (LL). The limb leads are defined as lead I (LA-RA), lead II (LL-RA), and lead III (LL-LA). The ECG waveforms can be continuously displayed on a monitor, and the devices can be set to sound an alarm if an abnormality of rate or rhythm is detected. Continuous ECG monitoring is widely available and applied to critically ill and perioperative patients. Monitoring of the ECG waveform is essential in patients with acute coronary syndromes or blunt myocardial injury, because dysrhythmias are the most common lethal complication. In patients with shock or sepsis, dysrhythmias can occur as a consequence of inadequate myocardial O₂ delivery or as a complication of vasoactive or inotropic drugs used to support blood pressure and cardiac output. Dysrhythmias can be detected by continuously monitoring the ECG tracing, and timely intervention may prevent serious complications. With appropriate computing hardware and software, continuous ST-segment analysis also can be performed to detect ischemia or infarction. This approach has proven useful to detect silent myocardial ischemia in patients undergoing weaning from mechanical ventilation.^{6,7}

Additional information can be obtained from a 12-lead ECG, which is essential for patients with potential myocardial ischemia or to rule out cardiac complications in other acutely ill patients. Continuous monitoring of the 12-lead ECG now is available and is proving to be beneficial in certain patient populations. In a study of 185 vascular surgical patients, continuous 12-lead ECG monitoring was able to detect transient myocardial ischemic episodes in 20.5% of the patients.⁷ This study demonstrated that the precordial lead V₄, which is not routinely monitored on a standard 3-lead ECG, is the most sensitive for detecting perioperative ischemia and infarction. To detect 95% of the ischemic episodes, two or more precordial leads were necessary. Thus, continuous 12-lead ECG monitoring may provide greater sensitivity than 3-lead ECG for the detection of perioperative myocardial ischemia, and is likely to become standard for monitoring high-risk surgical patients.

CARDIAC OUTPUT AND RELATED PARAMETERS

Bedside catheterization of the pulmonary artery was introduced into clinical practice in the 1970s. Although the pulmonary artery catheter (PAC) initially was used primarily to manage patients with cardiogenic shock and other acute cardiac diseases, indications for this form of invasive hemodynamic monitoring gradually expanded to encompass a wide variety of clinical conditions. Clearly, many clinicians believe that information valuable for the management of critically ill patients is afforded by having a PAC in place. However, unambiguous data in support of this view are scarce, and several studies

suggest that bedside pulmonary artery catheterization may not benefit most critically ill patients, and in fact lead to some serious complications, as is discussed in Effect of Pulmonary Artery Catheterization on Outcome below.

Determinants of Cardiac Performance

PRELOAD

Starling's law of the heart states that the force of muscle contraction depends on the initial length of the cardiac fibers. Using terminology that derives from early experiments using isolated cardiac muscle preparations, preload is the stretch of ventricular myocardial tissue just before the next contraction. Preload is determined by end-diastolic volume (EDV). For the right ventricle, central venous pressure (CVP) approximates right ventricular (RV) end-diastolic pressure (EDP). For the left ventricle, pulmonary artery occlusion pressure (PAOP), which is measured by transiently inflating a balloon at the end of a pressure monitoring catheter positioned in a small branch of the pulmonary artery, approximates left ventricular EDP. The presence of atrioventricular valvular stenosis will alter this relationship.

Clinicians frequently use EDP as a surrogate for EDV, but EDP is determined not only by volume but also by the diastolic compliance of the ventricular chamber. Ventricular compliance is altered by various pathologic conditions and pharmacologic agents. Furthermore, the relationship between EDP and true preload is not linear, but rather is exponential.

AFTERLOAD

Afterload is another term derived from in vitro experiments using isolated strips of cardiac muscle, and is defined as the force resisting fiber shortening once systole begins. Several factors comprise the in vivo correlate of ventricular afterload, including ventricular intracavitary pressure, wall thickness, chamber radius, and chamber geometry. Because these factors are difficult to assess clinically, afterload is commonly approximated by calculating systemic vascular resistance, defined as mean arterial pressure (MAP) divided by cardiac output.

CONTRACTILITY

Contractility is defined as the inotropic state of the myocardium. Contractility is said to increase when the force of ventricular contraction increases at constant preload and afterload. Clinically, contractility is difficult to quantify, because virtually all of the available measures are dependent to a certain degree on preload and afterload. If pressure-volume loops are constructed for each cardiac cycle, small changes in preload and/or afterload will result in shifts of the point defining the end of diastole. These end-diastolic points on the pressure-versus-volume diagram describe a straight line, known as the *isovolumic pressure line*. A steeper slope of this line indicates greater contractility.

Placement of the Pulmonary Artery Catheter

In its simplest form, the PAC has four channels. One channel terminates in a balloon at the tip of the catheter. The proximal end of this channel is connected to a syringe to permit inflation of the balloon with air. Before insertion of the PAC, the integrity of the balloon should be verified by inflating it. To minimize the risk of vascular or ventricular perforation by the relatively inflexible catheter, it is important to verify that the inflated balloon extends just beyond the tip of the device. A second channel in the catheter contains wires that are connected to a thermistor located near the tip of the catheter. At the proximal end of the PAC, the wires terminate in a fitting that permits connection to appropriate hardware for the calculation of cardiac output using the thermodilution technique (see Measurement of Cardiac Output by Thermodilution below). The final two channels are used for pressure monitoring and the injection of the thermal indicator for determinations of cardiac output.

One of these channels terminates at the tip of the catheter; the other terminates 20 cm proximal to the tip.

Placement of a PAC requires access to the central venous circulation. Such access can be obtained at a variety of sites, including the antecubital, femoral, jugular, and subclavian veins. Percutaneous placement through either the jugular or subclavian vein generally is preferred. Right internal jugular vein cannulation carries the lowest risk of complications, and the path of the catheter from this site into the right atrium is straight. In the event of inadvertent arterial puncture, local pressure is significantly more effective in controlling bleeding from the carotid artery as compared to the subclavian artery. Nevertheless, it is more difficult to keep occlusive dressings in place on the neck than in the subclavian fossa. Furthermore, the anatomic landmarks in the subclavian position are quite constant, even in patients with anasarca or massive obesity; the subclavian vein is always attached to the deep (concave) surface of the clavicle. In contrast, the appropriate landmarks to guide jugular venous cannulation are sometimes difficult to discern in obese or very edematous patients. However, ultrasonic guidance has been shown to facilitate bedside jugular venipuncture.⁸

Cannulation of the vein normally is performed percutaneously, using the Seldinger technique. A small-bore needle is inserted through the skin and subcutaneous tissue into the vein. After documenting return of venous blood, a guidewire with a flexible tip is inserted through the needle into the vein and the needle is withdrawn. A dilator/introducer sheath is passed over the wire, and the wire and the dilator are removed. The introducer sheath is equipped with a side port, which can be used for administering fluid. The introducer sheath also is equipped with a diaphragm that permits insertion of the PAC while preventing the backflow of venous blood. The proximal terminus of the distal port of the PAC is connected through low-compliance tubing to a strain-gauge transducer, and the tubing-catheter system is flushed with fluid. While constantly observing the pressure tracing on an oscilloscope, the PAC is advanced with the balloon deflated until respiratory excursions are observed. The balloon is then inflated, and the catheter advanced further, while monitoring pressures sequentially in the right atrium and right ventricle en route to the pulmonary artery. The pressure waveforms for the right atrium, right ventricle, and pulmonary artery are each characteristic and easy to recognize. The catheter is advanced out the pulmonary artery until a damped tracing indicative of the "wedged" position is obtained. The balloon is then deflated, taking care to ensure that a normal pulmonary arterial tracing is again observed on the monitor; leaving the balloon inflated can increase the risk of pulmonary infarction or perforation of the pulmonary artery. Unnecessary measurements of the PAOP are discouraged as rupture of the pulmonary artery may occur.

Hemodynamic Measurements

Even in its simplest embodiment, the PAC is capable of providing clinicians with a remarkable amount of information about the hemodynamic status of patients. Additional information may be obtained if various modifications of the standard PAC are used. By combining data obtained through use of the PAC with results obtained by other means (i.e., blood Hgb concentration and oxyhemoglobin saturation), derived estimates of systemic O₂ transport and utilization can be calculated. Direct and derived parameters obtainable by bedside pulmonary arterial catheterization are summarized in Table 13-1. The equations used to calculate the derived parameters are summarized in Table 13-2. The approximate normal ranges for a number of these hemodynamic parameters (in adults) are shown in Table 13-3.

Table 13-1 Directly Measured and Derived Hemodynamic Data Obtainable by Bedside Pulmonary Artery Catheterization		
Standard PAC	PAC with Additional Feature(s)	Derived Parameters
CVP	SV \bar{V} O ₂ (continuous)	SV (or SVI)

PAP	Q_T or Q_T^* (continuous)	SVR (or SVRI)
PAOP	RVEF	PVR (or PVRI)
$S\bar{V}O_2$ (intermittent)		RVEDV
Q_T or Q_T^* (intermittent)		$\dot{D}O_2$
		$\dot{V}O_2$
		ER
		Q_S/Q_T

CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; ER = systemic oxygen extraction ratio; PAC = pulmonary artery catheter; PAOP = pulmonary artery occlusion (wedge) pressure; PAP = pulmonary artery pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_S/Q_T = fractional pulmonary venous admixture (shunt fraction); Q_T = cardiac output; Q_T^* = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; $S\bar{V}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\dot{V}O_2$ = systemic oxygen utilization.

Table 13-2 Formulas for Calculation of Hemodynamic Parameters that Can Be Derived by Using Data Obtained by Pulmonary Artery Catheterization	
Q_T^* ($L \cdot \min^{-1} \cdot m^{-2}$) = Q_T/BSA , where BSA is body surface area (m^2)	
SV (mL) = Q_T/HR , where HR is heart rate (\min^{-1})	
SVR ($\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$) = $[(MAP - CVP) \times 80]/Q_T$, where MAP is mean arterial pressure (mmHg)	
SVRI ($\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot m^{-2}$) = $[(MAP - CVP) \times 80]/Q_T^*$	
PVR ($\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$) = $[(PAP - PAOP) \times 80]/Q_T$, where PPA is mean pulmonary artery pressure	
PVRI ($\text{dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot m^{-2}$) = $[(PAP - PAOP) \times 80]/Q_T^*$	
RVEDV (mL) = $SV/RVEF$	
$\dot{D}O_2$ ($mL \cdot \min^{-1} \cdot m^{-2}$) = $Q_T^* \times CaO_2 \times 10$, where CaO_2 is arterial oxygen content (mL/dL)	
$\dot{V}O_2$ ($mL \cdot \min^{-1} \cdot m^{-2}$) = $Q_T^* \times (CaO_2 - C\bar{V}O_2) \times 10$, where $C\bar{V}O_2$ is mixed venous oxygen content (mL/dL)	
$CaO_2 = (1.36 \times Hgb \times SaO_2) + (0.003 \times PaO_2)$, where Hgb is hemoglobin concentration (g/dL), SaO_2 is fractional arterial hemoglobin saturation, and PaO_2 is the partial pressure of oxygen in arterial blood	

$C\bar{V}O_2 = (1.36 \times \text{Hgb} \times S\bar{V}O_2) + (0.003 \times P\bar{V}O_2)$, where $P\bar{V}O_2$ is the partial pressure of oxygen in pulmonary arterial (mixed venous) blood

$Q_S/Q_T = (Cco_2 - CaO_2)/(Cco_2 - C\bar{V}O_2)$, where Cco_2 (mL/dL) is the content of oxygen in pulmonary end capillary blood

$Cco_2 = (1.36 \times \text{Hgb}) + (0.003 \times PAO_2)$, where PAO_2 is the alveolar partial pressure of oxygen

$PAO_2 = [FiO_2 \times (P_B - P_{H_2O})] - PaCO_2/RQ$, where FiO_2 is the fractional concentration of inspired oxygen, P_B is the barometric pressure (mmHg), P_{H_2O} is the water vapor pressure (usually 47 mmHg), $PaCO_2$ is the partial pressure of carbon dioxide in arterial blood (mmHg), and RQ is respiratory quotient (usually assumed to be 0.8)

$C\bar{V}O_2$ = central venous oxygen pressure; CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_S/Q_T = fractional pulmonary venous admixture (shunt fraction); Q_T = cardiac output; Q_T^* = cardiac output indexed to body surface area (cardiac index); RVEDV = right ventricular end-diastolic volume; RVEF = right ventricular ejection fraction; SV = stroke volume; SVI = stroke volume index; $S\bar{V}O_2$ = fractional mixed venous (pulmonary artery) hemoglobin saturation; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\dot{V}O_2$ = systemic oxygen utilization.

Table 13-3 Approximate Normal Ranges for Selected Hemodynamic Parameters in Adults

Parameter	Normal Range
CVP	0–6 mmHg
Right ventricular systolic pressure	20–30 mmHg
Right ventricular diastolic pressure	0–6 mmHg
PAOP	6–12 mmHg
Systolic arterial pressure	100–130 mmHg
Diastolic arterial pressure	60–90 mmHg
MAP	75–100 mmHg
Q_T	4–6 L/min
Q_T^*	$2.5\text{--}3.5 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$
SV	40–80 mL
SVR	$800\text{--}1400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$
SVRI	$1500\text{--}2400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot \text{m}^{-2}$
PVR	$100\text{--}150 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5}$
PVRI	$200\text{--}400 \text{ dyne} \cdot \text{sec} \cdot \text{cm}^{-5} \cdot \text{m}^{-2}$
CaO_2	16–22 mL/dL

$C\bar{V}O_2$	~15 mL/dL
$\dot{D}O_2$	400–660 mL·min ⁻¹ ·m ⁻²
$\dot{V}O_2$	115–165 mL·min ⁻¹ ·m ⁻²

CaO₂ = arterial oxygen content; C \bar{V} O₂ = central venous oxygen pressure; CVP = mean central venous pressure; $\dot{D}O_2$ = systemic oxygen delivery; MAP = mean arterial pressure; PAOP = pulmonary artery occlusion (wedge) pressure; PVR = pulmonary vascular resistance; PVRI = pulmonary vascular resistance index; Q_T = cardiac output; Q_T* = cardiac output indexed to body surface area (cardiac index); SV = stroke volume; SVI = stroke volume index; SVR = systemic vascular resistance; SVRI = systemic vascular resistance index; $\dot{V}O_2$ = systemic oxygen utilization.

Measurement of Cardiac Output by Thermodilution

Before the development of the PAC, determining cardiac output (Q_T) at the bedside required careful measurements of O₂ consumption (Fick method) or spectrophotometric determination of indocyanine green dye dilution curves. Measurements of Q_T using the thermodilution technique are simple and reasonably accurate. The measurements can be performed repetitively, and the principle is straightforward. If a bolus of an indicator is rapidly and thoroughly mixed with a moving fluid upstream from a detector, then the concentration of the indicator at the detector will increase sharply and then exponentially diminish back to zero. The area under the resulting time-concentration curve is a function of the volume of indicator injected and the flow rate of the moving stream of fluid. Larger volumes of indicator result in greater areas under the curve, and faster flow rates of the mixing fluid result in smaller areas under the curve. When Q_T is measured by thermodilution, the indicator is heat and the detector is a temperature-sensing thermistor at the distal end of the PAC. The relationship used for calculating Q_T is called the *Stewart-Hamilton equation*:

$$Q_T = [V \times (T_B - T_I) \times K_1 \times K_2] \div \int T_B(t)dt$$

where V is the volume of the indicator injected, T_B is the temperature of blood (i.e., core body temperature), T_I is the temperature of the indicator, K₁ is a constant that is the function of the specific heats of blood and the indicator, K₂ is an empirically derived constant that accounts for several factors (the dead space volume of the catheter, heat lost from the indicator as it traverses the catheter, and the injection rate of the indicator), and $\int T_B(t)dt$ is the area under the time-temperature curve. In clinical practice, the Stewart-Hamilton equation is solved by a microprocessor.

Determination of cardiac output by the thermodilution method is generally quite accurate, although it tends to systematically overestimate Q_T at low values. Changes in blood temperature and Q_T during the respiratory cycle can influence the measurement. Therefore, results generally should be recorded as the mean of two or three determinations obtained at random points in the respiratory cycle. Using cold injectate widens the difference between T_B and T_I and thereby increases signal-to-noise ratio. Nevertheless, most authorities recommend using room temperature injectate (normal saline or 5% dextrose in water) to minimize errors resulting from warming of the fluid as it transferred from its reservoir to a syringe for injection.

Technologic innovations have been introduced that permit continuous measurement of Q_T by thermodilution. In this approach, thermal transients are not generated by injecting a bolus of a cold indicator, but rather by heating the blood with a tiny filament located on the PAC upstream from the thermistor. By correlating the amount of current supplied to the heating

element with the downstream temperature of the blood, it is possible to estimate the average blood flow across the filament and thereby calculate Q_T . Based upon the results of several studies, continuous determinations of Q_T using this approach agree well with data generated by conventional measurements using bolus injections of a cold indicator.⁹ Information is lacking regarding the clinical value of being able to monitor Q_T continuously.

Mixed Venous Oximetry

The Fick equation can be written as $Q_T = \dot{V}_{O_2} / (Ca_{O_2} - C\bar{v}_{O_2})$, where Ca_{O_2} is the content of O_2 in arterial blood and $C\bar{v}_{O_2}$ is the content of O_2 in mixed venous blood. The Fick equation can be rearranged as follows: $C\bar{v}_{O_2} = Ca_{O_2} - \dot{V}_{O_2} / Q_T$. If the small contribution of dissolved O_2 to $C\bar{v}_{O_2}$ and Ca_{O_2} is ignored, the rearranged equation can be rewritten as $S\bar{v}_{O_2} = Sa_{O_2} - \dot{V}_{O_2} / (Q_T \times Hgb \times 1.36)$, where $S\bar{v}_{O_2}$ is the fractional saturation of Hgb in mixed venous blood, Sa_{O_2} is the fractional saturation of Hgb in arterial blood, and Hgb is the concentration of Hgb in blood. Thus, it can be seen that $S\bar{v}_{O_2}$ is a function of \dot{V}_{O_2} (i.e., metabolic rate), Q_T , Sa_{O_2} , and Hgb. Accordingly, subnormal values of $S\bar{v}_{O_2}$ can be caused by a decrease in Q_T (due, for example, to heart failure or hypovolemia), a decrease in Sa_{O_2} (due, for example, to intrinsic pulmonary disease), a decrease in Hgb (i.e., anemia), or an increase in metabolic rate (due, for example, to seizures or fever). With a conventional PAC, measurements of $S\bar{v}_{O_2}$ require aspirating a sample of blood from the distal (i.e., pulmonary arterial) port of the catheter and injecting the sample into a blood gas analyzer. Therefore for practical purposes, measurements of $S\bar{v}_{O_2}$ can be performed only intermittently.

By adding a fifth channel to the PAC, it has become possible to monitor $S\bar{v}_{O_2}$ continuously. The fifth channel contains two fiber-optic bundles, which are used to transmit and receive light of the appropriate wavelengths to permit measurements of Hgb saturation by reflectance spectrophotometry. A clinical study of the Abbott Oximetrix PAC has documented that the device provides measurements of $S\bar{v}_{O_2}$ that agree quite closely with those obtained by conventional analyses of blood aspirated from the pulmonary artery.¹⁰ Despite the theoretical value of being able to monitor $S\bar{v}_{O_2}$ continuously, data are lacking to show that this capability favorably improves outcome. Indeed, in several studies, the ability to monitor $S\bar{v}_{O_2}$ was not shown to affect the management of critically ill patients.^{11,12} Moreover, in another large study, titrating the resuscitation of critically ill patients to maintain $S\bar{v}_{O_2}$ greater than 69% (i.e., in the normal range) failed to improve mortality or change length of ICU stay.¹³ In a recent prospective, observational study of 3265 patients undergoing cardiac surgery with either a standard PAC or a PAC with continuous $S\bar{v}_{O_2}$ monitoring, the oximetric catheter was associated with fewer arterial blood gases and thermodilution cardiac output determinations, but no difference in patient outcome.¹⁴ Because PACs that permit continuous monitoring of $S\bar{v}_{O_2}$ are much more expensive than conventional PACs, the routine use of these devices cannot be recommended.

The saturation of O_2 in the right atrium or superior vena cava ($ScvO_2$) correlates closely with $S\bar{v}_{O_2}$ over a wide range of conditions,¹⁵ although the correlation between $ScvO_2$ and $S\bar{v}_{O_2}$ has recently been questioned.¹⁶ Since measurement of $ScvO_2$ requires placement of a central venous catheter (CVC) rather than a PAC, it is somewhat less invasive and easier to carry out. By using a CVC equipped to permit fiber-optic monitoring of $ScvO_2$, it may be possible to titrate the resuscitation of patients with shock using a less invasive device than the PAC.^{15,17}

Right Ventricular Ejection Fraction

Ejection fraction (EF) is calculated as $(EDV - ESV) / EDV$, where ESV is end-systolic volume. EF is an ejection-phase measure of myocardial contractility. By equipping a PAC with a thermistor with a short time constant, the thermodilution method can be used to estimate RVEF. Measurements of RVEF by thermodilution agree reasonably well with those obtained by other

means, although values obtained by thermodilution typically are lower than those obtained by radionuclide cardiography.¹⁸ Stroke volume (SV) is calculated as EDV – ESV. Left ventricular stroke volume (LVSV) also equals Q_T/HR , where HR is heart rate. Because LVSV is equal to RVSV, it is possible to estimate right ventricular end-diastolic volume by measuring RVEF, Q_T , and HR.

Several studies have attempted to assess the clinical value of RVEF measurements using these catheters. In one study, use of an RVEF catheter did not alter therapy in 93% of patients with sepsis, hemorrhagic shock, or acute respiratory distress syndrome (ARDS), but was useful in cases of abdominal compartment syndrome (ACS) with high PAOP despite low preload.¹⁹ In a series of 46 trauma patients who required more than 10 L of fluid in the first 24 hours of resuscitation, there was a better correlation between RV volume and Q_T than there was with PAOP.²⁰ However, data are lacking to show that outcomes are improved by making measurements of RVEF in addition to Q_T and other parameters measured by the conventional PAC.

Effect of Pulmonary Artery Catheterization on Outcome

In 1996, Connors and colleagues reported surprising results in a major observational study evaluating the value of pulmonary artery catheterization in critically ill patients.²¹ They took advantage of an enormous data set, which had been previously (and prospectively) collected for another purpose at five major teaching hospitals in the United States. These researchers compared two groups of patients: those who did and those who did not undergo placement of a PAC during their first 24 hours of ICU care. The investigators recognized that the value of their intended analysis was completely dependent on the robustness of their methodology for case-matching, because sicker patients (i.e., those at greater risk of mortality based upon the severity of their illness) were presumably more likely to undergo pulmonary artery catheterization. Accordingly, the authors used sophisticated statistical methods for generating a cohort of study (i.e., PAC) patients, each one having a paired control matched carefully for severity of illness. A critical assessment of their published findings supports the view that the cases and their controls were indeed remarkably well matched with respect to a large number of pertinent clinical parameters. Connors and associates concluded that placement of a PAC during the first 24 hours of stay in an ICU is associated with a significant increase in the risk of mortality, even when statistical methods are used to account for severity of illness.

Although the report by Connors and coworkers generated an enormous amount of controversy in the medical community, the results reported actually confirmed the results of two prior similar observational studies. The first of these studies used as a database 3263 patients with acute myocardial infarction treated in central Massachusetts in 1975, 1978, 1981, and 1984 as part of the Worcester Heart Attack Study.²² For all patients, hospital mortality was significantly greater for patients treated using a PAC, even when multivariate statistical methods were used to control for key potential confounding factors such as age, peak circulating creatine kinase concentration, and presence or absence of new Q waves on the ECG. The second large observational study of patients with acute myocardial infarction also found that hospital mortality was significantly greater for patients managed with the assistance of a PAC, even when the presence or absence of "pump failure" was considered in the statistical analysis.²³ In neither of these reports did the authors conclude that placement of a PAC was truly the cause of worsened survival after myocardial infarction.

The available prospective, randomized controlled trials of PACization are summarized in Table 13-4. The study by Pearson and associates was underpowered with only 226 patients enrolled.²⁴ In addition, the attending anesthesiologists were permitted to exclude patients from the CVP group at their discretion; thus randomization was compromised. The study by

Tuman and coworkers was large (1094 patients were enrolled), but different anesthesiologists were assigned to the different groups.²⁵ Furthermore, 39 patients in the CVP group underwent placement of a PAC because of hemodynamic complications. All of the individual single-institution studies of vascular surgery patients were relatively underpowered, and all excluded at least certain categories of patients (e.g., those with a history of recent myocardial infarction).^{26,27}

Table 13-4 Summary of Randomized, Prospective Clinical Trials Comparing Pulmonary Artery Catheter with Central Venous Pressure Monitoring

Author	Study Population	Groups	Outcomes
Pearson, et al ²⁴	"Low-risk" patients undergoing cardiac or vascular surgery	CVP catheter (group 1); PAC (group 2); PAC with continuous Sv-O ₂ , readout (group 3)	No differences among groups for mortality or length of ICU stay; significant differences in costs (group 1 < group 2 < group 3)
Tuman, et al ²⁵	Cardiac surgical patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or significant noncardiac complications
Bender, et al ²⁶	Vascular surgery patients	PAC; CVP	No differences between groups for mortality, length of ICU stay, or length of hospital stay
Valentine, et al ²⁷	Aortic surgery patients	PAC + hemodynamic optimization in ICU night before surgery; CVP	No difference between groups for mortality or length of ICU stay; significantly higher incidence of postoperative complications in PAC group
Sandham, et al ²⁸	"High-risk" major surgery	PAC; CVP	No differences between groups for mortality, length of ICU stay; increased incidence of pulmonary embolism in PAC group
Harvey, et al ²⁹	Medical and surgical ICU patients	PAC vs. no PAC, with option for alternative CO measuring device in non-PAC group	No difference in hospital mortality between the two groups, increased incidence of complications in the PAC group
Binanay, et al ³¹	Patients with CHF	PAC vs. no PAC	No difference in hospital mortality between the two groups, increased incidence of adverse events in the PAC group
Wheeler, et al ³²	Patients with ALI	PAC vs. CVC with a fluid and inotropic management protocol	No difference in ICU or hospital mortality, or incidence of organ failure between the two groups; increased incidence of adverse events in the PAC group

ALI = acute lung injury; CHF = congestive heart failure; CO = cardiac output; CVC = central venous catheter; CVP = central venous pressure; ICU = intensive care unit; PAC = pulmonary artery catheter; Sv-O₂ = fractional mixed venous (pulmonary artery) hemoglobin saturation.

In the largest randomized controlled trial of the PAC, Sandham and associates randomized 1994 American Society of Anesthesiologists class III and IV patients undergoing major thoracic, abdominal, or orthopedic surgery to placement of a PAC or CVP catheter.²⁸ In the patients assigned to receive a PAC, physiologic, goal-directed therapy was implemented by protocol. There were no differences in mortality at 30 days, 6 months, or 12 months between the two groups, and ICU length of stay was similar. There was a significantly higher rate of pulmonary emboli in the PAC group (0.9 vs. 0%). This study has been criticized because most of the patients enrolled were not in the highest risk category.

In the "PAC-Man" trial, a multicenter, randomized trial in 65 United Kingdom hospitals, more than 1000 ICU patients were managed with or without a PAC.²⁹ The specifics of the clinical management were then left up to the treating clinicians. There

was no difference in hospital mortality between the two groups (with PAC 68% vs. without PAC 66%, $P = .39$). However, a 9.5% complication rate was associated with the insertion or use of the PAC, although none of these complications was fatal. Clearly, these were critically ill patients, as noted by the high hospital mortality rates. Supporters of the PAC may cite methodology problems with this study, such as loose inclusion criteria and the lack of a defined treatment protocol.

A recent meta-analysis of 13 randomized studies of the PAC that included more than 5000 patients was recently published.³⁰ A broad spectrum of critically ill patients was included in these heterogeneous trials, and the hemodynamic goals and treatment strategies varied. Although the use of the PAC was associated with an increased use of inotropes and vasodilators, there were no differences in mortality or hospital length of stay between the patients managed with a PAC and those managed without a PAC.

Next, the ESCAPE trial (which was one of the studies included in the previous meta-analysis)³¹ evaluated 433 patients with severe or recurrent congestive heart failure admitted to the ICU. Patients were randomized to management by clinical assessment and a PAC or clinical assessment without a PAC. The goal in both groups was resolution of congestive heart failure, with additional PAC targets of a pulmonary capillary occlusion pressure of 15 mmHg and a right atrial pressure of 8 mmHg. There was no formal treatment protocol, but inotropic support was discouraged. Substantial reduction in symptoms, jugular venous pressure, and edema was noted in both groups. There was no significant difference in the primary endpoint of days alive and out of the hospital during the first 6 months, or hospital mortality (PAC 10%; vs. without PAC 9%). Adverse events were more common among patients in the PAC group (21.9% vs. 11.5%; $P = .04$).

Finally, the Fluids and Catheters Treatment Trial (FACTT) conducted by the Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network was recently published.³² The risks and benefits of PAC compared with CVCs were evaluated in 1000 patients with acute lung injury. Patients were randomly assigned to receive either a PAC or a CVC to guide management for 7 days via an explicit protocol. Patients also were randomly assigned to a conservative or liberal fluid strategy in a 2 x 2 factorial design (outcomes based on the fluid management strategy were published separately). Mortality during the first 60 days was similar in the PAC and CVC groups (27% and 26%; $P = .69$). The duration of mechanical ventilation and ICU length of stay also were not influenced by the type of catheter used. The type of catheter used did not affect the incidence of shock, respiratory or renal failure, ventilator settings, or requirement for hemodialysis or vasopressors. There was a 1% rate of crossover from CVC-guided therapy to PAC-guided therapy. The catheter used did not affect the administration of fluids or diuretics, and the fluid balance was similar in the two groups. The PAC group had approximately twice as many catheter-related adverse events (mainly arrhythmias).

Few subjects in critical care medicine generate more emotional responses among experts in the field than the use of the PAC. Some experts may be able to use the PAC to titrate vasoactive drugs and IV fluids for specific patients in ways that improve their outcomes. But, as these studies indicate, it is impossible to verify that use of the PAC saves lives when it is evaluated over a large population of patients. Certainly, given the current state of knowledge, routine use of the PAC cannot be justified. Whether very selective use of the device in a few relatively uncommon clinical situations is warranted or valuable remains a controversial issue. Consequently, a marked decline in the use of the PAC from 5.66 per 1000 medical admissions in 1993 to 1.99 per 1000 medical admissions in 2004 has been seen.³³ These significant reductions in the use of the PAC were noted for a variety of patients, including those admitted with myocardial infarction, surgical patients, and for patients with septicemia. Based upon the results and exclusion criteria in these prospective randomized trials, reasonable criteria for perioperative monitoring without use of a PAC are presented in Table 13-5.

--

Table 13-5 Suggested Criteria for Perioperative Monitoring Without Use of a Pulmonary Artery Catheter in Patients Undergoing Cardiac or Major Vascular Surgical Procedures

No anticipated need for suprarenal or supraceliac aortic cross-clamping
No history of myocardial infarction during 3 mo before operation
No history of poorly compensated congestive heart failure
No history of coronary artery bypass graft surgery during 6 wk before operation
No history of ongoing symptomatic mitral or aortic valvular heart disease
No history of ongoing unstable angina pectoris

One of the reasons for using a PAC to monitor critically ill patients is to optimize cardiac output and systemic O_2 delivery. Defining what constitutes the optimum cardiac output, however, has proven to be difficult. Based upon an extensive observational database and comparisons of the hemodynamic and O_2 transport values recorded in survivors and nonsurvivors, Bland and colleagues proposed that "goal-directed" hemodynamic resuscitation should aim to achieve a Q_T greater than 4.5 L/min per square meter and $\dot{D}O_2$ greater than 600 mL/min per square meter.³⁴ Prompted by these observational findings, a number of investigators have conducted randomized trials designed to evaluate the effect on outcome of goal-directed as compared to conventional hemodynamic resuscitation. Some studies provide support for the notion that interventions designed to achieve supraphysiologic goals for $\dot{D}O_2$, $\dot{V}O_2$, and Q_T improve outcome.^{35–37} However, other published studies do not support this view, and a meta-analysis concluded that interventions designed to achieve supraphysiologic goals for O_2 transport do not significantly reduce mortality rates in critically ill patients.^{19,38,39} At this time, supraphysiologic resuscitation of patients in shock cannot be endorsed.

There is no simple explanation for the apparent lack of effectiveness of pulmonary artery catheterization. Connors has offered several suggestions.⁴⁰ First, even though bedside pulmonary artery catheterization is quite safe, the procedure is associated with a finite incidence of serious complications, including ventricular arrhythmias, catheter-related sepsis, central venous thrombosis, pulmonary arterial perforation, and as noted above, pulmonary embolism.^{28,40} The adverse effects of these complications on outcome may equal or even outweigh any benefits associated with using a PAC to guide therapy. Second, the data generated by the PAC may be inaccurate, leading to inappropriate therapeutic interventions. Third, the measurements, even if accurate, are often misinterpreted in practice. A study by Iberti and associates showed that 47% of 496 clinicians were unable to accurately interpret a straightforward recording of a tracing obtained with a PAC, and 44% could not correctly identify the determinants of systemic $\dot{D}O_2$.⁴¹ A more recent study has confirmed that even well-trained intensivists are capable of misinterpreting results provided by pulmonary artery catheterization.⁴² Furthermore, the current state of understanding is primitive when it comes to deciding what is the best management for certain hemodynamic disturbances, particularly those associated with sepsis or septic shock. Taking all of this into consideration, it may be that interventions prompted by measurements obtained with a PAC are actually harmful to patients. As a result, the marginal benefit now available by placing a PAC may be quite small. Less invasive modalities are available that can provide clinically useful hemodynamic information.

It may be true that aggressive hemodynamic resuscitation of patients, guided by various forms of monitoring, is valuable only during certain critical periods, such as the first few hours after presentation with septic shock or during surgery. For example, Rivers and colleagues reported that survival of patients with septic shock is significantly improved when resuscitation in the emergency department is guided by a protocol that seeks to keep $ScvO_2$ greater than 70%.¹⁷ Similarly, a study using an ultrasound-based device (see Doppler Ultrasonography below) to assess cardiac filling and SV showed that

maximizing SV intraoperatively results in fewer postoperative complications and shorter hospital length of stay.⁴³

Minimally Invasive Alternatives to the Pulmonary Artery Catheter

Because of the cost, risks, and questionable benefit associated with bedside pulmonary artery catheterization, there has been interest for many years in the development of practical means for less invasive monitoring of hemodynamic parameters. Several approaches have been developed, which have achieved variable degrees of success. None of these methods render the standard thermodilution technique of the PAC obsolete. However, these strategies may contribute to improvements in the hemodynamic monitoring of critically ill patients.

DOPPLER ULTRASONOGRAPHY

When ultrasonic sound waves are reflected by moving erythrocytes in the bloodstream, the frequency of the reflected signal is increased or decreased, depending on whether the cells are moving toward or away from the ultrasonic source. This change in frequency is called the *Doppler shift*, and its magnitude is determined by the velocity of the moving red blood cells. Therefore, measurements of the Doppler shift can be used to calculate red blood cell velocity. With knowledge of both the cross-sectional area of a vessel and the mean red blood cell velocity of the blood flowing through it, one can calculate blood flow rate. If the vessel in question is the aorta, then Q_T can be calculated as:

$$QT = HR \times A \times \int V(t)dt$$

where A is the cross-sectional area of the aorta and $\int V(t)dt$ is the red blood cell velocity integrated over the cardiac cycle.

Two approaches have been developed for using Doppler ultrasonography to estimate Q_T . The first approach uses an ultrasonic transducer, which is manually positioned in the suprasternal notch and focused on the root of the aorta. Aortic cross-sectional area can be estimated using a nomogram, which factors in age, height, and weight, back calculated if an independent measure of Q_T is available, or by using two-dimensional transthoracic or transesophageal ultrasonography. Although this approach is completely noninvasive, it requires a highly skilled operator to obtain meaningful results, and is labor intensive. Moreover, unless Q_T measured using thermodilution is used to back-calculate aortic diameter, accuracy using the suprasternal notch approach is not acceptable.⁴⁴ Accordingly, the method is useful only for obtaining very intermittent estimates of Q_T , and has not been widely adopted by clinicians.

A more promising, albeit more invasive, approach has been introduced. In this method blood flow velocity is continuously monitored in the descending thoracic aorta using a continuous-wave Doppler transducer introduced into the esophagus in sedated or anesthetized patients. The probe is advanced into the esophagus to about 35 cm from the incisors (in adults) and connected to a monitor, which continuously displays the blood flow velocity profile in the descending aorta as well as the calculated Q_T . To maximize the accuracy of the device, the probe position must be adjusted to obtain the peak velocity in the aorta. To transform blood flow in the descending aorta into Q_T , a correction factor is applied that is based on the assumption that only 70% of the flow at the root of the aorta is still present in the descending thoracic aorta. Aortic cross-sectional area is estimated using a nomogram based on the patient's age, weight, and height. Results using these methods appear to be reasonably accurate across a broad spectrum of patients. In a multicenter study, good correlation was found between esophageal Doppler and thermodilution ($r = 0.95$), with a small systematic underestimation (bias 0.24 L/min) using esophageal Doppler.⁴⁵ The ultrasonic device also calculates a derived parameter termed *flow time corrected* (FTc), which is the systolic flow time in the descending aorta corrected for HR. FTc is a function of preload, contractility, and vascular input impedance. Although it is not a pure measure of preload, Doppler-based estimates of SV and FTc have been used successfully to guide volume resuscitation in high-risk surgical patients undergoing major operations.⁴³

IMPEDANCE CARDIOGRAPHY

The impedance to flow of alternating electrical current in regions of the body is commonly called *bioimpedance*. In the thorax, changes in the volume and velocity of blood in the thoracic aorta lead to detectable changes in bioimpedance. The first derivative of the oscillating component of thoracic bioimpedance (dZ/dt) is linearly related to aortic blood flow. On the basis of this relationship, empirically derived formulas have been developed to estimate SV, and subsequently Q_T , noninvasively. This methodology is called *impedance cardiography*. The approach is attractive because it is noninvasive, provides a continuous readout of Q_T , and does not require extensive training for use. Despite these advantages, studies suggest that measurements of Q_T obtained by impedance cardiography are not sufficiently reliable to be used for clinical decision making and have poor correlation with standard methods such as thermodilution and ventricular angiography.^{46,47} Impedance cardiography also has been proposed as a way to estimate LVEF, but the results obtained show poor agreement with those obtained by radionuclide ventriculography.^{48,49} Based upon these data, impedance cardiography cannot be recommended at the present time for hemodynamic monitoring of critically ill patients.

PULSE CONTOUR ANALYSIS

Another method for determining cardiac output is an approach called *pulse contour analysis* for estimating SV on a beat-to-beat basis. The mechanical properties of the arterial tree and SV determine the shape of the arterial pulse waveform. The pulse contour method of estimating Q_T uses the arterial pressure waveform as an input for a model of the systemic circulation to determine beat-to-beat flow through the circulatory system. The parameters of resistance, compliance, and impedance are initially estimated based on the patient's age and sex, and can be subsequently refined by using a reference standard measurement of Q_T . The reference standard estimation of Q_T is obtained periodically using the indicator dilution approach by injecting the indicator into a CVC and detecting the transient increase in indicator concentration in the blood using an arterial catheter.

Measurements of Q_T based on pulse contour monitoring are comparable in accuracy to standard PAC-thermodilution methods, but it uses an approach that is less invasive since arterial and central venous, but not transcardiac, catheterization is needed.⁵⁰ Using on-line pressure waveform analysis, the computerized algorithms can calculate SV, Q_T , systemic vascular resistance, and an estimate of myocardial contractility, the rate of rise of the arterial systolic pressure (dP/dT). The use of pulse contour analysis has been applied using noninvasive photoplethysmographic measurements of arterial pressure. However, the accuracy of this technique has been questioned and its clinical use remains to be determined.⁵¹

PARTIAL CARBON DIOXIDE REBREATHING

Partial carbon dioxide (CO_2) rebreathing uses the Fick principle to estimate Q_T noninvasively. By intermittently altering the dead space within the ventilator circuit via a rebreathing valve, changes in CO_2 production (V_{CO_2}) and end-tidal CO_2 ($ETCO_2$) are used to determine cardiac output using a modified Fick equation ($Q_T = \Delta V_{CO_2} / \Delta ETCO_2$). Commercially available devices use this Fick principle to calculate Q_T using intermittent partial CO_2 rebreathing through a disposable rebreathing loop. These devices consist of a CO_2 sensor based on infrared light absorption, an airflow sensor, and a pulse oximeter. Changes in intrapulmonary shunt and hemodynamic instability impair the accuracy of Q_T estimated by partial CO_2 rebreathing. Continuous in-line pulse oximetry and inspired fraction of inspired O_2 (FiO_2) are used to estimate shunt fraction to correct Q_T .

Some studies of the partial CO_2 rebreathing approach suggest that this technique is not as accurate as thermodilution, the

gold standard for measuring Q_T . However, other studies suggest that the partial CO_2 rebreathing method for determination of Q_T compares favorably to measurements made using a PAC in critically ill patients.⁵³

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) has made the transition from operating room to ICU. TEE requires that the patient be sedated and usually intubated for airway protection. Using this powerful technology, global assessments of LV and RV function can be made, including determinations of ventricular volume, EF, and Q_T . Segmental wall motion abnormalities, pericardial effusions, and tamponade can be readily identified with TEE. Doppler techniques allow estimation of atrial filling pressures. The technique is somewhat cumbersome and requires considerable training and skill to obtain reliable results.

Assessing Preload Responsiveness

Although pulse contour analysis or partial CO_2 rebreathing may be able to provide estimates of SV and Q_T , these approaches alone can offer little or no information about the adequacy of preload. Thus, if Q_T is low, some other means must be used to estimate preload. Most clinicians assess the adequacy of cardiac preload by determining CVP or PAOP. However, neither CVP nor PAOP correlate well with the true parameter of interest, left ventricular end-diastolic volume (LVEDV).⁵⁴ Extremely high or low CVP or PAOP results are informative, but readings in a large middle zone (i.e., 5 to 20 mmHg) are not very useful. Furthermore, changes in CVP or PAOP fail to correlate well with changes in SV.⁵⁵ Echocardiography can be used to estimate LVEDV, but this approach is dependent on the skill and training of the individual using it, and isolated measurements of LVEDV fail to predict the hemodynamic response to alterations in preload.⁵⁶

When intrathoracic pressure increases during the application of positive airway pressure in mechanically ventilated patients, venous return decreases, and as a consequence, LVSV also decreases. Therefore, pulse pressure variation (PPV) during a positive pressure episode can be used to predict the responsiveness of cardiac output to changes in preload.⁵⁷ PPV is defined as the difference between the maximal pulse pressure and the minimum pulse pressure divided by the average of these two pressures. This approach has been validated by comparing PPV, CVP, PAOP, and systolic pressure variation as predictors of preload responsiveness in a cohort of critically ill patients. Patients were classified as being "preload responsive" if their cardiac index increased by at least 15% after rapid infusion of a standard volume of IV fluid.⁵⁸ Receiver-operating characteristic curves demonstrated that PPV was the best predictor of preload responsiveness. Although atrial arrhythmias can interfere with the usefulness of this technique, PPV remains a useful approach for assessing preload responsiveness in most patients because of its simplicity and reliability.⁵⁶

Tissue Capnometry

Global indices of Q_T , $\dot{D}O_2$, or $\dot{V}O_2$ provide little useful information regarding the adequacy of cellular oxygenation and mitochondrial function. On theoretical grounds, measuring tissue pH to assess the adequacy of perfusion is an attractive concept. As a consequence of the stoichiometry of the reactions responsible for the substrate level phosphorylation of adenosine diphosphate to form adenosine triphosphate, anaerobiosis is associated with the net accumulation of protons. Accordingly, knowing that tissue pH is not in the acid range should be enough information to conclude that global perfusion as well as arterial O_2 content are sufficient to meet the metabolic demands of the cells, even without knowledge of the actual values for tissue blood flow or O_2 delivery. The detection of tissue acidosis should alert the clinician to the possibility that perfusion is inadequate. Thus, tonometric measurements of tissue PCO_2 in the stomach or sigmoid colon could be used to estimate mucosal pH (pH_i) and thereby monitor visceral perfusion in critically ill patients.

Unfortunately, the notion of using tonometric estimates of GI mucosal pH_i for monitoring perfusion is predicated on a number of assumptions, some of which may be partially or completely invalid. Furthermore, currently available methods for performing measurements of gastric mucosal PCO_2 in the clinical setting remain rather cumbersome and expensive. It is perhaps for these reasons that gastric tonometry for monitoring critically ill patients has primarily been used as a research tool.

Tonometric determination of mucosal CO_2 tension, $\text{PCO}_{2\text{muc}}$, can be used to calculate pH_i by using the Henderson-Hasselbalch equation as follows:

$$\text{pH}_i = \log ([\text{HCO}_3^-]_{\text{muc}} / 0.03 \times \text{PCO}_{2\text{muc}})$$

where $[\text{HCO}_3^-]_{\text{muc}}$ is the concentration of bicarbonate anion in the mucosa. Whereas $\text{PCO}_{2\text{muc}}$ can be measured with reasonable accuracy and precision using tonometric methods, $[\text{HCO}_3^-]_{\text{muc}}$ cannot be measured directly, but must be estimated by assuming that the concentration of bicarbonate anion in arterial blood, $[\text{HCO}_3^-]_{\text{art}}$, is approximately equal to $[\text{HCO}_3^-]_{\text{muc}}$. Under normal conditions, the assumption that $[\text{HCO}_3^-]_{\text{art}} \cong [\text{HCO}_3^-]_{\text{muc}}$ is probably valid. Under pathologic conditions, however, the assumption that $[\text{HCO}_3^-]_{\text{art}} \cong [\text{HCO}_3^-]_{\text{muc}}$ is almost certainly invalid. For example, when blood flow to the ileal mucosa is very low, HCO_3^- in the tissue is titrated by hydrogen ions produced as a result of anaerobic metabolism, and replenishment of tissue HCO_3^- stores from arterial blood is impeded by stagnant perfusion. Thus under such conditions, $[\text{HCO}_3^-]_{\text{muc}}$ is less than $[\text{HCO}_3^-]_{\text{art}}$, and tonometric estimates of pH_i based on the Henderson-Hasselbalch equation underestimate the degree of tissue acidosis present.⁵⁹

There is another inherent problem in using pH_i as an index of perfusion. As noted above, pH_i calculated using the Henderson-Hasselbalch equation is a function of both $\text{PCO}_{2\text{muc}}$ and $[\text{HCO}_3^-]_{\text{art}}$. Under steady-state conditions, the first of these parameters, $\text{PCO}_{2\text{muc}}$, reflects the balance between inflow of CO_2 into the interstitial space and outflow of CO_2 from the interstitial space. CO_2 can enter the interstitial compartment via three mechanisms: diffusion of CO_2 from arterial blood, production as a result of aerobic metabolism of carbon-containing fuels, and production as a result of titration of HCO_3^- by protons liberated during anaerobic metabolism. CO_2 leaves the interstitial compartment by diffusing into venous blood. If blood flow to the mucosa decreases, then $\text{PCO}_{2\text{muc}}$ increases as a result of decreased extraction of CO_2 into venous blood. If mucosal perfusion decreases sufficiently, (i.e., to less than the anaerobic threshold for the tissue), then $\text{PCO}_{2\text{muc}}$ also increases as a result of increased production due to titration of HCO_3^- .⁵² Clearly, therefore, an increase in $\text{PCO}_{2\text{muc}}$ *can* reflect a decrease in mucosal perfusion. However, as documented experimentally by Salzman and colleagues, an increase in $\text{PCO}_{2\text{muc}}$ also can be caused by arterial hypercarbia, leading to increased diffusion of CO_2 from arterial blood into the interstitium.⁶⁰ Similarly, changes in $[\text{HCO}_3^-]_{\text{art}}$ can occur as a result of factors unrelated to either tissue perfusion or the adequacy of aerobic metabolism (e.g., diabetic ketoacidosis, iatrogenic alkalinization due to administration of sodium bicarbonate solution). For these reasons, tonometrically derived estimates of pH_i are not a reliable way to assess mucosal perfusion.

Although PCO_2 and pH are affected by changes in perfusion in all tissues, efforts to monitor these parameters in patients using tonometric methods have focused on the mucosa of the GI tract, particularly the stomach, for both practical and theoretical reasons. From a practical standpoint, the stomach is already commonly intubated in clinical practice for purposes of decompression and drainage or feeding. However, there are theoretical reasons why monitoring GI mucosal perfusion might be more desirable than monitoring perfusion in other sites. First, when global perfusion is compromised, blood flow to the splanchnic viscera decreases to a greater extent than does perfusion to the body as a whole.⁶¹ Thus, the finding of compromised splanchnic perfusion may be an indicator of impending adverse changes in blood flow to other organs. Second,

the gut has been hypothesized to be the "motor" of the multiple organ dysfunction syndrome (MODS), and in experimental models, intestinal mucosal acidosis, whether due to inadequate perfusion or other causes, has been associated with hyperpermeability to hydrophilic solutes.⁶² Therefore, ensuring adequate splanchnic perfusion might be expected to minimize derangements in gut barrier function and, on this basis, improve outcome for patients.

The stomach, however, may not be an ideal location for monitoring tissue PCO_2 . First, CO_2 can be formed in the lumen of the stomach when hydrogen ions secreted by parietal cells in the mucosa titrate luminal bicarbonate anions, which are present either as a result of backwash of duodenal secretions or secretion by gastric mucosal cells. Measurements of gastric PCO_2 and pH_i can be confounded by gastric acid secretion.⁶³ Consequently, accurate measurements of gastric PCO_2 and pH_i depend on pharmacologic blockade of luminal proton secretion using histamine receptor antagonists or proton pump inhibitors. The need for using pharmacologic therapy adds to the cost and complexity of the monitoring strategy. Second, enteral feeding can interfere with measurements of gastric mucosal PCO_2 , necessitating temporary cessation of the administration of nutritional support or the placement of a postpyloric tube.⁶⁴

Despite the problems noted above, measurements of gastric pH_i and/or mucosal-arterial PCO_2 gap have been proven to be a remarkably reliable predictor of outcome in a wide variety of critically ill individuals, including general medical ICU patients, victims of multiple trauma, patients with sepsis, and patients undergoing major surgical procedures.^{65–67} In studies using endoscopic measurements of gastric mucosal blood flow by laser Doppler flowmetry, the development of gastric mucosal acidosis has been shown to correlate with mucosal hypoperfusion.⁶⁸ Moreover, in a landmark prospective, randomized, multicentric clinical trial of monitoring in medical ICU patients, titrating resuscitation to a gastric pH_i endpoint rather than conventional hemodynamic indices resulted in a higher 30-day survival rate.⁶⁹ In another study, trauma patients were randomized to resuscitation titrated to a gastric pH_i greater than 7.30, or to resuscitation titrated to achieve systemic $\dot{\text{V}}\text{O}_2$ or $\dot{\text{V}}\text{O}_2$ goals.⁷⁰ Although survival was not significantly different in the two arms of the study, failure to normalize gastric pH_i within 24 hours was associated with a high mortality rate (54%), whereas normalization of pH_i was associated with a significantly lower mortality rate (7%).

There is also interest in measuring tissue capnometry in less invasive sites. Results from some preliminary clinical studies support the view that the monitoring of tissue PCO_2 in the sublingual mucosa may provide valuable clinical information. Increased sublingual PCO_2 (PslCO_2) was associated with decreases in arterial blood pressure and Q_T in patients with shock due to hemorrhage or sepsis.⁷¹ In a study of critically ill patients with septic or cardiogenic shock, the PslCO_2 - PaCO_2 gradient was found to be a good prognostic indicator, being 9.2 ± 5.0 mmHg in the survivors and 17.8 ± 11.5 mmHg in nonsurvivors.⁷² This study also demonstrated that sublingual capnography was superior to gastric tonometry in predicting patient survival. The PslCO_2 - PaCO_2 gradient also correlated with the mixed venous-arterial PCO_2 gradient, but failed to correlate with blood lactate level, mixed venous O_2 saturation (Sv-O_2), or systemic $\dot{\text{V}}\text{O}_2$. These latter findings suggest that the PslCO_2 - PaCO_2 gradient may be a better marker of tissue hypoxia than are these other parameters.

Near Infrared Spectroscopic Measurement of Tissue Hemoglobin Oxygen Saturation

Near infrared spectroscopy (NIRS) allows continuous, noninvasive measurement of tissue Hgb O_2 saturation (StO_2) using near infrared wavelengths of light (700–1000 nm). This technology is based on Beer's law, which states that the transmission of light through a solution with a dissolved solute decreases exponentially as the concentration of the solute increases. In mammalian tissue, three compounds change their absorption pattern when oxygenated: cytochrome a, a_3 , myoglobin, and Hgb. Because of the distinct absorption spectra of oxyhemoglobin and deoxyhemoglobin, Beer's law can be

used to detect their relative concentrations within tissue. Thus, the relative concentrations of the types of Hgb can be determined by measuring the change in light intensity as it passes through the tissue. Because about 20% of blood volume is intra-arterial and the StO₂ measurements are taken without regard to systole or diastole, spectroscopic measurements are primarily indicative of the venous oxyhemoglobin concentration.

NIRS has been evaluated to assess the severity of traumatic shock in animal models and in trauma patients. Studies have shown that peripheral muscle StO₂, as determined by NIRS, is as accurate as other endpoints of resuscitation [i.e., base deficit (BD), mixed venous O₂ saturation] in a porcine model of hemorrhagic shock.⁷³ Continuously-measured StO₂ has been evaluated in blunt trauma patients as a predictor of the development of multiple organ dysfunction syndrome (MODS) and mortality.⁷⁴ At seven level 1 trauma centers, 383 patients were prospectively studied. StO₂ was monitored for 24 hours after admission along with vital signs and other endpoints of resuscitation such as BD. Minimum StO₂ (using a minimum StO₂ ≤75% as a cutoff) had a similar sensitivity and specificity in predicting the development of MODS as BD ≥6 mEq/L. StO₂ and BD were also comparable in predicting mortality. Thus, NIRS-derived muscle StO₂ measurements perform similarly to BD in identifying poor perfusion and predicting the development of MODS or death after severe torso trauma, yet have the additional advantages of being continuous and noninvasive. Ongoing prospective studies will help determine the clinical use of continuous monitoring of StO₂ in clinical scenarios such as trauma, hemorrhagic shock, sepsis, etc.

RESPIRATORY MONITORING

The ability to monitor various parameters of respiratory function is of utmost importance in critically ill patients. Many of these patients require mechanical ventilation. Monitoring of their respiratory physiology is necessary to assess the adequacy of oxygenation and ventilation, guide weaning and liberation from mechanical ventilation, and detect adverse events associated with respiratory failure and mechanical ventilation. These parameters include gas exchange, neuromuscular activity, respiratory mechanics, and patient effort.

Arterial Blood Gases

The standard for respiratory monitoring has been to carry out intermittent measurements of arterial blood gases. Blood gas analysis provides useful information when caring for patients with respiratory failure. However, even in the absence of respiratory failure or the need for mechanical ventilation, blood gas determinations also can be valuable to detect alterations in acid-base balance due to low Q_T, sepsis, renal failure, severe trauma, medication or drug overdose, or altered mental status. Arterial blood can be analyzed for pH, PO₂, PCO₂, HCO₃⁻ concentration, and calculated BD. When indicated, carboxyhemoglobin and methemoglobin levels also can be measured. In recent years, efforts have been made to decrease the unnecessary use of arterial blood gas analysis. Serial arterial blood gas determinations are not necessary for routine weaning from mechanical ventilation in the majority of postoperative patients.

Most bedside blood gas analyses still involve removal of an aliquot of blood from the patient, although continuous bedside arterial blood gas determinations are now possible without sampling via an indwelling arterial catheter that contains a biosensor. In studies comparing the accuracy of continuous arterial blood gas and pH monitoring with a conventional laboratory blood gas analyzer, excellent agreement between the two methods has been demonstrated.⁷⁵ Continuous monitoring can reduce the volume of blood loss due to phlebotomy and dramatically decrease the time necessary to obtain blood gas results. Continuous monitoring, however, is expensive and is not widely used.

Determinants of Oxygen Delivery

The primary goal of the cardiovascular and respiratory systems is to deliver oxygenated blood to the tissues. $\dot{V}O_2$ is dependent to a greater degree on the O_2 saturation of Hgb in arterial blood (SAO_2) than on the partial pressure of O_2 in arterial blood (PaO_2). $\dot{V}O_2$ also is dependent on Q_T and Hgb. Dissolved O_2 in blood, which is proportional to the PaO_2 , makes only a negligible contribution to $\dot{V}O_2$, as is apparent from the equation:

$$\dot{V}O_2 = Q_T \times [(Hgb \times SAO_2 \times 1.36) + (PaO_2 \times 0.0031)]$$

SAO_2 in mechanically ventilated patients depends on the mean airway pressure, the fraction of inspired O_2 (FiO_2), and $Sv-O_2$. Thus, when SAO_2 is low, the clinician has only a limited number of ways to improve this parameter. The clinician can increase mean airway pressure by increasing positive end-expiratory pressure (PEEP) or inspiratory time. FiO_2 can be increased to a maximum of 1.0 by decreasing the amount of room air mixed with the O_2 supplied to the ventilator. $Sv-O_2$ can be increased by increasing Hgb or Q_T or decreasing O_2 use (e.g., by administering a muscle relaxant and sedation).

Peak and Plateau Airway Pressure

Airway pressures are routinely monitored in mechanically ventilated patients. The peak airway pressure measured at the end of inspiration (P_{peak}) is a function of the tidal volume, the resistance of the airways, lung/chest wall compliance, and peak inspiratory flow. The airway pressure measured at the end of inspiration when the inhaled volume is held in the lungs by briefly closing the expiratory valve is termed *the plateau airway pressure* ($P_{plateau}$). As a static parameter, plateau airway pressure is independent of the airway resistance and peak airway flow, and is related to the lung/chest wall compliance and delivered tidal volume. Mechanical ventilators monitor P_{peak} with each breath and can be set to trigger an alarm if the P_{peak} exceeds a predetermined threshold. $P_{plateau}$ is not measured routinely with each delivered tidal volume, but rather is measured intermittently by setting the ventilator to close the exhalation circuit briefly at the end of inspiration and record the airway pressure when airflow is zero.

If both P_{peak} and $P_{plateau}$ are increased (and tidal volume is not excessive), then the problem is a decrease in the compliance in the lung/chest wall unit. Common causes of this problem include pneumothorax, hemothorax, lobar atelectasis, pulmonary edema, pneumonia, acute respiratory distress syndrome (ARDS), active contraction of the chest wall or diaphragmatic muscles, abdominal distention, and intrinsic PEEP, such as occurs in patients with bronchospasm and insufficient expiratory times. When P_{peak} is increased but $P_{plateau}$ is relatively normal, the primary problem is an increase in airway resistance, such as occurs with bronchospasm, use of a small-caliber endotracheal tube, or kinking or obstruction of the endotracheal tube. A low P_{peak} also should trigger an alarm, as it suggests a discontinuity in the airway circuit involving the patient and the ventilator.

Ventilator-induced lung injury is now an established clinical entity of great relevance to the care of critically ill patients. Excessive airway pressure and tidal volume adversely affect pulmonary and possibly systemic responses to critical illness. Subjecting the lung parenchyma to excessive pressure, known as *barotrauma*, can result in parenchymal lung injury, diffuse alveolar damage similar to ARDS, and pneumothorax, and can impair venous return and therefore limit cardiac output. Lung-protective ventilation strategies have been developed to prevent the development of ventilator-induced lung injury and improve patient outcomes. In a large, multicenter randomized trial of patients with ARDS from a variety of etiologies, limiting plateau airway pressure to less than 30 cm H_2O and tidal volume to less than 6 mL/kg of ideal body weight reduced 28-day mortality by 22% relative to a ventilator strategy that used a tidal volume of 12 mL/kg.⁷⁶ For this reason, monitoring of plateau pressure and using a low tidal volume strategy in patients with ARDS is now the standard of care.

Pulse Oximetry

The pulse oximeter is a microprocessor-based device that integrates oximetry and plethysmography to provide continuous noninvasive monitoring of the O₂ saturation of arterial blood (SaO₂). It is considered one of the most important and useful technologic advances in patient monitoring. Continuous, noninvasive monitoring of arterial O₂ saturation is possible using light-emitting diodes and sensors placed on the skin. Pulse oximetry uses two wavelengths of light (i.e., 660 nm and 940 nm) to analyze the pulsatile component of blood flow between the light source and sensor. Because oxyhemoglobin and deoxyhemoglobin have different absorption spectra, differential absorption of light at these two wavelengths can be used to calculate the fraction of O₂ saturation of Hgb. Under normal circumstances, the contributions of carboxyhemoglobin and methemoglobin are minimal. However, if carboxyhemoglobin levels are elevated, the pulse oximeter will incorrectly interpret carboxyhemoglobin as oxyhemoglobin and the arterial saturation displayed will be falsely elevated. When the concentration of methemoglobin is markedly increased, the SaO₂ will be displayed as 85%, regardless of the true arterial saturation.⁷⁷ The accuracy of pulse oximetry begins to decline at SaO₂ values less than 92%, and tends to be unreliable for values less than 85%.⁷⁸

Several studies have assessed the frequency of arterial O₂ desaturation in hospitalized patients and its effect on outcome. For example, in a study of general medical patients, Bowton and associates found that patients who had an episode of hypoxemia (SaO₂ <90% for 5 minutes) in the first 24 hours of hospital admission had a mortality rate three times higher than that of patients who did not have an episode of arterial desaturation.⁷⁹ Because of its clinical relevance, ease of use, noninvasive nature, and cost-effectiveness, pulse oximetry has become a routine monitoring strategy in patients with respiratory disease, intubated patients, and those undergoing surgical intervention under sedation or general anesthesia. Pulse oximetry is especially useful in the titration of FiO₂ and PEEP for patients receiving mechanical ventilation, and during weaning from mechanical ventilation. The widespread use of pulse oximetry has decreased the need for arterial blood gas determinations in critically ill patients.

Capnometry

Capnometry is the measurement of CO₂ in the airway throughout the respiratory cycle. Capnometry is most commonly measured by infrared light absorption. CO₂ absorbs infrared light at a peak wavelength of approximately 4.27 μ m. Capnometry works by passing infrared light through a sample chamber to a detector on the opposite side. More infrared light passing through the sample chamber (i.e., less CO₂) causes a larger signal in the detector relative to the infrared light passing through a reference cell. Capnometric determination of the partial pressure of CO₂ in end-tidal exhaled gas (PETCO₂) is used as a surrogate for the partial pressure of CO₂ in arterial blood (Paco₂) during mechanical ventilation. In healthy subjects, PETCO₂ is about 1 to 5 mmHg less than Paco₂.⁸⁰ Thus, PETCO₂ can be used to estimate Paco₂ without the need for blood gas determination. However, changes in PETCO₂ may not correlate with changes in Paco₂ during a number of pathologic conditions (see below).

Capnography allows the confirmation of endotracheal intubation and continuous assessment of ventilation, integrity of the airway, operation of the ventilator, and cardiopulmonary function. Capnometers are configured with either an in-line sensor or a sidestream sensor. The sidestream systems are lighter and easy to use, but the thin tubing that samples the gas from the ventilator circuit can become clogged with secretions or condensed water, preventing accurate measurements. The in-line devices are bulky and heavier, but are less likely to become clogged. Continuous monitoring with capnography has become routine during surgery under general anesthesia and for some intensive care patients. A number of situations can be promptly detected with continuous capnography. A sudden reduction in PETCO₂ suggests either obstruction of the sampling tubing with water or secretions, or a catastrophic event such as loss of the airway, airway disconnection or obstruction,

ventilator malfunction, or a marked decrease in Q_T . If the airway is connected and patent and the ventilator is functioning properly, then a sudden decrease in $PETCO_2$ should prompt efforts to rule out cardiac arrest, massive pulmonary embolism, or cardiogenic shock. $PETCO_2$ can be persistently low during hyperventilation or with an increase in dead space such as occurs with pulmonary embolization (even in the absence of a change in Q_T). Causes of an increase in $PETCO_2$ include reduced minute ventilation or increased metabolic rate.

RENAL MONITORING

Urine Output

Bladder catheterization with an indwelling catheter allows the monitoring of urine output, usually recorded hourly by the nursing staff. With a patent Foley catheter, urine output is a gross indicator of renal perfusion. The generally accepted normal urine output is 0.5 mL/kg per hour for adults and 1 to 2 mL/kg per hour for neonates and infants. Oliguria may reflect inadequate renal artery perfusion due to hypotension, hypovolemia, or low Q_T . Low urine flow also can be a sign of intrinsic renal dysfunction. It is important to recognize that normal urine output does not exclude the possibility of impending renal failure.

Bladder Pressure

The triad of oliguria, elevated peak airway pressures, and elevated intra-abdominal pressure is known as the *abdominal compartment syndrome* (ACS). This syndrome, first described in patients after repair of ruptured abdominal aortic aneurysm, is associated with interstitial edema of the abdominal organs, resulting in elevated intra-abdominal pressure. When intra-abdominal pressure exceeds venous or capillary pressures, perfusion of the kidneys and other intra-abdominal viscera is impaired. Oliguria is a cardinal sign. Although the diagnosis of ACS is a clinical one, measuring intra-abdominal pressure is useful to confirm the diagnosis. Ideally, a catheter inserted into the peritoneal cavity could measure intra-abdominal pressure to substantiate the diagnosis. In practice, transurethral bladder pressure measurement reflects intra-abdominal pressure and is most often used to confirm the presence of ACS. After instilling 50 to 100 mL of sterile saline into the bladder via a Foley catheter, the tubing is connected to a transducing system to measure bladder pressure. Most authorities recommend that a bladder pressure greater than 20 to 25 mmHg confirms the diagnosis of ACS.⁸¹ Less commonly, gastric or inferior vena cava pressures can be monitored with appropriate catheters to detect elevated intra-abdominal pressures.

NEUROLOGIC MONITORING

Intracranial Pressure

Because the brain is rigidly confined within the bony skull, cerebral edema or mass lesions increase intracranial pressure (ICP). Monitoring of ICP is currently recommended in patients with severe traumatic brain injury (TBI), defined as a Glasgow Coma Scale (GCS) score ≤ 8 with an abnormal CT scan, and in patients with severe TBI and a normal CT scan if two or more of the following are present: age greater than 40 years, unilateral or bilateral motor posturing, or systolic blood pressure less than 90 mmHg.⁸² ICP monitoring also is indicated in patients with acute subarachnoid hemorrhage with coma or neurologic deterioration, intracranial hemorrhage with intraventricular blood, ischemic middle cerebral artery stroke, fulminant hepatic failure with coma and cerebral edema on CT scan, and global cerebral ischemia or anoxia with cerebral edema on CT scan. The goal of ICP monitoring is to ensure that cerebral perfusion pressure (CPP) is adequate to support perfusion of the brain. CPP is equal to the difference between MAP and ICP: $CPP = MAP - ICP$.

One type of ICP measuring device, the ventriculostomy catheter, consists of a fluid-filled catheter inserted into a cerebral ventricle and connected to an external pressure transducer. This device permits measurement of ICP, but also allows drainage of cerebrospinal fluid (CSF) as a means to lower ICP and sample CSF for laboratory studies. Other devices locate the pressure transducer within the central nervous system and are used only to monitor ICP. These devices can be placed in the intraventricular, parenchymal, subdural, or epidural spaces. Ventriculostomy catheters are the accepted standard for monitoring ICP in patients with TBI due to their accuracy, ability to drain CSF, and low complication rate. The associated complications include infection (5%), hemorrhage (1.4%), catheter malfunction or obstruction (6.3 to 10.5%), and malposition with injury to cerebral tissue.⁸³

The purpose of ICP monitoring is to detect and treat abnormal elevations of ICP that may be detrimental to cerebral perfusion and function. In TBI patients, ICP greater than 20 mmHg is associated with unfavorable outcomes.⁸⁴ However, few studies have shown that treatment of elevated ICP improves clinical outcomes in human trauma patients. In a randomized, controlled, double-blind trial, Eisenberg and colleagues demonstrated that maintaining ICP less than 25 mmHg in patients without craniectomy and less than 15 mmHg in patients with craniectomy is associated with improved outcome.⁸⁵ In patients with low CPP, therapeutic strategies to correct CPP can be directed at increasing MAP or decreasing ICP. Although it often has been recommended that CPP be maintained above 70 mmHg, the evidence to support this recommendation is not overly compelling.⁸⁶ Furthermore, a retrospective cohort study of patients with severe TBI found that ICP/CPP-targeted neurointensive care was associated with prolonged mechanical ventilation and increased therapeutic interventions, without evidence for improved outcome in patients who survive beyond 24 h.⁸⁷

Electroencephalogram and Evoked Potentials

Electroencephalography offers the capacity to monitor global neurologic electrical activity, while evoked potential monitoring can assess pathways not detected by the conventional electroencephalogram (EEG). Continuous EEG (CEEG) monitoring in the ICU permits ongoing evaluation of cerebral cortical activity. It is especially useful in obtunded and comatose patients. CEEG also is useful for monitoring of therapy for status epilepticus and detecting early changes associated with cerebral ischemia. CEEG can be used to adjust the level of sedation, especially if high-dose barbiturate therapy is being used to manage elevated ICP. Somatosensory and brain stem evoked potentials are less affected by the administration of sedatives than is the EEG. Evoked potentials are useful for localizing brain stem lesions or proving the absence of such structural lesions in cases of metabolic or toxic coma. They also can provide prognostic data in posttraumatic coma.

A recent advance in EEG monitoring is the use of the bispectral index (BIS) to titrate the level of sedative medications. Although sedative drugs usually are titrated to the clinical neurologic examination, the BIS device has been used in the operating room to continuously monitor the depth of anesthesia. The BIS is an empiric measurement statistically derived from a database of more than 5000 EEGs.⁸⁸ The BIS is derived from bifrontal EEG recordings and analyzed for burst suppression ratio, relative alpha:beta ratio, and bicoherence. Using a multivariate regression model, a linear numeric index (BIS) is calculated, ranging from 0 (isoelectric EEG) to 100 (fully awake). Its use has been associated with lower consumption of anesthetics during surgery and earlier awakening and faster recovery from anesthesia.⁸⁹ The BIS also has been validated as a useful approach for monitoring the level of sedation for ICU patients, using the revised Sedation-Agitation Scale as a gold standard.⁹⁰

Transcranial Doppler Ultrasonography

This modality provides a noninvasive method for evaluating cerebral hemodynamics. Transcranial Doppler (TCD)

measurements of middle and anterior cerebral artery blood flow velocity are useful for the diagnosis of cerebral vasospasm after subarachnoid hemorrhage. Qureshi and associates demonstrated that an increase in the middle cerebral artery mean flow velocity as assessed by TCD is an independent predictor of symptomatic vasospasm in a prospective study of patients with aneurysmal subarachnoid hemorrhage.⁹¹ In addition, while some have proposed using TCD to estimate ICP, studies have shown that TCD is not a reliable method for estimating ICP and CPP, and currently cannot be endorsed for this purpose.⁹² TCD also is useful to confirm the clinical examination for determining brain death in patients with confounding factors such as the presence of central nervous system depressants or metabolic encephalopathy.

Jugular Venous Oximetry

When the arterial O₂ content, Hgb concentration, and the oxyhemoglobin dissociation curve are constant, changes in jugular venous O₂ saturation (SjO₂) reflect changes in the difference between cerebral O₂ delivery and demand. Generally, a decrease in SjO₂ reflects cerebral hypoperfusion, whereas an increase in SjO₂ indicates the presence of hyperemia. SjO₂ monitoring cannot detect decreases in regional cerebral blood flow if overall perfusion is normal or above normal. This technique requires the placement of a catheter in the jugular bulb, usually via the internal jugular vein. Catheters that permit intermittent aspiration of jugular venous blood for analysis or continuous oximetry catheters are available.

Low SjO₂ is associated with poor outcomes after TBI.⁹³ Nevertheless, the value of monitoring SjO₂ remains unproven. If it is used, it should not be the sole monitoring technique, but rather should be used in conjunction with ICP and CPP monitoring. By monitoring ICP, CPP, and SjO₂, early intervention with volume, vasopressors, and hyperventilation has been shown to prevent ischemic events in patients with TBI.⁹⁴

Transcranial Near Infrared Spectroscopy

Transcranial NIRS is a noninvasive continuous monitoring method to determine cerebral oxygenation. It uses technology similar to that of pulse oximetry to determine the concentrations of oxy- and deoxyhemoglobin with near infrared light and sensors, and takes advantage of the relative transparency of the skull to light in the near infrared region of the spectrum. McCormick and associates demonstrated that cerebral desaturation can occur more than 2 hours before any clinical deterioration in neurologic status.⁹⁵ Nevertheless, this form of monitoring remains largely a research tool at the present time.

Brain Tissue Oxygen Tension

Although the standard of care for patients with severe TBI includes ICP and CPP monitoring, this strategy does not always prevent secondary brain injury. Growing evidence suggests that monitoring local brain tissue O₂ tension (PbtO₂) may be a useful adjunct to ICP monitoring in these patients. Normal values for PbtO₂ are 20 to 40 mmHg, and critical levels are 8 to 10 mmHg. A recent clinical study sought to determine whether the addition of a PbtO₂ monitor to guide therapy in severe TBI was associated with improved patient outcomes.⁹⁶ Twenty-eight patients with severe TBI (GCS score ≤ 8) were enrolled in an observational study at a level I trauma center. These patients received invasive ICP and PbtO₂ monitoring and were compared with 25 historical controls matched for age, injuries, and admission GCS score that had undergone ICP monitoring alone. Goals of therapy in both groups included maintaining an ICP <20 mmHg and a CPP >60 mmHg. Among patients with PbtO₂ monitoring, therapy also was directed at maintaining PbtO₂ >25 mmHg. The groups had similar mean daily ICP and CPP levels. The mortality rate in the historical controls treated with standard ICP and CPP management was 44%. Mortality was significantly lower in the patients who had therapy guided by PbtO₂ monitoring in addition to ICP and CPP (25%; $P < .05$). The benefits of PbtO₂ monitoring may include the early detection of brain tissue ischemia despite normal ICP and CPP.

In addition, PbtO₂-guided management may reduce potential adverse effects associated with therapies to maintain ICP and CPP.

CONCLUSIONS

Modern intensive care is predicated by the need and ability to continuously monitor a wide range of physiologic parameters. This capability has dramatically improved the care of critically ill patients and advanced the development of the specialty of critical care medicine. In some cases, the technologic ability to measure such variables has surpassed our understanding of the significance or the knowledge of the appropriate intervention to ameliorate such pathophysiologic changes. In addition, the development of less invasive monitoring methods has been promoted by the recognition of complications associated with invasive monitoring devices. The future portends the continued development of noninvasive monitoring devices along with their application in an evidenced-based strategy to guide rational therapy.

Schwartz's Principles of Surgery > Part I. Basic Considerations > Chapter 14. Minimally Invasive Surgery, Robotics, and Natural Orifice Transluminal Endoscopic Surgery >

KEY POINTS

1. Minimally invasive surgery describes a philosophical approach to surgery in which access trauma is minimized without compromising the quality of the surgical procedure.
2. Minimally invasive surgery is dependent upon videoscopic, ultrasonographic, radiologic, and magnetic resonance imaging.
3. The carbon dioxide pneumoperitoneum used for laparoscopy induces some unique pathophysiologic consequences.
4. Training for laparoscopy requires practice outside of the operating room in a simulation laboratory and/or in animal models.
5. Laparoscopy during pregnancy is best performed in the second trimester and is safe if appropriate monitoring is performed.
6. Laparoscopic surgery for cancer is also appropriate if good tissue handling techniques are maintained.
7. Robotic surgery has been most valuable in the pelvis for performance of minimally invasive prostatectomy and gynecologic and fertility procedures.
8. Natural orifice transluminal endoscopic surgery represents a new opportunity to develop truly scar-free surgery.

MINIMALLY INVASIVE SURGERY, ROBOTICS, AND NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY: INTRODUCTION

Minimally invasive surgery describes an area of surgery that crosses all traditional disciplines, from general surgery to neurosurgery. It is not a discipline unto itself, but more a philosophy of surgery, a way of thinking. Minimally invasive surgery is a means of performing major operations through small incisions, often using miniaturized, high-tech imaging systems, to minimize the trauma of surgical exposure. Some believe that the term *minimal access surgery* more accurately describes the small incisions generally necessary to gain access to surgical sites in high-tech surgery, but John Wickham's term *minimally invasive surgery* (MIS) is widely used because it describes the paradox of postmodern high-tech surgery—small holes, big operations—and the "minimalness" of the access and invasiveness of the procedures, captured in three words.

Robotic surgery today is practiced using a single platform (Intuitive, Inc., Sunnyvale, CA) and should better be termed *computer enhanced surgery* as the term *robotics* assumes autonomous action that is not a feature of the da Vinci robotic system. Instead, the da Vinci robot couples an ergonomic workstation that features stereoptic video imaging and intuitive micromanipulators (surgeon side) with a set of arms delivering specialized laparoscopic instruments enhanced with more degrees of freedom than is allowed by laparoscopic surgery alone (patient side). A computer between the surgeon side and patient side removes surgical tremor and scales motion to allow precise microsurgery, helpful for microdissection and difficult anastomoses.

Natural orifice transluminal endoscopic surgery (NOTES) is a recent extension of interventional endoscopy. Using the mouth, the anus, the vagina, and the urethra (natural orifices), flexible endoscopes are passed through the wall of the esophagus, stomach, colon, bladder, or vagina entering the mediastinum, the pleural space, or the peritoneal cavity. The advantage of this method of minimal access is principally the elimination of the scar associated with laparoscopy or thoracoscopy. Other advantages are yet to be elucidated, including pain reduction, need for hospitalization, and cost savings.

HISTORICAL BACKGROUND

Although the term *minimally invasive surgery* is relatively recent, the history of its component parts is nearly 100 years old. What is considered the newest and most popular variety of MIS, laparoscopy, is, in fact, the oldest. Primitive laparoscopy, placing a cystoscope within an inflated abdomen, was first performed by Kelling in 1901.¹ Illumination of the abdomen required hot elements at the tip of the scope and was dangerous. In the late 1950s, Hopkins described the rod lens, a method of transmitting light through a solid quartz rod with no heat and little light loss.¹ Around the same time, thin quartz fibers were discovered to be capable of trapping light internally and conducting it around corners, opening the field of fiber-optics and allowing the rapid development of flexible endoscopes.^{2,3} In the 1970s, the application of flexible endoscopy grew faster than that of rigid endoscopy except in a few fields such as gynecology and orthopedics.⁴ By the mid-1970s, rigid and flexible endoscopes made a rapid transition from diagnostic instruments to therapeutic ones. The explosion of video-assisted surgery in the past 20 years was a result of the development of compact, high-resolution, charge-coupled devices (CCDs) that could be mounted on the internal end of flexible endoscopes or on the external end of a Hopkins telescope. Coupled with bright light sources, fiber-optic cables, and high-resolution video monitors, the videoendoscope has changed our understanding of surgical anatomy and reshaped surgical practice.

Flexible endoscopic imaging started in the 1960s with the first bundling of many quartz fibers into bundles, one for illumination and one for imaging. The earliest upper endoscopes revolutionized the diagnosis and treatment of gastroesophageal reflux, peptic ulcer disease, and made possible early detection of upper and lower GI cancer at a stage that could be cured. The first endoscopic surgical procedure was the colonoscopic polypectomy, developed by Shinya and Wolfe, two surgeons from New York City. The percutaneous endoscopic gastrostomy (PEG) invented by Gauderer and Ponsky may have been the first NOTES procedure, reported in 1981.⁵ Endoscopic pancreatic pseudocyst drainage is thought to be the next NOTES procedure developed; however, there was little energy and money put into the development of NOTES until a number of gastroenterologists claimed the ability to remove the gallbladder with a flexible endoscope, using a transgastric technique. With this pronouncement, the surgical community "woke up" and seized the momentum for NOTES research and development.

Although optical imaging produced the majority of MIS procedures, other (traditionally radiologic) imaging technologies allowed the development of innovative procedures in the 1970s. Fluoroscopic imaging allowed the adoption of percutaneous vascular procedures, the most revolutionary of which was balloon angioplasty. Balloon-based procedures spread into all fields of medicine used to open up clogged lumens with minimal access. Stents were then developed that were used in many disciplines to keep the newly ballooned segment open. The culmination of fluoroscopic balloon and stent proficiency is exemplified by the transvenous intrahepatic portosystemic shunt and by the aortic stent graft, which has nearly replaced open elective abdominal aortic aneurysm repair.

MIS procedures using ultrasound imaging have been limited to fairly crude exercises, such as fragmenting kidney stones and freezing liver tumors, because of the relatively low resolution of ultrasound devices. Newer, high-resolution ultrasound methods with high-frequency crystals may act as a guide while performing minimally invasive resections of individual layers of the intestinal wall.

Axial imaging, such as computed tomography (CT), has allowed the development of an area of MIS that often is not recognized because it requires only a CT scanner and a long needle. CT-guided drainage of abdominal fluid collections and percutaneous biopsy of abnormal tissues are minimally invasive means of performing procedures that previously required a celiotomy. CT-guided percutaneous radiofrequency (RF) ablation has emerged as a useful treatment for primary and metastatic liver tumors. This procedure also is performed laparoscopically under ultrasound guidance.⁶

A powerful, noninvasive method of imaging that will allow the development of the least invasive—and potentially noninvasive—surgery is magnetic resonance imaging (MRI).

MRI is an extremely valuable diagnostic tool, but it is only slowly coming to be of therapeutic value. One obstacle to the use of MRI for MIS is that image production and refreshment of the image as a procedure progresses are slow. Another is that all instrumentation must be nonmetallic when working with the powerful magnets of an MRI scanner. Moreover, MRI magnets are bulky and limit the surgeon's access to the patient. Open magnets have been developed that allow the surgeon to stand between two large MRI coils, obtaining access to the portion of the patient being scanned. The advantage of MRI, in addition to the superb images produced, is that there is no

radiation exposure to patient or surgeon. Some neurosurgeons are accumulating experience using MRI to perform frameless stereotactic surgery.

Robotic surgery has been dreamed about for some time, and many "Rube Goldberg" devices have been developed over the years to provide mechanical assistance for the surgeon. The first computer-assisted robot, the "RoboDoc" was designed to accurately drill femoral shaft bone for wobble-free placement of hip prostheses. Although the name was appealing, the robot proved no better than a skilled orthopedic surgeon and was a good deal slower. Following this, the first and only two commercially successful robots for laparoscopic surgery were in development in California. Computer Motion, founded by Yulun Wang in Santa Barbara, used National Science Foundation funds to create a mechanical arm, the Aesop robot, which held and moved the laparoscope with voice, foot, or hand control. In Northern California, a master-slave system first developed for surgery on the multinational space station by Philip Green was purchased by Fred Moll and Lonnie Smith, then re-engineered with the surgeon in mind to create a remarkably intuitive computer-enhanced surgical platform. The company, Intuitive Surgical, was aptly named, and their primary product, the da Vinci robot, is the only major "robotic" surgical device currently on the market. Although eschewed by many experienced laparoscopists, the da Vinci achieved a toehold among many skilled surgeons who found that the robot could facilitate MIS procedures that were difficult with standard laparoscopic procedures.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF MINIMALLY INVASIVE SURGERY

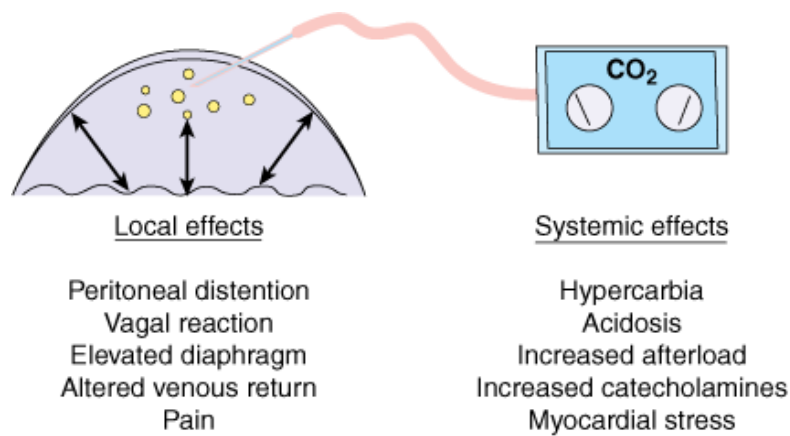

Even with the least invasive of the MIS procedures, physiologic changes occur. Many minimally invasive procedures require minimal or no sedation, and there are few adverse consequences to the cardiovascular, endocrinologic, or immunologic systems. The least invasive of such procedures include stereotactic biopsy of breast lesions and flexible GI endoscopy. Minimally invasive procedures that require general anesthesia have a greater physiologic impact because of the anesthetic agent, the incision (even if small), and the induced pneumoperitoneum.

Laparoscopy

The unique feature of laparoscopic surgery is the need to lift the abdominal wall from the abdominal organs. Two methods have been devised for achieving this.⁷ The first, used by most surgeons, is a pneumoperitoneum. Throughout the early twentieth century, intraperitoneal visualization was achieved by inflating the abdominal cavity with air, using a sphygmomanometer bulb.⁸ The problem with using air insufflation is that nitrogen is poorly soluble in blood and is slowly absorbed across the peritoneal surfaces. Air pneumoperitoneum was believed to be more painful than nitrous oxide (N₂O) pneumoperitoneum, but less painful than carbon dioxide (CO₂) pneumoperitoneum. Subsequently, carbon dioxide and N₂O were used for inflating the abdomen. N₂O had the advantage of being physiologically inert and rapidly absorbed. It also provided better analgesia for laparoscopy performed under local anesthesia when compared with CO₂ or air.⁹ Despite initial concerns that N₂O would not suppress combustion, controlled clinical trials have established its safety within the peritoneal cavity.¹⁰ In addition, N₂O has been shown to reduce the intraoperative end-tidal CO₂ and minute ventilation required to maintain homeostasis when compared to CO₂ pneumoperitoneum.¹⁰ The effect of N₂O on tumor biology and the development of port site metastasis are unknown. As such, caution should be exercised when performing laparoscopic cancer surgery with this agent. Finally, the safety of N₂O pneumoperitoneum in pregnancy has yet to be elucidated.

The physiologic effects of CO₂ pneumoperitoneum can be divided into two areas: (a) gas-specific effects and (b) pressure-specific effects (Fig. 14-1). CO₂ is rapidly absorbed across the peritoneal membrane into the circulation. In the circulation, CO₂ creates a respiratory acidosis by the generation of carbonic acid.¹¹ Body buffers, the largest reserve of which lies in bone, absorb CO₂ (up to 120 L) and minimize the development of hypercarbia or respiratory acidosis during brief endoscopic procedures.¹¹ Once the body buffers are saturated, respiratory acidosis develops rapidly, and the respiratory system assumes the burden of keeping up with the absorption of CO₂ and its release from these buffers.

Fig. 14-1.

Carbon dioxide gas insufflated into the peritoneal cavity has both local and systemic effects that cause a complex set of hemodynamic and metabolic alterations.

[Reproduced with permission from Hunter JG (ed): *Baillieres Clinical Gastroenterology Laparoscopic Surgery*. London/Philadelphia: Bailliere Tindall, 1993, p 758.]

In patients with normal respiratory function, this is not difficult; the anesthesiologist increases the ventilatory rate or vital capacity on the ventilator. If the respiratory rate required exceeds 20 breaths per minute, there may be less efficient gas exchange and increasing hypercarbia.¹² Conversely, if vital capacity is increased substantially, there is a greater opportunity for barotrauma and greater respiratory motion-induced disruption of the upper abdominal operative field. In some situations, it is advisable to evacuate the pneumoperitoneum or reduce the intra-abdominal pressure to allow time for the anesthesiologist to adjust for hypercarbia.¹³ Although mild respiratory acidosis probably is an insignificant problem, more severe respiratory acidosis leading to cardiac arrhythmias has been reported.¹⁴ Hypercarbia also causes tachycardia and increased systemic vascular resistance, which elevates blood pressure and increases myocardial oxygen demand.^{11,14}

The pressure effects of the pneumoperitoneum on cardiovascular physiology also have been studied. In the hypovolemic individual, excessive pressure on the inferior vena cava and a reverse Trendelenburg position with loss of lower extremity muscle tone may cause decreased venous return and decreased cardiac output.^{11,15} This is not seen in the normovolemic patient. The most common arrhythmia created by laparoscopy is bradycardia. A rapid stretch of the peritoneal membrane often causes a vagovagal response with bradycardia and, occasionally, hypotension.¹⁶ The appropriate management of this event is desufflation of the abdomen, administration of vagolytic agents (e.g., atropine), and adequate volume replacement.¹⁷

With the increased intra-abdominal pressure compressing the inferior vena cava, there is diminished venous return from the lower extremities. This has been well documented in the patient placed in the reverse Trendelenburg position for upper abdominal operations. Venous engorgement and decreased venous return promote venous thrombosis.^{18,19} Many series of advanced laparoscopic procedures in which deep venous thrombosis (DVT) prophylaxis was not used demonstrate the frequency of pulmonary embolus. This usually is an avoidable complication with the use of sequential compression stockings, subcutaneous heparin, or low molecular weight heparin.²⁰ In short-duration laparoscopic procedures, such as appendectomy, hernia repair, or cholecystectomy, the risk of DVT may not be sufficient to warrant extensive DVT prophylaxis.

The increased pressure of the pneumoperitoneum is transmitted directly across the paralyzed diaphragm to the thoracic cavity, creating increased central venous pressure and increased filling pressures of the right and left sides of the heart. If the intra-abdominal pressures are kept under 20 mmHg, the cardiac output usually is well maintained.^{19–21} The direct effect of the pneumoperitoneum on increasing intrathoracic pressure increases peak inspiratory pressure, pressure across the chest wall, and also, the likelihood of barotrauma. Despite these concerns, disruption of blebs and consequent pneumothoraces are rare after uncomplicated laparoscopic surgery.²¹ Pneumothoraces occurring with laparoscopic esophageal surgery may be very significant. The pathophysiology and management are

discussed at the end of this section. Increased intra-abdominal pressure decreases renal blood flow, glomerular filtration rate, and urine output. These effects may be mediated by direct pressure on the kidney and the renal vein.^{22,23} The secondary effect of decreased renal blood flow is to increase plasma renin release, thereby increasing sodium retention. Increased circulating antidiuretic hormone levels also are found during the pneumoperitoneum, increasing free water reabsorption in the distal tubules.²⁴ Although the effects of the pneumoperitoneum on renal blood flow are immediately reversible, the hormonally mediated changes such as elevated antidiuretic hormone levels decrease urine output for up to 1 hour after the procedure has ended. Intraoperative oliguria is common during laparoscopy, but the urine output is not a reflection of intravascular volume status; IV fluid administration during an uncomplicated laparoscopic procedure should not be linked to urine output. Because insensible fluid losses through the open abdomen are eliminated with laparoscopy, the need for supplemental fluid during a laparoscopic surgical procedure should only keep up with venous pooling in the lower limbs, third-space losses into the bowel, and blood loss, which is generally less than occurs with an equivalent open operation.

The hemodynamic and metabolic consequences of pneumoperitoneum are well tolerated by healthy individuals for a prolonged period and by most individuals for at least a short period. Difficulties can occur when a patient with compromised cardiovascular function is subjected to a long laparoscopic procedure. It is during these procedures that alternative approaches should be considered or insufflation pressure reduced. Alternative gases that have been suggested for laparoscopy include the inert gases helium, neon, and argon. These gases are appealing because they cause no metabolic effects, but are poorly soluble in blood (unlike CO₂ and N₂O) and are prone to create gas emboli if the gas has direct access to the venous system.¹⁹ Gas emboli are rare but serious complications of laparoscopic surgery.^{20,25} They should be suspected if hypotension develops during insufflation. Diagnosis may be made by listening (with an esophageal stethoscope) for the characteristic "mill wheel" murmur. The treatment of gas embolism is to place the patient in a left lateral decubitus position with the head down to trap the gas in the apex of the right ventricle.²⁰ A rapidly placed central venous catheter then can be used to aspirate the gas out of the right ventricle.

In some situations, minimally invasive abdominal surgery should be performed without insufflation. This has led to the development of an abdominal lift device that can be placed through a 10- to 12-mm trocar at the umbilicus.²⁶ These devices have the advantage of creating little physiologic derangement, but they are bulky and intrusive. The exposure and working room offered by lift devices also are inferior to those accomplished by pneumoperitoneum. Lifting the anterior abdominal wall causes a "pinching in" of the lateral flank walls, displacing the bowel medially and anteriorly into the operative field. A pneumoperitoneum, with its well-distributed intra-abdominal pressure, provides better exposure. Abdominal lift devices also cause more postoperative pain, but they do allow the performance of MIS with standard (nonlaparoscopic) surgical instruments.

Endocrine responses to laparoscopic surgery are not always intuitive. Serum cortisol levels after laparoscopic operations are often higher than after the equivalent operation performed through an open incision.²⁷ The greatest difference between the endocrine response of open and laparoscopic surgery is the more rapid equilibration of most stress-mediated hormone levels after laparoscopic surgery. Immune suppression also is less after laparoscopy than after open surgery. There is a trend toward more rapid normalization of cytokine levels after a laparoscopic procedure than after the equivalent procedure performed by celiotomy.²⁸

Transhiatal mobilization of the distal esophagus is commonly performed as a component of many laparoscopic upper abdominal procedures. If there is compromise of the mediastinal pleura with resultant CO₂ pneumothorax, the defect should be enlarged so as to prevent a tension pneumothorax. Even with such a strategy, tension pneumothorax may develop, as mediastinal structures may seal the hole during inspiration, allowing the chest to fill during expiration. In addition to enlargement of the hole, a thoracostomy tube (chest tube) should be placed across the breach into the abdomen with intra-abdominal pressures reduced below 8 mmHg, or a standard chest tube may be placed. When a pneumothorax occurs with laparoscopic Nissen fundoplication or Heller myotomy, it is preferable to place an 18 F red rubber catheter with multiple side holes cut out of the distal end across the defect. At the end of the procedure, the distal end of the tube is pulled out a 10-mm port site (as the port is removed), and the pneumothorax is evacuated to a primitive water seal using a bowl of sterile water or saline. During laparoscopic esophagectomy, it is preferable to leave a standard chest tube, as residual intra-abdominal fluid will tend to be siphoned through the defect postoperatively, if the tube is removed at the end of the case.

Thoracoscopy

The physiology of thoracic MIS (thoracoscopy) is different from that of laparoscopy. Because of the bony confines of the thorax, it is unnecessary to use positive pressure when working in the thorax.²⁹ The disadvantages of positive pressure in the chest include decreased venous return, mediastinal shift, and the need to keep a firm seal at all trocar sites. Without positive pressure, it is necessary to place a double-lumen endotracheal tube so that the ipsilateral lung can be deflated when the operation starts. By collapsing the ipsilateral lung, working space within the thorax is obtained. Because insufflation is unnecessary in thoracoscopic surgery, it can be beneficial to use standard instruments via extended port sites in conjunction with thoracoscopic instruments. This approach is particularly useful when performing advanced procedures such as thoracoscopic anatomic pulmonary resection.

Extracavitary Minimally Invasive Surgery

Many MIS procedures create working spaces in extrathoracic and extraperitoneal locations. Laparoscopic inguinal hernia repair usually is performed in the anterior extraperitoneal Retzius space.^{30,31} Laparoscopic nephrectomy often is performed with retroperitoneal laparoscopy. Endoscopic retroperitoneal approaches to pancreatic necrosectomy have seen some limited use.³² Lower extremity vascular procedures and plastic surgical endoscopic procedures require the development of working space in unconventional planes, often at the level of the fascia, sometimes below the fascia, and occasionally in nonanatomic regions.³³ Some of these techniques use insufflation of gas, but many use balloon inflation to develop the space, followed by low-pressure gas insufflation or lift devices to maintain the space (Fig. 14-2). These techniques produce fewer and less severe adverse physiologic consequences than does the pneumoperitoneum, but the insufflation of carbon dioxide into extraperitoneal locations can spread widely, causing subcutaneous emphysema and metabolic acidosis.

Balloons are used to create extra-anatomic working spaces. In this example (**A** through **C**), a balloon is introduced into the space between the posterior rectus sheath and the rectus abdominal muscle. The balloon is inflated in the preperitoneal space to create working room for extraperitoneal endoscopic hernia repair.

Anesthesia

Proper anesthesia management during laparoscopic surgery requires a thorough knowledge of the pathophysiology of the CO₂ pneumoperitoneum.¹⁷ The laparoscopic surgeon can influence cardiovascular performance by reducing or removing the CO₂ pneumoperitoneum. Insensible fluid losses are negligible, and therefore, IV fluid administration should not exceed that necessary to maintain circulating volume. MIS procedures are often outpatient procedures, so short-acting anesthetic agents are preferable. Because the factors that require hospitalization after laparoscopic procedures include the management of nausea, pain, and urinary retention, the anesthesiologist should minimize the use of agents that provoke these conditions and maximize the use of medications that prevent such problems. Critical to the anesthesia management of these patients is the use of nonnarcotic analgesics (e.g., ketorolac) when hemostasis allows it, and the liberal use of antiemetic agents, including ondansetron and steroids.

The Minimally Invasive Team

From the beginning, the tremendous success of MIS was founded on the understanding that a team approach was necessary. The many laparoscopic procedures performed daily range from basic to advanced complexity, and require that the surgical team have an intimate understanding of the operative conduct (Table 14-1). Minimally invasive procedures require complicated and fragile equipment that demands constant maintenance. In addition, multiple intraoperative adjustments to the equipment, camera, insufflator, monitors, and patient/surgeon position are made during these procedures. As such, a coordinated team approach is mandated to ensure patient safety and excellent outcomes. More and more, flexible endoscopes are used to guide or provide quality control for laparoscopic procedures. As NOTES evolves, hybrid procedures (laparoscopy and endoscopy) and sophisticated NOTES technology will require a nursing staff capable of maintaining flexible endoscopes and understanding the operation of sophisticated endoscopic technology.

Table 14-1 Laparoscopic Surgical Procedures	
Basic	Advanced
Appendectomy	Nissen fundoplication
Cholecystectomy	Heller myotomy
Hernia repair	Gastrectomy
	Esophagectomy
	Enteral access
	Bile duct exploration
	Colectomy
	Splenectomy
	Adrenalectomy
	Nephrectomy
	Lymph node dissection
	Robotics
	Stereo imaging
	Telemedicine
	Laparoscopy-assisted procedures
	Hepatectomy
	Pancreatectomy
	Prostatectomy
	Hysterectomy

A typical MIS team may consist of a laparoscopic surgeon and an operating room (OR) nurse with an interest in laparoscopic and endoscopic surgery. Adding dedicated assistants and circulating staff with an intimate knowledge of the equipment will add to and enhance the team nucleus. Studies have demonstrated that having a designated laparoscopic team increases the efficiency and safety of laparoscopic surgery, which is translated into a benefit for patient and hospital.³⁴

Room Setup and the Minimally Invasive Suite

Nearly all MIS, whether using fluoroscopic, ultrasound, or optical imaging, incorporates a video monitor as a guide. Occasionally, two images are necessary to adequately guide the operation, as in procedures such as endoscopic retrograde cholangiopancreatography, laparoscopic common bile duct exploration, and laparoscopic ultrasonography. When two images are necessary, the images should be displayed on two adjacent video monitors or projected on a single screen with a picture-in-picture effect. The video monitor(s) should be set across the operating table from the surgeon. The patient should be interposed between the surgeon and the video monitor; ideally, the operative field also lies between the surgeon and the monitor. In pelviscopic surgery it is best to place the video monitor at the patient's feet, and in laparoscopic cholecystectomy, the monitor is placed at the 10 o'clock position (relative to the patient) while the

surgeon stands on the patient's left at the 4 o'clock position. The insufflating and patient-monitoring equipment ideally also is placed across the table from the surgeon, so that the insufflating pressure and the patient's vital signs and end-tidal CO₂ tension can be monitored.

The development of the minimally invasive surgical suite has been a tremendous contribution to the field of laparoscopy in that it has facilitated the performance of advanced procedures and techniques (Fig. 14-3). By having the core equipment (monitors, insufflators, and imaging equipment) located within mobile, ceiling-mounted consoles, the surgery team is able to accommodate and make small adjustments rapidly and continuously throughout the procedure. The specifically designed minimally invasive surgical suite serves to decrease equipment and cable disorganization, ease the movements of operative personnel around the room, improve ergonomics, and facilitate the use of advanced imaging equipment such as laparoscopic ultrasound.³⁵ Although having a minimally invasive surgical suite available is very useful, it is not essential to successfully carry out advanced laparoscopic procedures.

Fig. 14-3.

An example of a typical minimally invasive surgery suite. All core equipment is located on easily movable consoles.

Patient Positioning

Patients usually are placed in the supine position for laparoscopic surgery. When the operative field is the gastroesophageal junction or the left lobe of the liver, it is easiest to operate from between the legs. The legs may be elevated in Allen stirrups or abducted on leg boards to achieve this position. When pelvic procedures are performed, it usually is necessary to place the legs in Allen stirrups to gain access to the perineum. A lateral decubitus position with the table flexed provides the best access to the retroperitoneum when performing nephrectomy or adrenalectomy. For laparoscopic splenectomy, a 45°-tilt of the patient provides excellent access to the lesser sac and the lateral peritoneal attachments to the spleen. For thoracoscopic surgery, the patient is placed in the lateral position with table flexion to open the intercostal spaces and the distance between the iliac crest and costal margin (Fig. 14-4).

Fig. 14-4.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Proper padding and protection of pressure points is an essential consideration in laparoscopic and thoracoscopic approaches. In preparation for thoracoscopy, this patient is placed in left lateral decubitus position with the table flexed, which serves to open the intercostal spaces and increase the distance between the iliac crest and the inferior costal margin.

When the patient's knees are to be bent for extended periods or the patient is going to be placed in a reverse Trendelenburg position for more than a few minutes, DVT prophylaxis should be used. Sequential compression of the lower extremities during prolonged (>90 minutes) laparoscopic procedures increases venous return and provides inhibition of thromboplastin activation.

General Principles of Access

The most natural ports of access for MIS and NOTES are the anatomic portals of entry and exit. The nares, mouth, urethra, and anus are used to access the respiratory, GI, and urinary systems. The advantage of using these points of access is that no incision is required. The disadvantages lie in the long distances between the orifice and the region of interest. For NOTES procedures, the vagina may serve as another point of access, entering the abdomen via the posterior cul-de-sac of the pelvis. Similarly, the peritoneal cavity may be reached through the side wall of the stomach or colon.

Access to the vascular system may be accomplished under local anesthesia by cutting down and exposing the desired vessel, usually in the groin. Increasingly, vascular access is obtained with percutaneous techniques using a small incision, a needle, and a guidewire, over which are passed a variety of different sized access devices. This approach, known as the *Seldinger technique*, is most frequently used by general surgeons for placement of Hickman catheters, but also is used to gain access to the arterial and venous system for performance of minimally invasive procedures. Guidewire-assisted, Seldinger-type techniques also are helpful for gaining access to the gut for procedures such as PEG, for gaining access to the biliary system through the liver, and for gaining access to the upper urinary tract.

In thoracoscopic surgery, the access technique is similar to that used for placement of a chest tube. In these procedures general anesthesia and single lung ventilation are essential. A small incision is made over the top of a rib and, under direct vision, carried down through the pleura. The lung is collapsed, and a trocar is inserted across the chest wall to allow access with a telescope. Once the lung is completely collapsed, subsequent access may be obtained with direct puncture, viewing all entry sites through the videoendoscope. Because insufflation of the chest is unnecessary, simple ports that keep the small incisions open are all that is required to allow repeated access to the thorax.

Laparoscopic Access

The requirements for laparoscopy are more involved, because the creation of a pneumoperitoneum requires that instruments of access (trocars) contain valves to maintain abdominal inflation.

Two methods are used for establishing abdominal access during laparoscopic procedures.^{36,37} The first, direct puncture laparoscopy, begins with the elevation of the relaxed abdominal wall with two towel clips or a well-placed hand. A small incision is made in the umbilicus, and a specialized spring-loaded (Veress) needle is placed in the abdominal cavity (Fig. 14-5). With the Veress needle, two distinct pops are felt as the surgeon passes the needle through the abdominal wall fascia and the peritoneum. The umbilicus usually is selected as the preferred point of access because, in this location, the abdominal wall is quite thin, even in obese patients. The abdomen is inflated with a pressure-limited insufflator. CO₂ gas usually is used, with maximal pressures in the range of 14 to 15 mmHg. During the process of insufflation, it is essential that the surgeon observe the pressure and flow readings on the monitor to confirm an intraperitoneal location of the Veress needle tip (Fig. 14-6). Laparoscopic surgery can be performed under local anesthesia, but general anesthesia is preferable. Under local anesthesia, N₂O is used as the insufflating agent, and insufflation is stopped after 2 L of gas is insufflated or when a pressure of 10 mmHg is reached.

Fig. 14-5.

It is essential to be able to interpret the insufflator pressure readings and flow rates. These readings indicate proper intraperitoneal placement of the Veress needle.

After peritoneal insufflation, direct access to the abdomen is obtained with a 5- or 10-mm trocar. The critical issues for safe direct-puncture laparoscopy include the use of a vented stylet for the trocar, or a trocar with a safety shield or dilating tip. The trocar must be

pointed away from the sacral promontory and the great vessels.³⁸ Patient position should be surveyed before trocar placement to ensure a proper trajectory. For performance of laparoscopic cholecystectomy, the trocar is angled toward the right upper quadrant.

Occasionally, the direct peritoneal access (Hasson) technique is advisable.³⁹ With this technique, the surgeon makes a small incision just below the umbilicus and under direct vision locates the abdominal fascia. Two Kocher clamps are placed on the fascia, and with curved Mayo scissors, a small incision is made through the fascia and underlying peritoneum. A finger is placed into the abdomen to make sure that there is no adherent bowel. A sturdy suture is placed on each side of the fascia and secured to the wings of a specialized trocar, which is then passed directly into the abdominal cavity (Fig. 14-7). Rapid insufflation can make up for some of the time lost with the initial dissection. This technique is preferable for the abdomen of patients who have undergone previous operations in which small bowel may be adherent to the undersurface of the abdominal wound. The close adherence of bowel to the peritoneum in the previously operated abdomen does not eliminate the possibility of intestinal injury but should make great vessel injury extremely unlikely. Because of the difficulties in visualizing the abdominal region immediately adjacent to the primary trocar, it is recommended that the telescope be passed through a secondary trocar to inspect the site of initial abdominal access.³⁷ Secondary punctures are made with 5- and 10-mm trocars. For safe access to the abdominal cavity, it is critical to visualize all sites of trocar entry.^{38,39} At the completion of the operation, all trocars are removed under direct vision, and the insertion sites are inspected for bleeding. If bleeding occurs, direct pressure with an instrument from another trocar site or balloon tamponade with a Foley catheter placed through the trocar site generally stops the bleeding within 3 to 5 minutes. When this is not successful, a full-thickness abdominal wall suture has been used successfully to tamponade trocar site bleeding.

Fig. 14-7.

The open laparoscopy technique involves identification and incision of the peritoneum, followed by the placement of a specialized trocar with a conical sleeve to maintain a gas seal. Specialized wings on the trocar are attached to sutures placed through the fascia to prevent loss of the gas seal.

It is generally agreed that 5-mm trocars need no site suturing. Ten-millimeter trocars placed off the midline and above the transverse mesocolon do not require repair. Conversely, if the fascia has been dilated to allow the passage of the gallbladder or other organ, it should be repaired at the fascial level with interrupted sutures. The port site may be closed with suture delivery systems similar to crochet needles enabling mass closure of the abdominal wall. This is especially helpful in obese patients where direct fascial closure may

be challenging, through a small skin incision. Failure to close lower abdominal trocar sites that are 10 mm in diameter or larger can lead to an incarcerated hernia.

Access for Subcutaneous and Extraperitoneal Surgery

There are two methods for gaining access to nonanatomic spaces. For retroperitoneal locations, balloon dissection is effective. This access technique is appropriate for the extraperitoneal repair of inguinal hernias and for retroperitoneal surgery for adrenalectomy, nephrectomy, lumbar discectomy, pancreatic necrosectomy, or para-aortic lymph node dissection.^{40,41} The initial access to the extraperitoneal space is performed in a way similar to direct puncture laparoscopy, except that the last layer (the peritoneum) is not traversed. Once the transversalis fascia has been punctured, a specialized trocar with a balloon on the end is introduced. The balloon is inflated in the extraperitoneal space to create a working chamber. The balloon then is deflated and a Hasson trocar is placed. An insufflation pressure of 10 mmHg usually is adequate to keep the extraperitoneal space open for dissection and will limit subcutaneous emphysema. Higher gas pressures force CO₂ into the soft tissues and may contribute to hypercarbia. Extraperitoneal endosurgery provides less working space than laparoscopy but eliminates the possibility of intestinal injury, intestinal adhesion, herniation at the trocar sites, and ileus. These issues are important for laparoscopic hernia repair because extraperitoneal approaches prevent the small bowel from sticking to the prosthetic mesh.³¹

Subcutaneous surgery has been most widely used in cardiac, vascular, and plastic surgery.³³ In cardiac surgery, subcutaneous access has been used for saphenous vein harvesting, and in vascular surgery for ligation of subfascial perforating veins (Linton procedure). With minimally invasive techniques, the entire saphenous vein above the knee may be harvested through a single incision^{42,43} (Fig. 14-8). Once the saphenous vein is located, a long retractor that holds a 5-mm laparoscope allows the coaxial dissection of the vein and coagulation or clipping of each side branch. A small incision above the knee also can be used to ligate perforating veins in the lower leg.

Fig. 14-8.

A. With two small incisions, virtually the entire saphenous vein can be harvested for bypass grafting. **B.** The lighted retractor in the subcutaneous space during saphenous vein harvest is seen illuminating the skin.

[Reproduced with permission from Jones GE, Eaves FE III, Howell RL et al: Harvest of muscle, nerve, fascia, and vein, in Bostwick J III, Eaves FE III, Nahai F (eds): *Endoscopic Plastic Surgery*. St Louis: Quality Medical Publishing, Inc., 1995, p 542.]

Subcutaneous access also is used for plastic surgery procedures.⁴³ Minimally invasive approaches are especially well suited to cosmetic surgery, in which attempts are made to hide the incision. It is easier to hide several 5-mm incisions than one long incision. The technique of blunt dissection along fascial planes combined with lighted retractors and endoscope-holding retractors is most successful for extensive subcutaneous surgery. Some prefer gas insufflation of these soft tissue planes. The primary disadvantage of soft tissue insufflation is that subcutaneous emphysema can be created.

Hand-Assisted Laparoscopic Access

Hand-assisted laparoscopic surgery is thought to combine the tactile advantages of open surgery with the minimal access of laparoscopy and thoracoscopy. This approach commonly is used to assist with difficult cases before conversion to celiotomy is necessary. Additionally, hand-assisted laparoscopic surgery is used to help surgeons negotiate the steep learning curve associated with advanced laparoscopic procedures.⁴⁴ This technology uses a "port" for the hand that preserves the pneumoperitoneum and enables endoscopic visualization in combination with the use of minimally invasive instruments (Fig. 14-9). Formal investigation of this modality has been limited primarily to case reports and small series, and has focused primarily on solid organ and colon surgery.

Fig. 14-9.

This is an example of hand-assisted laparoscopic surgery during left colectomy. The surgeon uses a hand to provide retraction and counter tension during mobilization of the colon from its retroperitoneal attachments, as well as during division of the mesocolon. This technique is particularly useful in the region of the transverse colon.

Intraperitoneal, intrathoracic, and retroperitoneal access for robotic surgery adheres to the principles of laparoscopic and thoracoscopic access; however, the port size for the primary puncture is 12 mm to allow placement of the stereo laparoscope.

Port Placement

Trocars for the surgeon's left and right hand should be placed at least 10 cm apart. For most operations, it is possible to orient the telescope between these two trocars and slightly back from them. The ideal trocar orientation creates an equilateral triangle between the surgeon's right hand, left hand, and the telescope, with 10 to 15 cm on each leg. If one imagines the target of the operation (e.g., the gallbladder or gastroesophageal junction) oriented at the apex of a second equilateral triangle built on the first, these four points of reference create a diamond (Fig. 14-10). The surgeon stands behind the telescope, which provides optimal ergonomic orientation but frequently requires that a camera operator (or mechanical camera holder) reach between the surgeon's hands to guide the telescope.

Fig. 14-10.

THE DIAMOND OF SUCCESS

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

The diamond configuration created by placing the telescope between the left and the right hand, recessed from the target by about 15 cm. The distance between the left and the right hand is also ideally 10 to 15 cm. In this "baseball diamond" configuration, the surgical target occupies the second base position.

The position of the operating table should permit the surgeon to work with both elbows in at the sides, with arms bent 90° at the elbow.⁴⁵ It usually is necessary to alter the operating table position with left or right tilt with the patient in the Trendelenburg or reverse Trendelenburg position, depending on the operative field.^{46,47}

Imaging Systems

Two methods of videoendoscopic imaging are widely used. Both methods use a camera with a CCD, which is an array of photosensitive sensor elements (pixels) that convert the incoming light intensity to an electric charge. The electric charge is subsequently converted into a black-and-white image.⁴⁸

With videoendoscopy, the CCD chip is placed on the internal end of a long, flexible endoscope. With older flexible endoscopes, thin quartz fibers are packed together in a bundle, and the CCD camera is mounted on the external end of the endoscope. Most standard GI endoscopes have the CCD chip at the distal end, but small, delicate choledochoscopes and nephroscopes are equipped with fiber-optic bundles.⁴⁹ Distally mounted CCD chips were developed for laparoscopy as well but have not become popular.

Video cameras come in two basic designs. Nearly all laparoscopic cameras contain a red, green, and blue input, and are identical to the color cameras used for television production.⁴⁸ An additional feature of many video cameras is digital enhancement. Digital enhancement detects edges, areas where there are drastic color or light changes between two adjacent pixels.⁵⁰ By enhancing this difference, the image appears sharper and surgical resolution is improved. New laparoscopic cameras contain a high-definition (HD) chip which increases the lines of resolution from 480 to 1080 lines. To enjoy the benefit of the clarity of HD video imaging, HD monitors also are necessary. Although this technology will inevitably replace more standard video imaging, it is not clear that the safety or efficiency of laparoscopic surgery is benefited by HD video imaging.

Priorities in a video imaging system for MIS are illumination first, resolution second, and color third. Without the first two attributes, video surgery is unsafe. Illumination and resolution are as dependent on the telescope, light source, and light cable as on the video camera used. Imaging for laparoscopy, thoracoscopy, and subcutaneous surgery uses a rigid metal telescope, usually 30 cm in length. Longer telescopes are available for obese patients and for reaching the mediastinum and deep in the pelvis from a periumbilical entry site. The standard telescope contains a series of quartz optical rods and focusing lenses.⁵¹ Telescopes vary in size from 2 to 12 mm in

diameter. Because light transmission is dependent on the cross-sectional area of the quartz rod, when the diameter of a rod/lens system is doubled, the illumination is quadrupled. Little illumination is needed in highly reflective, small spaces such as the knee, and a very small telescope will suffice. When working in the abdominal cavity, especially if blood is present, the full illumination of a 10-mm telescope usually is necessary.

Rigid telescopes may have a flat or angled end. The flat end provides a straight view (0°), and the angled end provides an oblique view (30 or 45°).⁴⁸ Angled telescopes allow greater flexibility in viewing a wider operative field through a single trocar site (Fig. 14-11); rotating an angled telescope changes the field of view. The use of an angled telescope has distinct advantages for most videoendoscopic procedures, particularly in visualizing the common bile duct during laparoscopic cholecystectomy or visualizing the posterior esophagus or the tip of the spleen during laparoscopic fundoplication.

Fig. 14-11.

Source: Brunicaardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

The laparoscope tips come in a variety of angled configurations. All laparoscopes have a 70° field of view. A 30° -angled scope enables the surgeon to view this field at a 30° angle to the long axis of the scope.

Light is delivered to the endoscope through a fiber-optic light cable. These light cables are highly inefficient, losing $>90\%$ of the light delivered from the light source. Extremely bright light sources (300 watts) are necessary to provide adequate illumination for laparoscopic surgery.

The quality of the videoendoscopic image is only as good as the weakest component in the imaging chain (Fig. 14-12). Therefore, it is important to use a video monitor that has a resolution equal to or greater than the camera being used.⁵¹ *Resolution* is the ability of the optical system to distinguish between line pairs. The larger the number of line pairs per millimeter, the sharper and more detailed the image. Most high-resolution monitors have up to 700 horizontal lines. High-definition television can deliver up to eight times more resolution than standard monitors; when combined with digital enhancement, a very sharp and well-defined image can be achieved.^{48,51} A heads-up display is a high-resolution liquid crystal monitor that is built into eyewear worn by the surgeon.⁵² This technology allows the surgeon to view the endoscopic image and operative field simultaneously. The proposed advantages of heads-up display include a high-resolution monocular image, which affords the surgeon mobility and reduces vertigo and eyestrain. However, this technology has not yet been widely adopted.

Interest in three-dimensional (3-D) laparoscopy has waxed and waned. 3-D laparoscopy provides the additional depth of field that is lost with two-dimensional endosurgery and improves performance of novice laparoscopists performing complex tasks of dexterity, including suturing and knot tying.⁵³ The advantages of 3-D systems are less obvious to experienced laparoscopists. Additionally, because 3-D systems require the flickering of two similar images, which are resolved with special glasses, the images' edges become fuzzy and resolution is lost. The optical accommodation necessary to rectify these slightly differing images is tiring and may induce headaches when one uses these systems for a long period of time. The da Vinci robot uses a specialized laparoscope with two optical bundles on opposite sides of the telescope. A specialized binocular eyepiece receives input from two CCD chips, each capturing the image from one of the two quartz rod lens systems, thereby creating true 3-D imaging without using the "tricks" that have made 3-D laparoscopy so disappointing.

Energy Sources for Endoscopic and Endoluminal Surgery

Many MIS procedures use conventional energy sources, but the benefits of bloodless surgery to maintain optimal visualization has spawned new ways of applying energy. The most common energy source is RF electrosurgery using an alternating current with a frequency of 500,000 cycles/s (Hz). Tissue heating progresses through the well-known phases of coagulation [60°C (140°F)], vaporization and desiccation [100°C (212°F)], and carbonization [>200°C (392°F)].⁵⁴

The two most common methods of delivering RF electrosurgery are with monopolar and bipolar electrodes. With monopolar electrosurgery, a remote ground plate on the patient's leg or back receives the flow of electrons that originate at a point source, the surgical electrode. A fine-tipped electrode causes a high current density at the site of application and rapid tissue heating. Monopolar electrosurgery is inexpensive and easy to modulate to achieve different tissue effects.⁵⁵ A short-duration, high-voltage discharge of

current (coagulation current) provides extremely rapid tissue heating. Lower-voltage, higher-wattage current (cutting current) is better for tissue desiccation and vaporization. When the surgeon desires tissue division with the least amount of thermal injury and least coagulation necrosis, a cutting current is used.

With bipolar electrosurgery, the electrons flow between two adjacent electrodes. The tissue between the two electrodes is heated and desiccated. There is little opportunity for tissue cutting when bipolar current is used, but the ability to coapt the electrodes across a vessel provides the best method of small-vessel coagulation without thermal injury to adjacent tissues⁵⁶ (Fig. 14-13).

Fig. 14-13.

An example of bipolar coagulation devices. The flow of electrons passes from one electrode to the other, and the intervening tissue is heated and desiccated.

To avoid thermal injury to adjacent structures, the laparoscopic field of view must include all uninsulated portions of the electrosurgical electrode. In addition, the integrity of the insulation must be maintained and assured. Capacitive coupling occurs when a plastic trocar insulates the abdominal wall from the current; in turn, the current is bled off of a metal sleeve or laparoscope into the viscera⁵⁴ (Fig. 14-14A). This may result in thermal necrosis and a delayed fecal fistula. Another potential mechanism for unrecognized visceral injury may occur with the direct coupling of current to the laparoscope and adjacent bowel⁵⁴ (Fig. 14-14B).

Fig. 14-14.

A. Capacitive coupling occurs as a result of high current density bleeding from a port sleeve or laparoscope into adjacent bowel. **B.** Direct coupling occurs when current is transmitted directly from the electrode to a metal instrument or laparoscope, and then into adjacent tissue.

(Reproduced with permission from Odell.⁵⁴)

Another method of delivering RF electrosurgery is argon beam coagulation. This is a type of monopolar electrosurgery in which a uniform field of electrons is distributed across a tissue surface by the use of a jet of argon gas. The argon gas jet distributes electrons more evenly across the surface than does spray electrofulguration. This technology has its greatest application for coagulation of diffusely bleeding surfaces such as the cut edge of liver or spleen. It is of less value in laparoscopic procedures because the increased intra-abdominal pressures created by the argon gas jet can increase the chances of a gas embolus. It is paramount to vent the ports and closely monitor insufflation pressure when using this source of energy within the context of laparoscopy.

With endoscopic endoluminal surgery, RF alternating current in the form of a monopolar circuit represents the mainstay for procedures such as snare polypectomy, sphincterotomy, lower esophageal sphincter ablation, and "hot" biopsy.^{57,58} A grounding ("return") electrode is necessary for this form of energy. Bipolar electrocoagulation is used primarily for thermal hemostasis. The electrosurgical generator is activated by a foot pedal so the endoscopist may keep both hands free during the endoscopic procedure.

Gas, liquid, and solid-state lasers have been available for medical application since the mid-1960s.⁵⁹ The CO₂ laser (wavelength 10.6 μ m) is most appropriately used for cutting and superficial ablation of tissues. It is most helpful in locations unreachable with a scalpel such as excision of vocal cord granulomas. The CO₂ laser beam must be delivered with a series of mirrors and is therefore somewhat cumbersome to use. The next most popular laser is the neodymium yttrium-aluminum garnet (Nd:YAG) laser. Nd:YAG laser light is 1.064 μ m (1064 nm) in wavelength. It is in the near-infrared portion of the spectrum, and, like CO₂ laser light, is invisible to the naked eye. A unique feature of the Nd:YAG laser is that 1064-nm light is poorly absorbed by most tissue pigments and therefore travels deep into tissue.⁶⁰ Deep tissue penetration provides deep tissue heating (Fig. 14-15). For this reason, the Nd:YAG laser is capable of the greatest amount of tissue destruction with a single application.⁵⁹ Such capabilities make it the ideal laser for destruction of large fungating tumors of the rectosigmoid, tracheobronchial tree, or esophagus. A disadvantage is that the deep tissue heating may cause perforation of

a hollow viscus.

Fig. 14-15.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery*, 9th Edition: <http://www.accessmedicine.com>

This graph shows the absorption of light by various tissue compounds (water, melanin, and oxyhemoglobin) as a function of the wavelength of the light. The nadir of the oxyhemoglobin and melanin curves is close to 1064 nm, the wavelength of the neodymium yttrium-aluminum garnet laser.

[Reproduced with permission from Hunter JG, Sackier JM (eds): *Minimally Invasive Surgery*. New York: McGraw-Hill, 1993, p 28.]

When it is desirable to coagulate flat lesions in the cecum, a different laser should be chosen. The frequency-doubled Nd:YAG laser, also known as the *KTP laser* (potassium thionyl phosphate crystal is used to double the Nd:YAG frequency), provides 532-nm light. This is in the green portion of the spectrum, and at this wavelength, selective absorption by red pigments in tissue (such as hemangiomas and arteriovenous malformations) is optimal. The depth of tissue heating is intermediate, between those of the CO_2 and the Nd:YAG lasers. Coagulation (without vaporization) of superficial vascular lesions can be obtained without intestinal perforation.⁶⁰

In flexible GI endoscopy, the CO_2 and Nd:YAG lasers have largely been replaced by heater probes and endoluminal stents. The heater probe is a metal ball that is heated to a temperature [60 to 100°C (140 to 212°F)] that allows coagulation of bleeding lesions without perforation.

Photodynamic therapy is a palliative treatment for obstructing cancers of the GI tract.⁶¹ Patients are given an IV dose of porfimer sodium, which is a photosensitizing agent that is taken up by malignant cells. Two days after administration, the drug is endoscopically activated using a laser. The activated porfimer sodium generates oxygen free radicals, which kill the tumor cells. The tumor is later endoscopically débrided. The use of this modality for definitive treatment of early cancers is in experimental phases and has yet to become established.

A unique application of laser technology provides extremely rapid discharge ($<10^{-6}$ s) of large amounts of energy ($>10^3$ volts). These high-energy lasers, of which the pulsed dye laser has seen the most clinical use, allow the conversion of light energy to mechanical disruptive energy in the form of a shock wave. Such energy can be delivered through a quartz fiber, and with rapid repetitive discharges, can provide sufficient shock-wave energy to fragment kidney stones and gallstones.⁶² Shock waves also may be created with miniature electric spark-plug discharge systems known as *electrohydraulic lithotriptors*. These devices also are inserted through thin probes for endoscopic application. Lasers have the advantage of pigment selectivity, but electrohydraulic lithotriptors are more popular because they

are substantially less expensive and are more compact.

Methods of producing shock waves or heat with ultrasonic energy are also of interest. Extracorporeal shockwave lithotripsy creates focused shock waves that intensify as the focal point of the discharge is approached. When the focal point is within the body, large amounts of energy are capable of fragmenting stones. Slightly different configurations of this energy can be used to provide focused internal heating of tissues. Potential applications of this technology include the ability to noninvasively produce sufficient internal heating to destroy tissue without an incision.

A third means of using ultrasonic energy is to create rapidly oscillating instruments that are capable of heating tissue with friction; this technology represents a major step forward in energy technology.⁶³ An example of its application is the laparoscopic coagulation shears device (Harmonic Scalpel), which is capable of coagulating and dividing blood vessels by first occluding them and then providing sufficient heat to weld the blood vessel walls together and to divide the vessel. This nonelectric method of coagulating and dividing tissue with a minimal amount of collateral damage has facilitated the performance of numerous endosurgical procedures.⁶⁴ It is especially useful in the control of bleeding from medium-sized vessels that are too big to manage with monopolar electrocautery and require bipolar desiccation followed by cutting.

Instrumentation

Hand instruments for MIS usually are duplications of conventional surgical instruments made longer, thinner, and smaller at the tip. It is important to remember that when grasping tissue with laparoscopic instruments, a greater force is applied over a smaller surface area, which increases the risk for perforation or injury.⁶⁵

Certain conventional instruments such as scissors are easy to reproduce with a diameter of 3 to 5 mm and a length of 20 to 45 cm, but other instruments such as forceps and clamps cannot provide remote access. Different configurations of graspers were developed to replace the various configurations of surgical forceps and clamps. Standard hand instruments are 5 mm in diameter and 30 cm in length, but smaller and shorter hand instruments are now available for pediatric surgery, for microlaparoscopic surgery, and for arthroscopic procedures.⁶⁵ A unique laparoscopic hand instrument is the monopolar electrical hook. This device usually is configured with a suction and irrigation apparatus to eliminate smoke and blood from the operative field. The monopolar hook allows tenting of tissue over a bare metal wire with subsequent coagulation and division of the tissue.

Instrumentation for NOTES is still evolving, but many long micrograspers, microscissors, suturing devices, clip appliers, and visceral closure devices are evolving in design and application.

Robotic Surgery

The term *robot* defines a device that has been programmed to perform specific tasks in place of those usually performed by people. The devices that have earned the title "surgical robots" would be more aptly termed *computer-enhanced surgical devices*, as they are controlled entirely by the surgeon for the purpose of improving performance. The first computer-assisted surgical device was the laparoscopic camera holder (Aesop, Computer Motion, Goleta, Calif), which enabled the surgeon to maneuver the laparoscope either with a hand control, foot control, or voice activation (Fig. 14-16). Randomized studies with such camera holders demonstrated a reduction in operative time, steadier image, and a reduction in the number of required laparoscope cleanings.⁶⁶ This device had the advantage of eliminating the need for a human camera holder, which served to free valuable OR personnel for other duties. This technology has now been eclipsed by simpler systems using passive positioning of the camera with a mechanical arm, but the benefit of a steadier image and fewer members of the OR team remain.

Fig. 14-16.

Robotic instruments and hand controls. The surgeon is in a sitting position and the arms and wrists are in an ergonomic and relaxed position.

The "Big Bang" in robotic surgery was the development of a *master-slave* surgical platform that returned the wrist to laparoscopic surgery and improved manual dexterity by developing an ergonomically comfortable work station, with 3-D imaging, tremor elimination, and scaling of movement (e.g., large, gross hand movements can be scaled down to allow suturing with microsurgical precision) (see Fig. 14-16). The surgeon is physically separated from the operating table, and the working arms of the device are placed over the patient (Fig. 14-17). An assistant remains at the bedside and changes the instruments as needed, providing retraction as needed to facilitate the procedure. This "robotic" platform (da Vinci, Intuitive Surgical, Sunnyvale, Calif) was initially greeted with some skepticism by expert laparoscopists, as it was difficult to prove additional value for operations performed with the da Vinci robot. Not only were the operations longer, and the equipment more expensive, but additional quality could not be demonstrated. Two randomized controlled trials compared robotic and conventional laparoscopic approaches to Nissen fundoplication.^{67,68} In both these trials, the operative time was longer for robotic surgery, and there was no difference in ultimate outcome. Similar results were achieved for laparoscopic cholecystectomy.⁶⁹ Nevertheless, the increased dexterity provided by the da Vinci robot convinced many surgeons and health administrators that robotic platforms were worthy of investment, for marketing purposes if for no other reason.

Fig. 14-17.

Room setup and position of surgeon and assistant for robotic surgery.

The success story for computer-enhanced surgery with the da Vinci started with cardiac surgery and migrated to the pelvis. Mitral valve surgery, performed with right thoracoscopic access became one of the more popular procedures performed with "the robot."⁷⁰

The tidal wave of enthusiasm for robotic surgery came when most minimally invasive urologists declared robotic prostatectomy to be preferable to laparoscopic and open prostatectomy.⁷¹ The great advantage—it would appear—of robotic prostatectomy is the ability to visualize and spare the pelvic nerves responsible for erectile function. In addition, the creation of the neocystourethrotomy, following prostatectomy, was greatly facilitated by needle holders and graspers with a wrist in them. Female pelvic surgery with the "robot" also is picking up steam. The magnified imaging provided makes this approach ideal for microsurgical tasks such as reanastomosis of the Fallopian tubes.

The final frontier for computer-enhanced surgery is the promise of telesurgery, in which the surgeon is a great distance from the patient (e.g., combat or space). This application has rarely been used, as the safety provided by having the surgeon at bedside cannot be sacrificed to prove the concept. However, remote laparoscopic cholecystectomy has been performed when a team of surgeons located in New York performed a cholecystectomy on a patient located in France.⁷²

Endoluminal and Endovascular Surgery

The fields of vascular surgery, interventional radiology, neuroradiology, gastroenterology, general surgery, pulmonology, and urology all encounter clinical scenarios that require the urgent restoration of luminal patency of a "biologic cylinder." Based on this need, fundamental techniques have been pioneered that are applicable to all specialties and virtually every organ system. As a result, all minimally invasive surgical procedures, from coronary artery angioplasty to palliation of pancreatic malignancy, involve the use of access devices, catheters, guidewires, balloon dilators, stents, and other devices (e.g., lasers, atherectomy catheters) that are capable of opening up the occluded biologic cylinder⁷³ (Table 14-2). Endoluminal balloon dilators may be inserted through an endoscope, or they

may be fluoroscopically guided. Balloon dilators all have low compliance—that is, the balloons do not stretch as the pressure within the balloon is increased. The high pressures achievable in the balloon create radial expansion of the narrowed vessel or orifice, usually disrupting the atherosclerotic plaque, the fibrotic stricture, or the muscular band (e.g., esophageal achalasia).⁷⁴

Table 14-2 Modalities and Techniques of Restoring Luminal Patency

Modality	Technique
Core out	Photodynamic therapy
	Laser
	Coagulation
	Endoscopic biopsy forceps
	Chemical
Fracture	Ultrasound
	Endoscopic biopsy
	Balloon
	Balloon
	Bougie
Dilate	Angioplasty
	Endoscope
	Transvenous intrahepatic portosystemic shunt
	Surgical (synthetic or autologous conduit)
	Self-expanding metal stent
Stent	Plastic stent

Once the dilation has been attained, it is frequently beneficial to hold the lumen open with a stent.⁷⁵ Stenting is particularly valuable in treating malignant lesions and atherosclerotic occlusions or aneurysmal disease (Fig. 14-18). Stenting is also of value to seal leaky cylinders, including aortic dissections, traumatic vascular injuries, leaking GI anastomoses, and fistulas. Stenting usually is not applicable for long-term management of benign GI strictures except in patients with limited life expectancy^{75–77} (Fig. 14-19).

This is an esophagram in a patient with severe dysphagia secondary to advanced esophageal cancer (**A**) before and (**B**) after placement of a covered self-expanding metal stent.

A variety of stents are available that are divided into six basic categories: plastic stents, metal stents, drug-eluting stents (to decrease fibrovascular hyperplasia), covered metal stents, anchored stent grafts, and removable covered plastic stents⁷⁶ (Fig. 14-20). Plastic stents came first and are used widely as endoprotheses for temporary bypass of obstructions in the biliary or urinary systems. Metal stents generally are delivered over a balloon and expanded with the balloon to the desired size. These metal stents usually are made of titanium or nitinol, and are still used in coronary stenting. A chemotherapeutic agent was added to coronary stents several years ago to decrease endothelial proliferation. These drug-eluting stents provide greater long-term patency but require long-term anticoagulation with antiplatelet agents to prevent thrombosis.⁷⁸ Coated metal stents are used to prevent tissue ingrowth. Ingrowth may be an advantage in preventing stent migration, but such tissue ingrowth may occlude the lumen and cause obstruction anew. This is a particular problem when stents are used for palliation of GI malignant growth, and may be a problem for the long-term use of stents in vascular disease. Filling the interstices with Silastic or other materials may prevent tumor ingrowth but also makes stent migration more likely. In an effort to minimize stent migration, stents have been incorporated with hooks and barbs at the proximal end of the stent to anchor it to the wall of the vessel. Endovascular stenting of aortic aneurysms has nearly replaced open surgery for this condition. Lastly, self-expanding plastic stents have been developed as temporary devices to be used in the GI tract to close internal fistulas and bridge leaking anastomoses.

Covered self-expanding metal stents. These devices can be placed fluoroscopically or endoscopically.

Natural Orifice Transluminal Endoscopic Surgery

The "latest rage" in MIS is NOTES, the use of the flexible endoscope to enter the GI, urinary, or reproductive tracts, then traverse the wall of the structure to enter the peritoneal cavity, the mediastinum, or the chest. In truth, transluminal surgery has been performed in the stomach for a long time, either from the inside out (e.g. percutaneous, PEG, and transgastric pseudocyst drainage) or from the outside in (e.g., laparoscopic assisted intragastric tumor resection). The catalyzing event for NOTES was the demonstration that a porcine

gallbladder could be removed with a flexible endoscope passed through the wall of the stomach, then removed through the mouth, and the demonstration in a series of 10 human cases from India of the ability to perform transgastric appendectomy. Since that time, a great deal of money has been invested by endoscopic and MIS companies to help surgeons and gastroenterologists explore this new territory. To date, the most headline-grabbing procedures have been the transvaginal and transgastric removal of the gallbladder⁷⁹⁻⁸¹ (Fig. 14-21). To ensure safety, all cases thus far have involved laparoscopic assistance to aid in retraction, and ensure adequate closure of the stomach. As such, the benefits of NOTES cholecystectomy have not been demonstrated convincingly, but when all laparoscopic assistance has been eliminated, this approach will surely appeal to many. Additional procedures performed with NOTES might include staging of intra-abdominal malignancy, segmental colectomy, gastrojejunostomy, and a host of other procedures capable of exciting the curious mind. In addition, the rapid growth of endoscopic technology catalyzed by NOTES has already spun off new technologies capable of performing a wide variety of endoscopic surgical procedures from endoscopic mucosal resection to ablation of Barrett's esophagus, to creation of competent antireflux valves in patients with gastroesophageal reflux disease. Although some of these applications are still considered experimental, there is little doubt that when equivalent operations can be performed with less pain, fewer scars, and less disability, patients will flock to it. Surgeons should engage only when they can perform these procedures with the safety and efficacy demanded by our profession.

SPECIAL CONSIDERATIONS

Pediatric Laparoscopy

The advantages of MIS in children may be more significant than in the adult population. MIS in the adolescent is little different from that in the adult, and standard instrumentation and trocar positions usually can be used. However, laparoscopy in the infant and young child requires specialized instrumentation. The instruments are shorter (15 to 20 cm), and many are 3 mm in diameter rather than 5 mm. Because the abdomen of the child is much smaller than that of the adult, a 5-mm telescope provides sufficient illumination for most operations. The development of 5-mm clippers and bipolar devices has obviated the need for 10-mm trocars in pediatric laparoscopy.⁸² Because the abdominal wall is much thinner in infants, a pneumoperitoneum pressure of 8 mmHg can provide adequate exposure. DVT is

rare in children, so prophylaxis against thrombosis probably is unnecessary. A wide variety of pediatric surgical procedures are frequently performed with MIS access, from pull-through procedures for colonic aganglionosis (Hirschsprung's disease) to repair of congenital diaphragmatic hernias.⁸³

Laparoscopy during Pregnancy

Concerns about the safety of laparoscopic cholecystectomy or appendectomy in the pregnant patient have been thoroughly investigated and are readily managed. Access to the abdomen in the pregnant patient should take into consideration the height of the uterine fundus, which reaches the umbilicus at 20 weeks. In order not to damage the uterus or its blood supply, most surgeons feel that the open (Hasson) approach should be used in favor of direct puncture laparoscopy. The patient should be positioned slightly on the left side to avoid compression of the vena cava by the uterus. Because pregnancy poses a risk for thromboembolism, sequential compression devices are essential for all procedures. Fetal acidosis induced by maternal hypercarbia also has been raised as a concern. The arterial pH of the fetus follows the pH of the mother linearly; and therefore, fetal acidosis may be prevented by avoiding a respiratory acidosis in the mother.⁸⁴ The pneumoperitoneum pressure induced by laparoscopy is not a safety issue either as it has been proved that midpregnancy uterine contractions provide a much greater pressure in utero than a pneumoperitoneum of 15 mmHg. Experience in >100 cases of laparoscopic cholecystectomy in pregnancy have been reported with uniformly good results.⁸⁵ The operation should be performed during the second trimester of pregnancy if possible. Protection of the fetus against intraoperative x-rays is imperative. Some believe it advisable to track fetal pulse rates with a transvaginal ultrasound probe; however, the significance of fetal tachycardia or bradycardia is a bit unclear in the second trimester of pregnancy. To be prudent, however, heart rate decelerations reversibly associated with pneumoperitoneum creation might signal the need to convert to open cholecystectomy or appendectomy.

Minimally Invasive Surgery and Cancer Treatment

MIS techniques have been used for many decades to provide palliation for the patient with an obstructive cancer. Laser treatment, intracavitary radiation, stenting, and dilation are outpatient techniques that can be used to re-establish the continuity of an obstructed esophagus, bile duct, ureter, or airway. MIS techniques also have been used in the staging of cancer. Mediastinoscopy is still used occasionally before thoracotomy to assess the status of the mediastinal lymph nodes. Laparoscopy also is used to assess the liver in patients being evaluated for pancreatic, gastric, or hepatic resection. New technology and greater surgical skills allow for accurate minimally invasive staging of cancer.⁸⁶ Occasionally, it is appropriate to perform palliative measures (e.g., laparoscopic gastrojejunostomy to bypass a pancreatic cancer) at the time of diagnostic laparoscopy if diagnostic findings preclude attempts at curative resection.

Initially controversial, the role of MIS to provide a safe curative treatment of cancer has proven to be no different from the principles of open surgery. All gross and microscopic tumor should be removed (an R0 resection), and an adequate lymphadenectomy should be performed to allow accurate staging. Generally, this number has been 10 to 15 lymph nodes, although there is still debate as to the value of more extensive lymphadenectomy. All of the major abdominal cancer operations have been performed with laparoscopy. Of the three major cancer resections of GI cancer (liver lobe, pancreatic head, and esophagus), only esophagectomy is routinely performed by a fair number of centers.^{87,88} Laparoscopic hepatectomy has attracted a loyal following, and distal pancreatectomy frequently is performed with laparoscopic access. In Japan, laparoscopic-assisted gastrectomy has become quite popular for early gastric cancer, an epidemic in Japan far exceeding that of colon cancer in North America and Northern Europe. The most common cancer operation performed laparoscopically is segmental colectomy, which has proven itself safe and efficacious in a multicenter controlled randomized trial.⁸⁹

Considerations in the Elderly and Infirm

Laparoscopic cholecystectomy has made possible the removal of a symptomatic gallbladder in many patients previously thought to be too elderly or too ill to undergo a laparotomy. Older patients are more likely to require conversion to celiotomy because of disease chronicity.⁸⁹

Operations on these patients require close monitoring of anesthesia. The intraoperative management of these patients may be more

difficult with laparoscopic access than with open access. The advantage of MIS lies in what happens after the operation. Much of the morbidity of surgery in the elderly is a result of impaired mobility. In addition, pulmonary complications, urinary tract sepsis, DVT, pulmonary embolism, congestive heart failure, and myocardial infarction often are the result of improper fluid management and decreased mobility. By allowing rapid and early mobilization, laparoscopic surgery has made possible the safe performance of procedures in the elderly and infirm.

Cirrhosis and Portal Hypertension

Patients with hepatic insufficiency pose a significant challenge for any type of surgical intervention.⁹⁰ The ultimate surgical outcome in this population relates directly to the degree of underlying hepatic dysfunction.⁹¹ Often, this group of patients has minimal reserve, and the stress of an operation will trigger complete hepatic failure or hepatorenal syndrome. These patients are at risk for major hemorrhage at all levels, including trocar insertion, operative dissection in a field of dilated veins, and secondary to an underlying coagulopathy. Additionally, ascitic leak from a port site may occur, leading to bacterial peritonitis. Therefore, a watertight port site closure should be carried out in all patients.

It is essential that the surgeon be aware of the severity of hepatic cirrhosis as judged by a MELD score (Model of Endstage Liver Disease) or Child's classification. Additionally, the presence of portal hypertension is a relative contraindication to laparoscopic surgery until the portal pressures are reduced with portal decompression. For example, if a patient has an incarcerated umbilical hernia and ascites, a preoperative paracentesis or transjugular intrahepatic portosystemic shunt procedure in conjunction with aggressive diuresis may be considered. Because these patients commonly are intravascularly depleted, insufflation pressures should be reduced to prevent a decrease in cardiac output and minimal amounts of Na⁺ sparing IV fluids should be given.

Economics of Minimally Invasive Surgery

Minimally invasive surgical procedures reduce the costs of surgery most when length of hospital stay can be shortened and return to work is quickened. For example, shorter hospital stays can be demonstrated in laparoscopic cholecystectomy, Nissen fundoplication, splenectomy, and adrenalectomy. Procedures such as inguinal herniorrhaphy that are already performed as outpatient procedures are less likely to provide cost savings. Procedures that still require a 4- to 7-day hospitalization, such as laparoscopy-assisted colectomy, are less likely to deliver a lower bottom line than their open surgery counterparts. Nonetheless, with responsible use of disposable instrumentation and a commitment to the most effective use of the inpatient setting, most laparoscopic procedures can be made less expensive than their conventional equivalents.

Education and Skill Acquisition

Historically, surgeons in training (residents, registrars, and fellows) acquired their skills in minimally invasive techniques through a series of operative experiences of graded complexity. This training occurred on patients. Although such a paradigm did not compromise patient safety, learning in the OR is costly. In addition, the recent worldwide constraint placed on resident work hours makes it attractive to teach laparoscopic skills outside of the OR.

Skills labs started at nearly every surgical training center in the 1990s with a "box trainer," a rudimentary or sophisticated simulated abdominal cavity with a video camera, a monitor, trocars, laparoscopic instruments, and target models as simple as a pegboard and rubber rings, or a latex drain to practice suturing and knot tying. Virtual reality training devices present a unique opportunity to improve and enhance experiential learning in endoscopy and laparoscopy for all surgeons. This technology has the advantage of enabling objective measurement of psychomotor skills, which can be used to determine progress in skill acquisition, and ultimately, technical competency.⁹² Several of these devices have been validated as a means of measuring proficiency in skill performance. More importantly, training on virtual reality platforms has proven to translate to improved operative performance in randomized trials.^{93,94} In the near future, and today in some institutions, simulator training to the expert level will become a prerequisite for performance of laparoscopic procedures in the OR. The American College of Surgeons has taken a leadership position in accrediting these skills labs at American College of Surgeons–accredited educational institutes.

Telementoring

In response to the Institute of Medicine's call for the development of unique technologic solutions to deliver health care to rural and underserved areas, surgeons are beginning to explore the feasibility of telementoring. Teleconsultation or telementoring is two-way audio and visual communication between two geographically separated providers. This communication can take place in the office setting or directly in the OR when complex scenarios are encountered. Although local communication channels may limit its performance in rural areas, the technology is available and currently is being used, especially in states and provinces with large geographically remote populations⁹⁴ (Fig. 14-22).

Fig. 14-22.

Teleconsultation and telementoring are carried out between two providers who are geographically separated. The console has a video camera, microphone, and flat screen display that can be positioned at the operating room table or in the clinic.

Innovation and Introduction of New Procedures

The revolution in minimally invasive general surgery, which occurred in 1990, created ethical challenges for the profession. The problem was this: If competence is gained from experience, how was the surgeon to climb the competence curve (otherwise known as the *learning curve*) without injuring patients? If it was indeed impossible to achieve competence without making mistakes along the way, how should one effectively communicate this to patients such that they understand the weight of their decisions? Even more fundamentally important is determining the path that should be followed before one recruits the first patient for a new procedure.

Although procedure development is fundamentally different than drug development (i.e., there is great individual variation in the performance of procedures, but no difference between one tablet and the next), adherence to a process similar to that used to develop a new drug is a reasonable path for a surgical innovator. At the outset, the surgeon must identify the problem that is not solved with current surgical procedures. For example, although the removal of a gallbladder through a Kocher incision is certainly effective, it creates

a great deal of disability, pain, and scarification. As a result of those issues, many patients with very symptomatic biliary colic delayed operation until life-threatening complications occurred. Clearly, there was a need for developing a less invasive approach (Fig. 14-23).

Fig. 14-23.

The progress of general surgery can be reflected by a series of performance curves. General anesthesia and sterile technique allowed the development of maximally invasive open surgery over the last 125 years. Video optics allowed the development of minimally invasive surgery over the last 25 years. Noninvasive (seamless) surgery will result when a yet undiscovered transformational event allows surgery to occur without an incision, and perhaps without anesthesia.

Once the opportunity has been established, the next step involves a search through other disciplines for technologies and techniques that might be applied. Again, this is analogous to the drug industry, where secondary drug indications have often turned out to be more therapeutically important than the primary indication for drug development. The third step is in vivo studies in the most appropriate animal model. These types of studies are controversial because of the resistance to animal experimentation, and yet without such studies, many humans would be injured or killed during the developmental phase of medical drugs, devices, and techniques. These steps often are called the *preclinical phase of procedure development*.

The decision as to when such procedures are ready to come out of the lab is a difficult one. Put simply, the procedure should be reproducible, provide the desired effect, and not have serious side effects. Once these three criteria are reached, the time for human application has arrived. Before the surgeon discusses the new procedure with patients, it is important to achieve full institutional support. Involvement of the medical board, the chief of the medical staff, and the institutional review board is essential before commencing on a new procedure. These bodies are responsible for the use of safe, high-quality medical practices within their institution, and they will demand that great caution and all possible safeguards are in place before proceeding.

The dialogue with the patient who is to be first must be thorough, brutally honest, and well documented. The psychology that allows a patient to decide to be first is quite interesting, and may, under certain circumstances, require psychiatric evaluation. Certainly if a dying cancer patient has a chance with a new drug, this makes sense. Similarly, if the standard surgical procedure has a high attendant morbidity and the new procedure offers a substantially better outcome, the decision to be first is understandable. On the other hand, when the benefits of the new approach are small and the risks are largely unknown, a more complete psychological profile may be necessary before proceeding.

For new surgical procedures, it generally is wise to assemble the best possible operative team, including a surgeon experienced with the

old technique, and assistants who have participated in the earlier animal work. This initial team of experienced physicians and nurses should remain together until full competence with the procedure is attained. This may take 10 procedures, or it may take 50 procedures. The team will know that it has achieved competence when the majority of procedures take the same length of time, and the team is relaxed and sure of the flow of the operation. This will complete phase I of the procedure development.

In phase II, the efficacy of the procedure is tested in a nonrandomized fashion. Ideally, the outcome of new techniques must be as good or better than the procedure that is being replaced. This phase should occur at several medical centers to prove that good outcomes are achievable outside of the pioneering institution. These same requirements may be applied to the introduction of new technology into the OR. The value equation requires that the additional measurable procedure quality exceeds the additional measurable cost to the patient or health care system. In phase III, a randomized trial pits the new procedure against the old.

Once the competence curve has been climbed, it is appropriate for the team to engage in the education of others. During the ascension of the competence curve, other learners in the institution (i.e., surgical residents) may not have the opportunity to participate in the first case series. Although this may be difficult for them, the best interest of the patient must be put before the education of the resident.

The second stage of learning occurs when the new procedure has proven its value and a handful of experts exist, but the majority of surgeons have not been trained to perform the new procedure. In this setting, it is relatively unethical for surgeons to forge ahead with a new procedure in humans as if they had spent the same amount of time in intensive study that the first team did. The fact that one or several surgical teams were able to perform an operation does not ensure that all others with the same medical degrees can perform the operation with equal skill. It behooves the learners to contact the experts and request their assistance to ensure an optimal outcome at the new center. Although it is important that the learners contact the experts, it is equally important that the experts be willing to share their experience with their fellow professionals. As well, the experts should provide feedback to the learners as to whether they feel the learners are equipped to forge ahead on their own. If not, further observation and assistance from the experts are required. Although this approach may sound obvious, it is fraught with difficulties. In many situations ego, competitiveness, and monetary concerns have short-circuited this process and led to poor patient outcomes. To a large extent, MIS has recovered from the black eye it received early in development, when inadequately trained surgeons caused an excessive number of significant complications.

If innovative procedures and technologies are to be developed and applied without the mistakes of the past, surgeons must be honest when they answer these questions: Is this procedure safe? Would I consider undergoing this procedure if I developed a surgical indication? Is the procedure as good or better than the procedure it is replacing? Do I have the skills to apply this procedure safely and with equivalent results to the more experienced surgeon? If the answer to any of these questions is "no," or "I don't know," there is a professional obligation to seek another procedure or outside assistance before subjecting a patient to the new procedure.

Schwartz's Principles of Surgery > Part I. Basic Considerations > Chapter 15. Molecular and Genomic Surgery >

KEY POINTS

1. The advent of recombinant DNA technology, polymerase chain reaction techniques, and completion of the human genome have revolutionized the understanding of disease development and also radically transformed the practice of medicine and surgery.
2. Genes govern cell activity in different cell types, which ultimately leads to the health of the human organism. The cellular diversity is controlled by the *genome* and accomplished by tight regulation of gene expression in a given cell at a given time.
3. Human diseases arise from improper changes in the genome. The continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. The goal of personalized genomic medicine is to attack the disease by choosing personalized treatments that work with the individual's genomic profile. Personalized genomic medicine will undoubtedly revolutionize the practice of modern medicine.
4. Improving the outlook for human diseases can only come from a better understanding of the molecular signaling mechanisms that cause these diseases and subsequent successful therapeutic regimens.

OVERVIEW OF MOLECULAR CELL BIOLOGY

One of the goals of modern biology is to analyze the molecular structure and gain a fuller understanding of how cells, tissues, organs, and entire organisms function, both in a normal state and under pathologic conditions. Significant progress has been made in molecular studies of metabolism pathways, gene expression, cellular signaling, and organ development in human beings. The advent of recombinant DNA technology, polymerase chain reaction (PCR) techniques, and completion of the Human Genome Project are positively affecting human society by not only broadening our knowledge and understanding of disease development but also by bringing about necessary changes in disease treatment.

Today's practicing surgeons are becoming increasingly aware that many modern surgical procedures rely on the information gained through molecular research. Genomic information, such as *BRCA* and *RET* proto-oncogene, is being used to help direct prophylactic procedures to remove potentially harmful tissues before they do damage to patients. Molecular engineering has led to cancer-specific gene therapy that could serve in the near future as a more effective adjunct to surgical debulking of tumors than radiation or chemotherapy, so surgeons will benefit from a clear introduction to how basic biochemical and biologic principles relate to the developing area of molecular biology.

This chapter reviews the current information on modern molecular biology for the surgical community. It is written with the intent of serving two functions. The first is to introduce or update the readers about the general concepts of molecular cell biology, which are essential for comprehending the real power and potential of modern molecular technology. The second aim is to inform the reader about the modern molecular techniques that are commonly used for surgical research and to provide a fundamental introduction on the background of how these techniques are developed and applied to benefit patients.

Basic Concepts of Molecular Research

The modern era of molecular biology, which has been mainly concerned with how genes govern cell activity, began in 1953 when James D. Watson and Francis H. C. Crick made one of the greatest scientific discoveries by deducing the double-helical structure of deoxyribonucleic acid, or DNA.^{1,2} The year 2003 marked the fiftieth anniversary of this great discovery. Before 1953, one of the most mysterious aspects of biology was how genetic material was precisely duplicated from one generation to the next. Although DNA had been implicated as genetic material, it was the base-paired structure of DNA that provided a logical interpretation of how a double helix could "unzip" to make copies of itself. This DNA synthesis, termed *replication*, immediately gave rise to the notion that a template was involved in the transfer of information between generations, and thus confirmed the suspicion that DNA carried an organism's hereditary information.

Within cells, DNA is packed into chromosomes. One important feature of DNA as genetic material is its ability to encode important information for all of a cell's functions (Fig. 15-1). Based on the principles of base complementarity, scientists also discovered how information in DNA is accurately transferred into the protein structure. DNA serves as a template for RNA synthesis, termed *transcription*, including messenger RNA (mRNA, or the protein-encoding RNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). mRNA carries the information from DNA to make proteins, termed *translation*, with the assistance of rRNA and tRNA. Each of these steps is precisely controlled in such a way that genes are properly expressed in each cell at a specific time and location. In recent years, new classes of noncoding RNAs, for example, microRNA (or miRNA) and Piwi-interacting RNA (or piRNA), have been identified that regulate gene expression through mRNA degradation. Consequently, the differential gene activity in a cell determines its actions, properties, and functions.

Fig. 15-1.

The flow of genetic information from DNA to protein to cell functions. The process of transmission of genetic information from DNA to RNA is called *transcription*, and the process of transmission from RNA to protein is called *translation*. Proteins are the essential controlling components for cell structure, cell signaling, and metabolism. *Genomics* and *proteomics* are the study of the genetic composition of a living organism at the DNA and protein level, respectively. The study of the relationship between genes and their cellular functions is called *functional genomics*.

Molecular Approaches to Surgical Research

Rapid advances in molecular and cellular biology over the past half century have revolutionized the understanding of disease and will radically transform the practice of surgery. In the future, molecular techniques will be increasingly applied to surgical disease and will lead to new strategies for the selection and implementation of operative therapy. Surgeons should be familiar with the fundamental principles of molecular and cellular biology so that emerging scientific breakthroughs can be translated into improved care of the surgical patient.

The greatest advances in the field of molecular biology have been in the areas of analysis and manipulation of DNA.¹ Since Watson and Crick's discovery of DNA structure, an intensive effort has been made to unlock the deepest biologic secrets of DNA. Among the avalanche of technical advances, one discovery in particular has drastically changed the world of molecular biology: the uncovering of the enzymatic and microbiologic techniques that produce recombinant DNA. Recombinant DNA technology involves the enzymatic manipulation of DNA and, subsequently, the cloning of DNA. DNA molecules are cloned for a variety of purposes including safeguarding DNA samples, facilitating sequencing, generating probes, and expressing recombinant proteins in one or more host organisms. DNA can be produced by a number of means, including restricted digestion of an existing vector, PCR, and cDNA synthesis. As DNA cloning techniques have developed over the last quarter century, researchers have moved from studying DNA to studying the functions of proteins, and from cell and animal models to molecular therapies in humans. Expression of recombinant proteins provides a method for analyzing gene regulation, structure, and function. In recent years the uses for recombinant proteins have expanded to include a variety of new applications, including gene therapy and biopharmaceuticals. The basic molecular approaches for modern surgical research include DNA cloning, cell manipulation, disease modeling in animals, and clinical trials in human patients.

FUNDAMENTALS OF MOLECULAR AND CELL BIOLOGY

DNA and Heredity

DNA forms a right-handed, double-helical structure that is composed of two antiparallel strands of unbranched polymeric deoxyribonucleotides linked by phosphodiester bonds between the 5' carbon of one deoxyribose moiety to the 3' carbon of the next (Fig. 15-2). DNA is composed of four types of deoxyribonucleotides: adenine (A), cytosine (C), guanine (G), and thymine (T). The nucleotides are joined together by phosphodiester bonds. In the double-helical structure deduced by Watson and Crick, the two strands of DNA are complementary to each other. Because of size, shape, and chemical composition, A always pairs with T, and C with G, through the formation of hydrogen bonds between complementary bases that stabilize the double helix.

Fig. 15-2.

Schematic representation of a DNA molecule forming a double helix. DNA is made of four types of nucleotides, which are linked covalently into a DNA strand. A DNA molecule is composed of two DNA strands held together by hydrogen bonds between the pair bases. The arrowheads at the ends of the DNA molecule indicate the polarities of the two strands, which run antiparallel to each other in the DNA molecule. The diagram at the bottom left of the figure shows the DNA molecule straightened out. In reality, the DNA molecule is twisted into a double helix, of which each turn of DNA is made up of 10.4 nucleotide pairs, as shown on the right.

(From Alberts et al,¹ with permission.)

Recognition of the hereditary transmission of genetic information is attributed to the Austrian monk, Gregor Mendel. His seminal work, ignored upon publication until its rediscovery in 1900, established the laws of segregation and of independent assortment. These two principles established the existence of paired elementary units of heredity and defined the statistical laws that govern them.³ DNA was isolated in 1869, and a number of important observations of the inherited basis of certain diseases were made in the early part of the twentieth century. Although today it appears easy to understand how DNA replicates, before the 1950s, the idea of DNA as the primary genetic material was not appreciated. The modern era of molecular biology began in 1944 with the demonstration that DNA was the substance that carried genetic information. The first experimental evidence that DNA was genetic material came from simple transformation experiments conducted in the 1940s using *Streptococcus pneumoniae*. One strain of the bacteria could be converted into another by incubating it with DNA from the other, just as the treatment of the DNA with deoxyribonuclease would inactivate the transforming activity of the DNA. Similarly, in the early 1950s, before the discovery of the double-helical structure of DNA, the entry of viral DNA and not the protein into the host bacterium was believed to be necessary to initiate infection by the bacterial virus or bacteriophage. Key historical events concerning genetics are outlined in Table 15-1.

Table 15-1 Historical Events in Genetics and Molecular Biology		
Year	Investigator	Event
1865	Mendel	Laws of genetics established
1869	Miescher	DNA isolated
1905	Garrod	Human inborn errors of metabolism
1913	Sturtevant	Linear map of genes
1927	Muller	X-rays cause inheritable genetic damage
1928	Griffith	Transformation discovered
1941	Beadle and Tatum	"One gene, one enzyme" concept
1944	Avery, MacLeod, McCarty	DNA as material of heredity
1950	McKlintock	Existence of transposons confirmed
1953	Watson and Crick	Double-helical structure of DNA
1957	Benzer and Kornberg	Recombination and DNA polymerase
1966	Nirenberg, Khorana, Holley	Genetic code determined
1970	Temin and Baltimore	Reverse transcriptase
1972	Cohen, Boyer, Berg	Recombinant DNA technology
1975	Southern	Transfer of DNA fragments from sizing gel to nitrocellulose (Southern blot)
1977	Sanger, Maxim, Gilbert	DNA sequencing methods
1982	—	GenBank database established
1985	Mullis	Polymerase chain reaction
1986	—	Automated DNA sequencing
1989	Collins	Cystic fibrosis gene identified by positional cloning and linkage analysis
1990	—	Human Genome Project initiated
1997	Roslin Institute	Mammalian cloning (Dolly)
2001	IHGSC and Celera Genomics	Draft versions of human genome sequence published
2003	—	Human Genome Project completed

IHGSC = International Human Genome Sequencing Consortium.

For cells to pass on the genetic material (DNA) to each progeny, the amount of DNA must be doubled. Watson and Crick recognized that the complementary base-pair structure of DNA implied the existence of a template-like mechanism for the copying of genetic material.² The transfer of DNA material from the mother cell to daughter cells takes place during somatic cell division (also called *mitosis*). Before a cell divides, DNA must be precisely duplicated. During replication, the two strands of DNA separate and each strand creates a new complementary strand by precise base-pair matching (Fig. 15-3). The two, new, double-stranded DNAs carry the same genetic information, which can then be

passed on to two daughter cells. Proofreading mechanisms ensure that the replication process occurs in a highly accurate manner. The fidelity of DNA replication is absolutely crucial to maintaining the integrity of the genome from generation to generation. However, mistakes can still occur during this process, resulting in *mutations*, which may lead to a change of the DNA's encoded protein and, consequently, a change of the cell's behavior. The reliable dependence of many features of modern organisms on subtle changes in genome is linked to Mendelian inheritance and also contributes to the processes of Darwinian evolution. In addition, massive changes, so-called *genetic instability*, can occur in the genome of somatic cells such as cancer cells.

Fig. 15-3.

DNA replication. As the nucleotide A only pairs with T, and G with C, each strand of DNA can determine the nucleotide sequence in its complementary strand. In this way, double-helical DNA can be copied precisely.

(From Alberts et al,¹ with permission.)

Gene Regulation

Living cells have the necessary machinery to enzymatically transcribe DNA into RNA and translate the mRNA into protein. This machinery accomplishes the two major steps required for gene expression in all organisms: transcription and translation (Fig. 15-4). However, gene regulation is far more complex, particularly in eukaryotic organisms. For example, many gene transcripts must be spliced to remove the intervening sequences. The sequences that are spliced off are called *introns*, which appear to be useless, but in fact may carry some regulatory information. The sequences that are joined together, and are eventually translated into protein, are called *exons*. Additional regulation of gene expression includes modification of mRNA, control of mRNA stability, and its nuclear export into cytoplasm (where it is assembled into ribosomes for translation). After mRNA is translated into protein, the levels and functions of the proteins can be further regulated posttranslationally. However, the following sections will mainly focus on gene regulation at transcriptional and translational levels.

Fig. 15-4.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Four major steps in the control of eukaryotic gene expression. Transcriptional and posttranscriptional control determine the level of messenger RNA (mRNA) that is available to make a protein, while translational and posttranslational control determine the final outcome of functional proteins. Note that posttranscriptional and posttranslational controls consist of several steps.

TRANSCRIPTION

Transcription is the enzymatic process of RNA synthesis from DNA.⁴ In bacteria, a single RNA polymerase carries out all RNA synthesis, including that of mRNA, rRNA, and tRNA. Transcription often is coupled with translation in such a way that an mRNA molecule is completely accessible to ribosomes, and bacterial protein synthesis begins on an mRNA molecule even while it is still being synthesized. Therefore, a discussion of gene regulation with a look at the simpler prokaryotic system precedes that of the more complex transcription and posttranscriptional regulation of eukaryotic genes.

Transcription in Bacteria

Initiation of transcription in prokaryotes begins with the recognition of DNA sequences by RNA polymerase. First, the bacterial RNA polymerase catalyzes RNA synthesis through loose binding to any region in the double-stranded DNA and then through specific binding to the *promoter* region with the assistance of accessory proteins called σ factors (sigma factors). A promoter region is the DNA region upstream of the transcription initiation site. RNA polymerase binds tightly at the promoter sites and causes the double-stranded DNA structure to unwind. Consequently, few nucleotides can be base-paired with the DNA template to begin transcription. Once transcription begins, the σ factor is released. The growing RNA chain may begin to peel off as the chain elongates. This occurs in such a way that there are always about 10 to 12 nucleotides of the growing RNA chains that are base-paired with the DNA template.

The bacterial promoter contains a region of about 40 bases that include two conserved elements called *-35 region* and *-10 region*. The numbering system begins at the initiation site, which is designated +1 position, and counts backward (in negative numbers) on the promoter and forward on the transcribed region. Although both regions on different promoters are not the same sequences, they are fairly conserved and very similar. This conservation provides the accurate and rapid initiation of transcription for most bacterial genes. It is also common in bacteria that one promoter serves to transcribe a series of clustered genes, called an *operon*. A single transcribed mRNA contains a series of coding regions, each of which is later independently translated. In this way, the protein products are synthesized in a coordinated manner. Most of the time these proteins are involved in the same metabolic pathway, thus demonstrating that the control by one operon is an efficient system. After initiation of transcription, the polymerase moves along the DNA to elongate the chain of RNA, although at a certain point, it will stop. Each step of RNA synthesis, including initiation, elongation, and termination, will require the integral functions of RNA polymerase as well as the interactions of the polymerase with regulatory proteins.

Transcription in Eukaryotes

Transcription mechanisms in eukaryotes differ from those in prokaryotes. The unique features of eukaryotic transcription are as follows: (a)

Eukaryotic gene transcription also involves the recognition and binding of RNA polymerase to the promoter DNA. However, the interaction between the polymerase and DNA is far more complex in eukaryotes than in prokaryotes. Because the majority of studies have been focused on the regulation and functions of proteins, this chapter primarily focuses on how protein-encoding mRNA is made by RNA polymerase II.

DNA directs the synthesis of RNA; RNA in turn directs the synthesis of proteins. Proteins are variable-length polypeptide polymers composed of various combinations of 20 different amino acids and are the working molecules of the cell. The process of decoding information on mRNA to synthesize proteins is called *translation* (see Fig. 15-1). Translation takes place in ribosomes composed of rRNA and ribosomal proteins. The numerous discoveries made during the 1950s made it easy to understand how DNA replication and transcription involves base-pairing between DNA and DNA, or DNA and RNA. However, at that time it was still impossible to comprehend how mRNA transfers the information to the protein-synthesizing machinery. The genetic information on mRNA is composed of arranged sequences of four bases that are transferred to the linear arrangement of 20 amino acids on a protein. Amino acids are characterized by a central carbon unit linked to four side chains: an amino group ($-\text{NH}_2$), a carboxy group ($-\text{COOH}$), a hydrogen, and a variable ($-\text{R}$) group. The amino acid chain is assembled via peptide bonds between the amino group of one amino acid and the carboxy group of the next. Because of this decoding, the information carried on mRNA relies on tRNA. Translation involves all three RNAs. The precise transfer of information from mRNA to protein is governed by *genetic code*, the set of rules by which codons are translated into an amino acid (Table 15-2). A *codon*, a triplet of three bases, codes for one amino acid. In this case, random combinations of the four bases form $4 \times 4 \times 4$, or 64 codes. Because 64 codes are more than enough for 20 amino acids, most amino acids are coded by more than one codon. The start codon is AUG, which also corresponds to methionine; therefore, almost all proteins begin with this amino acid. The sequence of nucleotide triplets that follows the start codon signal is termed the *reading frame*. The codons on mRNA are sequentially recognized by tRNA adaptor proteins. Specific enzymes termed *aminoacyl-tRNA synthetases* link a specific amino acid to a specific tRNA. The translation of mRNA to protein requires the ribosomal complex to move stepwise along the mRNA until the initiator methionine sequence is identified. In concert with various protein initiator factors, the methionyl-tRNA is positioned on the mRNA and protein synthesis begins. Each new amino acid is added sequentially by the appropriate tRNA in conjunction with proteins called *elongation factors*. Protein synthesis proceeds in the amino-to-carboxy-terminus direction.

[illegible]

	AUG	Met	[M]	ACG	Thr	[T]	AAG	Lys	[K]	AGG	Arg	[R]	G
	GUU	Val	[V]	GCU	Ala	[A]	GAU	Asp	[D]	GGU	Gly	[G]	U
	GUC	Val	[V]	GCC	Ala	[A]	GAC	Asp	[D]	GGC	Gly	[G]	C
G	GUA	Val	[V]	GCA	Ala	[A]	GAA	Glu	[E]	GGA	Gly	[G]	A
	GUG	Val	[V]	GCG	Ala	[A]	GAG	Glu	[E]	GGG	Gly	[G]	G

A = adenine; C = cytosine; G = guanine; U = uracil; Ala = alanine; Arg = arginine; Asn = asparagine; Asp = aspartic acid; Cys = cysteine; Glu = glutamic acid; Gln = glutamine; Gly = glycine; His = histidine; Ile = isoleucine; Leu = leucine; Lys = lysine; Met = methionine; Phe = phenylalanine; Pro = proline; Ser = serine; Thr = threonine; Trp = tryptophan; Tyr = tyrosine; Val = valine. Letter in [] indicates single lettercode for amino acid.

The biologic versatility of proteins is astounding. Among many other functions, proteins serve as enzymes that catalyze critical biochemical reactions, carry signals to and from the extracellular environment, and mediate diverse signaling and regulatory functions in the intracellular environment. They also transport ions and various small molecules across plasma membranes. Proteins make up the key structural components of cells and the extracellular matrix and are responsible for cell motility. The unique functional properties of proteins are largely determined by their structure (Fig. 15-5).

Fig. 15-5.

Maturation of a functional protein. Although the linear amino acid sequence of a protein often is shown, the function of a protein also is controlled by its correctly folded three-dimensional structure. In addition, many proteins also have covalent posttranslational modifications such as phosphorylation or noncovalent binding to a small molecule or a protein.

REGULATION OF GENE EXPRESSION

The human organism is made up of a myriad of different cell types that, despite their vastly different characteristics, contain the same genetic material. This cellular diversity is controlled by the *genome* and accomplished by tight regulation of gene expression. This leads to the synthesis and accumulation of different complements of RNA and, ultimately, to the proteins found in different cell types. For example, muscle and bone express different genes or the same genes at different times. Moreover, the choice of which genes are expressed in a given cell at a given time

depends on signals received from its environment. There are multiple levels at which gene expression can be controlled along the pathway from DNA to RNA to protein (see Fig. 15-4). *Transcriptional control* refers to the mechanism for regulating when and how often a gene is transcribed. Splicing of the primary RNA transcript (*RNA processing control*) and selection of completed mRNAs for nuclear export (*RNA transport control*) represent additional potential regulatory steps. The mRNAs in the cytoplasm can be selectively translated by ribosomes (*translational control*), or selectively stabilized or degraded (*mRNA degradation control*). Finally, the resulting proteins can undergo selective activation, inactivation, or compartmentalization (*protein activity control*).

Because a large number of genes are regulated at the transcriptional level, regulation of gene transcripts (i.e., mRNA) often is referred to as *gene regulation* in a narrow definition. Each of the steps during transcription is properly regulated in eukaryotic cells. Because genes are differentially regulated from one another, one gene can be differentially regulated in different cell types or at different developmental stages. Therefore, gene regulation at the level of transcription is largely context dependent. However, there is a common scheme that applies to transcription at the molecular level (Fig. 15-6). Each gene promoter possesses unique sequences called *TATA boxes* that can be recognized and bound by a large complex containing RNA polymerase II, forming the basal transcription machinery. Usually located upstream of the TATA box (but sometimes longer distances) are a number of regulatory sequences referred to as *enhancers* that are recognized by regulatory proteins called *transcription factors*. These transcription factors specifically bind to the enhancers, often in response to environmental or developmental cues, and cooperate with each other and with basal transcription factors to initiate transcription. Regulatory sequences that negatively regulate the initiation of transcription also are present on the promoter DNA. The transcription factors that bind to these sites are called *repressors*, in contrast to the *activators* that activate transcription. The molecular interactions between transcription factors and promoter DNA, as well as between the cooperative transcription factors, are highly regulated and context-dependent. Specifically, the recruitment of transcription factors to the promoter DNA occurs in response to physiologic signals. A number of structural motifs in these DNA-binding transcription factors facilitate this recognition and interaction. These include the helix-turn-helix, the homeodomain motif, the zinc finger, the leucine zipper, and the helix-loop-helix motifs.

Transcriptional control by RNA polymerase. DNA is packaged into a chromatin structure. TATA = the common sequence on the promoter recognized by TBP and polymerase II holoenzyme; TBP = TATA-binding protein and associated factors; TF = hypothetical transcription factor; TFBS = transcription factor binding site; ball-shaped structures = nucleosomes. Coactivator or corepressor are factors linking the TF with the Pol II complex.

Human Genome

Genome is a collective term for all genes present in one organism. The human genome contains DNA sequences of 3 billion base-pairs, carried by 23 pairs of chromosomes. The human genome has an estimated 25,000 to 30,000 genes, and overall it is 99.9% identical in all people.^{5,6} Approximately 3 million locations where single-base DNA differences exist have been identified and termed *single nucleotide polymorphisms*. Single nucleotide polymorphisms may be critical determinants of human variation in disease susceptibility and responses to environmental factors.

The completion of the human genome sequence in 2003 represented another great milestone in modern science. The human genome project created the field of *genomics*, which is the study of genetic material in detail (see Fig. 15-1). The medical field is building upon the knowledge, resources, and technologies emanating from the human genome to further the understanding of the relationship of the genes and their

mutations to human health and disease. This expansion of genomics into human health applications resulted in the field of genomic medicine.

The emergence of genomics as a science will transform the practice of medicine and surgery in this century. This breakthrough has allowed scientists the opportunity to gain remarkable insights into the lives of humans. Ultimately, the goal is to use this information to develop new ways to treat, cure, or even prevent the thousands of diseases that afflict humankind. In the twenty-first century, work will begin to incorporate the information embedded in the human genome sequence into surgical practices. By doing so, the genomic information can be used for diagnosing and predicting disease and disease susceptibility. Diagnostic tests can be designed to detect errant genes in patients suspected of having particular diseases or of being at risk for developing them. Furthermore, exploration into the function of each human gene is now possible, which will shed light on how faulty genes play a role in disease causation. This knowledge also makes possible the development of a new generation of therapeutics based on genes. Drug design is being revolutionized as researchers create new classes of medicines based on a reasoned approach to the use of information on gene sequence and protein structure function rather than the traditional trial-and-error method. Drugs targeted to specific sites in the body promise to have fewer side effects than many of today's medicines. Finally, other applications of genomics will involve the transfer of genes to replace defective versions or the use of gene therapy to enhance normal functions such as immunity.

Proteomics refers to the study of the structure and expression of proteins as well as the interactions among proteins encoded by a human genome (see Fig. 15-1).⁷ A number of Internet-based repositories for protein sequences exist, including Swiss-Prot (<http://www.expasy.ch>). These databases allow comparisons of newly identified proteins with previously characterized sequences to allow prediction of similarities, identification of splice variants, and prediction of membrane topology and posttranslational modifications. Tools for proteomic profiling include two-dimensional gel electrophoresis, time-of-flight mass spectrometry, matrix-assisted laser desorption/ionization, and protein microarrays. *Structural proteomics* aims to describe the three-dimensional structure of proteins that is critical to understanding function. *Functional genomics* seeks to assign a biochemical, physiologic, cell biologic, and/or developmental function to each predicted gene. An ever-increasing arsenal of approaches, including transgenic animals, RNA interference (RNAi), and various systematic mutational strategies, will allow dissection of functions associated with newly discovered genes. Although the potential of this field of study is vast, it is in its early stages.

It is anticipated that a genomic and proteomic approach to human disease will lead to a new understanding of pathogenesis that will aid in the development of effective strategies for early diagnosis and treatment.⁸ For example, identification of altered protein expression in organs, cells, subcellular structures, or protein complexes may lead to development of new biomarkers for disease detection. Moreover, improved understanding of how protein structure determines function will allow rational identification of therapeutic targets, and thereby not only accelerate drug development, but also lead to new strategies to evaluate therapeutic efficacy and potential toxicity.⁷

Cell Cycle and Apoptosis

Every organism has many different cell types. Many cells grow, while some cells such as nerve cells and striated muscle cells do not. All growing cells have the ability to duplicate their genomic DNA and pass along identical copies of this genetic information to every daughter cell. Thus, the cell cycle is the fundamental mechanism to maintain tissue homeostasis. A cell cycle comprises four periods: G₁ (first gap phase before DNA synthesis), S (synthesis phase when DNA replication occurs), G₂ (the gap phase before mitosis), and M (mitosis, the phase when two daughter cells with identical DNA are generated) (Fig. 15-7). After a full cycle, the daughter cells enter G₁ again, and when they receive appropriate signals, undergo another cycle, and so on. The machinery that drives cell cycle progression is made up of a group of enzymes called *cyclin-dependent kinases* (CDK). Cyclin expression fluctuates during the cell cycle, and cyclins are essential for CDK activities and form complexes with CDK. The cyclin A/CDK1 and cyclin B/CDK1 drive the progression for the M phase, while cyclin A/CDK2 is the primary S phase complex. Early G₁ cyclin D/CDK4/6 or late G₁ cyclin E/CDK2 controls the G₁-S transition. There also are negative regulators for CDK termed *CDK inhibitors*, which inhibit the assembly or activity of the cyclin-CDK complex. Expression of cyclins and CDK inhibitors often are regulated by developmental and environmental factors.

Fig. 15-7.

The cell cycle and its control system. M is the mitosis phase, when the nucleus and the cytoplasm divide; S is the phase when DNA is duplicated; G_1 is the gap between M and S; G_2 is the gap between S and M. A complex of cyclin and cyclin-dependent kinase (CDK) controls specific events of each phase. Without cyclin, CDK is inactive. Different cyclin/CDK complexes are shown around the cell cycle. A, B, D, and E stand for cyclin A, cyclin B, cyclin D, and cyclin E, respectively.

The cell cycle is connected with signal transduction pathways as well as gene expression. While the S and M phases rarely are subjected to changes imposed by extracellular signals, the G_1 and G_2 phases are the primary periods when cells decide whether to move on to the next phase or not. During the G_1 phase, cells receive green- or red-light signals, S phase entry or G_1 arrest, respectively. Growing cells proliferate only when supplied with appropriate mitogenic growth factors. Cells become committed to entry of the cell cycle only toward the end of G_1 . Mitogenic signals stimulate the activity of early G_1 CDKs (e.g., cyclin D/CDK4) that inhibit the activity of pRb protein and activate the transcription factor called *E2F* to induce the expression of batteries of genes essential for G_1 -S progression. Meanwhile, cells also receive antiproliferative signals such as those from tumor suppressors. These antiproliferative signals also act in the G_1 phase to stop cells' progress into the S phase by inducing CKI production. For example, when DNA is damaged, cells will repair the damage before entering the S phase. Therefore, G_1 contains one of the most important checkpoints for cell cycle progression. If the analogy is made that CDK is to a cell as an engine is to a car, then cyclins and CKI are the gas pedal and brake, respectively. Accelerated proliferation or improper cell cycle progression with damaged DNA would be disastrous. Genetic gain-of-function mutations in oncogenes (that often promote expression or activity of the cyclin/CDK complex) or loss-of-function mutations in tumor suppressor (that stimulate production of CKI) are causal factors for malignant transformation.

In addition to cell cycle control, cells use genetically programmed mechanisms to kill cells. This cellular process, called *apoptosis* or *programmed cell death*, is essential for the maintenance of tissue homeostasis (Fig. 15-8).

Fig. 15-8.

A simplified view of the apoptosis pathways. Extracellular death receptor pathways include the activation of Fas and tumor necrosis factor (TNF) receptors, and consequent activation of the caspase pathway. Intracellular death pathway indicates the release of cytochrome c from mitochondria, which also triggers the activation of the caspase cascade. During apoptosis, cells undergo DNA fragmentation, nuclear and cell membrane breakdown, and are eventually digested by other cells.

Normal tissues undergo proper apoptosis to remove unwanted cells, those that have completed their jobs or have been damaged or improperly proliferated. Apoptosis can be activated by many physiologic stimuli such as death receptor signals (e.g., Fas or cytokine tumor necrosis factor), growth factor deprivation, DNA damage, and stress signals. Two major pathways control the biochemical mechanisms governing apoptosis: the death receptor and mitochondrial. However, recent advances in apoptosis research suggest an interconnection of the two pathways. What is central to the apoptotic machinery is the activation of a cascade of proteinases called caspases. Similarly to CDK in the cell cycle, activities and expression of caspases are well controlled by positive and negative regulators. The complex machinery of apoptosis must be tightly controlled. Perturbations of this process can cause neoplastic transformation or other diseases.

Signal Transduction Pathways

Gene expression in a genome is controlled in a temporal and spatial manner, at least in part by signaling pathways.⁹ A signaling pathway generally begins at the cell surface and, after a signaling relay by a cascade of intracellular effectors, ends up in the nucleus (Fig. 15-9). All cells have the ability to sense changes in their external environment. The bioactive substances to which cells can respond are many and include proteins, short peptides, amino acids, nucleotides/nucleosides, steroids, retinoids, fatty acids, and dissolved gases. Some of these substances are lipophilic and thereby can cross the plasma membrane by diffusion to bind to a specific target protein within the cytoplasm (intracellular receptor). Other substances bind directly with a transmembrane protein (cell-surface receptor). Binding of ligand to receptor initiates a series of biochemical reactions (*signal transduction*) typically involving protein-protein interactions and the transfer of high-energy phosphate groups, leading to various cellular end responses.

Cell-surface and intracellular receptor pathways. Extracellular signaling pathway: Most growth factors and other hydrophilic signaling molecules are unable to move across the plasma membrane and directly activate cell-surface receptors such as G-protein coupled receptors and enzyme-linked receptors. The receptor serves as the receiver, and in turn activates the downstream signals in the cell. Intracellular signaling pathway: Hormones or other diffusible molecules enter the cell and bind to the intracellular receptor in the cytoplasm or in the nucleus. Either extracellular or intracellular signals often reach the nucleus to control gene expression.

Control and specificity through simple protein-protein interactions—referred to as *adhesive interactions*—is a common feature of signal transduction pathways in cells.¹⁰ Signaling also involves catalytic activities of signaling molecules, such as protein kinases/phosphatases, that modify the structures of key signaling proteins. Upon binding and/or modification by upstream signaling molecules, downstream effectors undergo a conformational (allosteric) change and, consequently, a change in function. The signal that originates at the cell surface and is relayed by the cytoplasmic proteins often ultimately reaches the transcriptional apparatus in the nucleus. It alters the DNA binding and activities of transcription factors that directly turn genes on or off in response to the stimuli. Abnormal alterations in signaling activities and capacities in otherwise normal cells can lead to diseases such as cancer.

Advances in biology in the last two decades have dramatically expanded the view on how cells are wired with signaling pathways. In a given cell, many signaling pathways operate simultaneously and crosstalk with one another. A cell generally may react to a hormonal signal in a variety of ways: (a) by changing its metabolite or protein, (b) by generating an electric current, or (c) by contracting. Cells continually are subject to multiple input signals that simultaneously and sequentially activate multiple receptor and non-receptor-mediated signal transduction pathways, which form a signaling network. Although the regulators responsible for cell behavior are rapidly identified as a result of genomic and proteomic techniques, the specific functions of the individual proteins, how they assemble, and the networks that control cellular behavior remain to be defined. An increased understanding of cell regulatory pathways—and how they are disrupted in disease—will likely reveal common themes based on protein interaction domains that direct associations of proteins with other polypeptides, phospholipids, nucleic acids, and other regulatory molecules. Advances in the understanding of signaling networks will require methods of investigation that move beyond traditional "linear" approaches into medical informatics and computational biology. The bewildering biocomplexity of such networks mandates

multidisciplinary and transdisciplinary research collaboration. The vast amount of information that is rapidly emerging from genomic and proteomic data mining will require the development of new modeling methodologies within the emerging disciplines of medical mathematics and physics.

Signaling pathways often are grouped according to the properties of signaling receptors. Many hydrophobic signaling molecules are able to diffuse across plasma membranes and directly reach specific cytoplasmic targets. Steroid hormones, thyroid hormones, retinoids, and vitamin D are examples that exert their activity upon binding to structurally related receptor proteins that are members of the *nuclear hormone receptor superfamily*. Ligand binding induces a conformational change that enhances transcriptional activity of these receptors. Most extracellular signaling molecules interact with transmembrane protein receptors that couple ligand binding to intracellular signals, leading to biologic actions.

There are three major classes of cell-surface receptors: *transmitter-gated ion channels*, *seven-transmembrane G-protein coupled receptors (GPCRs)*, and *enzyme-linked receptors*. The superfamily of GPCRs is one of the largest families of proteins, representing over 800 genes of the human genome. Members of this superfamily share a characteristic seven-transmembrane configuration. The ligands for these receptors are diverse and include hormones, chemokines, neurotransmitters, proteinases, inflammatory mediators, and even sensory signals such as odorants and photons. Most GPCRs signal through *heterotrimeric G proteins*, which are guanine-nucleotide regulatory complexes. Thus the receptor serves as the receiver, the G protein serves as the transducer, and the enzyme serves as the effector arm. *Enzyme-linked receptors* possess an extracellular ligand-recognition domain and a cytosolic domain that either has intrinsic enzymatic activity or directly links with an enzyme. Structurally, these receptors usually have only one transmembrane-spanning domain. Of at least five forms of enzyme-linked receptors classified by the nature of the enzyme activity to which they are coupled, the growth factor receptors such as tyrosine kinase receptor or serine/threonine kinase receptors mediate diverse cellular events including cell growth, differentiation, metabolism, and survival/apoptosis. Dysregulation (particularly mutations) of these receptors is thought to underlie conditions of abnormal cellular proliferation in the context of cancer. The following sections will further review two examples of growth factor signaling pathways and their connection with human diseases.

INSULIN PATHWAY AND DIABETES¹¹

The discovery of insulin in the early 1920s is one of the most dramatic events in the treatment of human disease. *Insulin* is a peptide hormone that is secreted by the β -cell of the pancreas. Insulin is required for the growth and metabolism of most mammalian cells, which contain cell-surface insulin receptors (InsR). Insulin binding to InsR activates the kinase activity of InsR. InsR then adds phosphoryl groups, a process referred to as *phosphorylation*, and subsequently activates its immediate intracellular effector, called *insulin receptor substrate (IRS)*. IRS plays a central role in coordinating the signaling of insulin by activating distinct signaling pathways, the PI3K-Akt pathway and MAPK pathway, both of which possess multiple protein kinases that can control transcription, protein synthesis, and glycolysis (Fig. 15-10).

Insulin-signaling pathway. Insulin is a peptide growth factor that binds to and activates the heterotetrameric receptor complex (InsR). InsR possesses protein tyrosine kinase activity and is able to phosphorylate the downstream insulin receptor substrate (IRS). Phosphorylated IRS serves as a scaffold and controls the activation of multiple downstream pathways for gene expression, cell survival, and glucose metabolism. Inactivation of the insulin pathway can lead to type 2 diabetes.

The primary physiologic role of insulin is in glucose homeostasis, which is accomplished through the stimulation of glucose uptake into insulin-sensitive tissues such as fat and skeletal muscle. Defects in insulin synthesis/secretion and/or responsiveness are major causal factors in diabetes, one of the leading causes of death and disability in the United States, affecting an estimated 16 million Americans. Type 2 diabetes accounts for about 90% of all cases of diabetes. Clustering of type 2 diabetes in certain families and ethnic populations points to a strong genetic background for the disease. More than 90% of affected individuals have insulin resistance, which develops when the body is no longer able to respond correctly to insulin circulating in the blood. Although relatively little is known about the biochemical basis of this metabolic disorder, it is clear that the insulin-signaling pathways malfunction in this disease. It is also known that genetic mutations in the InsR or IRS cause type 2 diabetes, although which one is not certain. The majority of type 2 diabetes cases may result from defects in downstream-signaling components in the insulin-signaling pathway. Type 2 diabetes also is associated with declining α -cell function, resulting in reduced insulin secretion; these pathways are under intense study. A full understanding of the basis of insulin resistance is crucial for the development of new therapies for type 2 diabetes. Furthermore, apart from type 2 diabetes, insulin resistance is a central feature of several other common human disorders, including atherosclerosis and coronary artery disease, hypertension, and obesity.

TRANSFORMING GROWTH FACTOR β (TGF β) PATHWAY AND CANCERS¹²

Growth factor signaling controls cell growth, differentiation, and apoptosis. Although insulin and many mitogenic growth factors promote cell proliferation, some growth factors and hormones inhibit cell proliferation. Transforming growth factor β (TGF β) is one of them. The balance between mitogens and TGF β plays an important role in controlling the proper pace of cell cycle progression. The growth inhibition function of TGF β signaling in epithelial cells plays a major role in maintaining tissue homeostasis.

The TGF β superfamily comprises a large number of structurally related growth and differentiation factors that act through a receptor complex at the cell surface (Fig. 15-11). The complex consists of transmembrane serine/threonine kinases. The receptor signals through activation of heterotrimeric complexes of intracellular effectors called SMADs (which are contracted from homologous *Caenorhabditis elegans* Sma and *Drosophila* Mad, two evolutionarily conserved genes for TGF β signaling). Upon phosphorylation by the receptors, SMAD complexes translocate

into the nucleus, where they bind to gene promoters and cooperate with specific transcription factors to regulate the expression of genes that control cell proliferation and differentiation. For example, $TGF\beta$ strongly induces the transcription of a gene called $p15^{INK4B}$ (a type of CKI) and, at the same time, reduces the expression of many oncogenes such as *c-Myc*. The outcome of the altered gene expression leads to the inhibition of cell cycle progression. Meanwhile, the strength and duration of $TGF\beta$ signaling is fine-tuned by a variety of positive or negative modulators, including protein phosphatases. Therefore, controlled activation of $TGF\beta$ signaling is an intrinsic mechanism for cells to ensure controlled proliferation.

Fig. 15-11.

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

$TGF\beta$ signaling pathway. The $TGF\beta$ family has at least 29 members encoded in the human genome. They are also peptide growth factors. Each member binds to a heterotetrameric complex consisting of a distinct set of type I and type II receptors. $TGF\beta$ receptors are protein serine/threonine kinases and can phosphorylate the downstream substrates called *SMAD proteins*. Phosphorylated SMADs are directly transported into the nucleus, where they bind to the DNA and regulate gene expression that is responsible for inhibition of cell proliferation. Inactivation of the $TGF\beta$ pathway through genetic mutations in the $TGF\beta$ receptors or SMADs is frequent in human cancer, leading to the uncontrolled proliferation of cancer cells.

Resistance to $TGF\beta$'s anticancer action is one hallmark of human cancer cells. $TGF\beta$ receptors and SMADs are identified as tumor suppressors. The $TGF\beta$ signaling circuit can be disrupted in a variety of ways and in different types of human tumors. Some lose $TGF\beta$ responsiveness through downregulation or mutations of their $TGF\beta$ receptors. The cytoplasmic SMAD4 protein, which transduces signals from ligand-activated $TGF\beta$ receptors to downstream targets, may be eliminated through mutation of its encoding gene. The locus encoding cell cycle inhibitor $p15^{INK4B}$ may be deleted. Alternatively, the immediate downstream target of its actions, cyclin-dependent kinase 4 (CDK4), may become unresponsive to the inhibitory actions of $p15^{INK4B}$ because of mutations that block $p15^{INK4B}$ binding. The resulting cyclin D/CDK4 complexes constitutively inactivate tumor suppressor pRb by hyperphosphorylation. Finally, functional pRb, the end target of this pathway, may be lost through mutation of its gene. For example, in pancreatic and colorectal cancers, 100% of cells derived from these cancers carry genetic defects in the $TGF\beta$ signaling pathway. Therefore, the antiproliferative pathway converging onto pRb and the cell division cycle is, in one way or another, disrupted in a majority of human cancer cells. Besides cancer, dysregulation of $TGF\beta$ signaling also has been associated with other human diseases such as Marfan syndrome and thoracic aortic aneurysm.

Gene Therapy and Molecular Drugs in Cancer

Modern advances in the use of molecular biology to manipulate genomes have greatly contributed to the understanding of the molecular basis

for how cells live, die, or differentiate. Given the fact that human diseases arise from improper changes in the genome, the continuous understanding of how the genome functions will make it possible to tailor medicine on an individual basis. Although significant hurdles remain, the course toward therapeutic application of molecular biology already has been mapped out by many proof-of-principle studies in the literature. In this section, cancer is used as an example to elaborate some therapeutic applications of molecular biology. Modern molecular medicine includes gene therapy and molecular drugs that target genes or gene products that wire human cells.

Cancer is a complex disease, involving uncontrolled growth and spread of tumor cells (Fig. 15-12). Cancer development depends on the acquisition and selection of specific characteristics that set the tumor cell apart from normal somatic cells. Cancer cells have defects in regulatory circuits that govern normal cell proliferation and homeostasis. Many lines of evidence indicate that tumorigenesis in humans is a multistep process and that these steps reflect genetic alterations that drive the progressive transformation of normal human cells into highly malignant derivatives. The genomes of tumor cells are invariably altered at multiple sites, having suffered disruption through lesions as subtle as point mutations and as obvious as changes in chromosome complement. A succession of genetic changes, each conferring one or another type of growth advantage, leads to the progressive conversion of normal human cells into cancer cells.

Tumor clonal evolution and metastasis. A tumor develops from mutant cells with multiple genetic mutations. Through repeated alterations in the genome, mutant epithelial cells are able to develop into a cluster of cells (called a *tumor clone*) that proliferates in an uncontrollable

fashion. Further changes in the tumor cells can transform the tumor cells into a population of cells that can enter the blood vessels and repopulate in a new location.

Cancer research in the past 20 years has generated a rich and complex body of knowledge, revealing cancer to be a disease involving dynamic changes in the genome. The causes of cancer include genetic predisposition, environmental influences, infectious agents, and aging. These transform normal cells into cancerous ones by derailing a wide spectrum of regulatory pathways including signal transduction pathways, cell cycle machinery, or apoptotic pathways.¹³ The early notion that cancer was caused by mutations in genes critical for the control of cell growth implied that genome stability is important for preventing oncogenesis. There are two classes of cancer genes in which alteration has been identified in human and animal cancer cells: oncogenes, with dominant gain-of-function mutations, and tumor suppressor genes, with recessive loss-of-function mutations. In normal cells, oncogenes promote cell growth by activating cell cycle progression, while tumor suppressors counteract oncogenes' functions. Therefore, the balance between oncogenes and tumor suppressors maintains a well-controlled state of cell growth.

During the development of most types of human cancer, cancer cells can break away from primary tumor masses, invade adjacent tissues, and hence travel to distant sites where they form new colonies. This spreading process of tumor cells, called *metastasis*, is the cause of 90% of human cancer deaths. Metastatic cancer cells that enter the bloodstream can reach virtually all tissues of the body. Bones are one of the most common places for these cells to settle and start growing again. Bone metastasis is one of the most frequent causes of pain in people with cancer. It also can cause bones to break and create other symptoms and problems for patients.

The progression in the knowledge of cancer biology has been accelerating in recent years. All of the scientific knowledge acquired through hard work and discovery has made it possible for cancer treatment and prevention. As a result of explosive new discoveries, some modern treatments were developed. The success of these therapies, together with traditional treatments such as surgical procedures, is further underscored by the fact that in 2002 the cancer rate was reduced in the United States. Current approaches to the treatment of cancer involve killing cancer cells with toxic chemicals, radiation, or surgery. Alternatively, several new biologic- and gene-based therapies are aimed at enhancing the body's natural defenses against invading cancers. Understanding the biology of cancer cells has led to the development of designer therapies for cancer prevention and treatment. Gene therapy, immune system modulation, genetically engineered antibodies, and molecularly designed chemical drugs are all promising fronts in the war against cancer.

IMMUNOTHERAPY

The growth of the body is controlled by many natural signals through complex signaling pathways. Some of these natural agents have been used in cancer treatment and have been proven effective for fighting several cancers through the clinical trial process. These naturally occurring biologic agents, such as interferons, interleukins, and other cytokines, can now be produced in the laboratory. These agents, as well as the synthetic agents that mimic the natural signals, are given to patients to influence the natural immune response agents either by directly altering the cancer cell growth, or by acting indirectly to help healthy cells control the cancer. One of the most exciting applications of immunotherapy has come from the identification of certain tumor targets called *antigens* and the aiming of an antibody at these targets. This was first used as a means of localizing tumors in the body for diagnosis, and was more recently used to attack cancer cells. Trastuzumab (Herceptin) is an example of such a drug.¹⁴ Trastuzumab is a monoclonal antibody that neutralizes the mitogenic activity of cell-surface growth factor receptor HER-2. Approximately 25% of breast cancers overexpress HER-2. These tumors tend to grow faster and generally are more likely to recur than tumors that do not overproduce HER-2. Trastuzumab is designed to attack cancer cells that overexpress HER-2. Trastuzumab slows or stops the growth of these cells and increases the survival of HER-2-positive breast cancer patients. Another significant example is the administration of interleukin-2 (IL-2) to patients with metastatic melanoma or kidney cancer, which has been shown to mediate the durable regression of metastatic cancer. IL-2, a cytokine produced by human helper T lymphocytes, has a wide range of immune regulatory effects, including the expansion of lymphocytes following activation by a specific antigen. IL-2 has no direct impact on cancer cells. The impact of IL-2 on cancers in vivo derives from its ability to expand lymphocytes with antitumor activity. The expanded lymphocytes somehow recognize the antigen on cancer cells. Thus, the molecular identification of cancer antigens has opened new possibilities for the development of effective immunotherapies for patients with cancer. Clinical studies using immunization with peptides derived from cancer antigens have shown that high levels of lymphocytes with antitumor activity can be produced in cancer-bearing patients. Highly avid antitumor lymphocytes can be isolated from immunized patients and grown in vitro for use in cell-transfer therapies.

CHEMOTHERAPY

The primary function of anticancer chemicals is to block different steps involved in cell growth and replication. These chemicals often block a critical chemical reaction in a signal transduction pathway or during DNA replication or gene expression. For example, STI571, also known as *Gleevec*, is one of the first molecularly targeted drugs based on the changes that cancer causes in cells.¹⁵ STI571 offers promise for the treatment of chronic myeloid leukemia (CML) and may soon surpass interferon- γ as the standard treatment for the disease. In CML, STI571 is targeted at the Bcr-Abl kinase, an activated oncogene product in CML (Fig. 15-13). Bcr-Abl is an overly activated protein kinase resulting from a specific genetic abnormality generated by chromosomal translocation that is found in the cells of patients with CML. STI571-mediated inhibition of Bcr-Abl-kinase activity not only prevents cell growth of Bcr-Abl-transformed leukemic cells, but also induces apoptosis. Clinically, the drug quickly corrects the blood cell abnormalities caused by the leukemia in a majority of patients, achieving a complete disappearance of the leukemic blood cells and the return of normal blood cells. Additionally, the drug appears to have some effect on other cancers including certain brain tumors and GI stromal tumors, a very rare type of stomach cancer.

Mechanism of STI571 as a molecular drug. Bcr-Abl is an overly activated oncogene product resulting from a specific genetic abnormality generated by chromosomal translocation that is found in cells of patients with chronic myeloid leukemia. Bcr-Abl is an activated protein kinase and thus requires adenosine triphosphate (ATP) to phosphorylate substrates, which in turn promote cell proliferation. STI571 is a small molecule that competes with the ATP-binding site and thus blocks the transfer of phosphoryl group to substrate. PO₄ = phosphate; Tyr = tyrosine.

GENE THERAPY

Gene therapy is an experimental treatment that involves genetically altering a patient's own tumor cells or lymphocytes (cells of the immune system, some of which can attack cancer cells). For years, the concept of gene therapy has held promise as a new, potentially potent weapon to attack cancer. Although a rapid progression in the understanding of the molecular and clinical aspects of gene therapy has been witnessed in the past decade, gene therapy treatment has not yet been shown to be superior to standard treatments in humans.

Several problems must be resolved to transform it into a clinically relevant form of therapy. The major issues that limit its translation to the clinic are improving the selectivity of tumor targeting, improving the delivery to the tumor, and the enhancement of the transduction rate of the cells of interest. In most gene therapy trials for malignant diseases, tumors can be accessed and directly injected (in situ gene therapy). The in situ gene therapy also offers a better distribution of the vector virus throughout the tumor. Finally, a combination of gene therapy strategies will be more effective than the use of a single gene therapy system. An important aspect of effective gene therapy involves the choice of appropriate genes for manipulation. Genes that promote the production of messenger chemicals or other immune-active substances can be transferred into the patient's cells. These include genes that inhibit cell cycle progression, induce apoptosis, enhance host immunity against cancer cells, block the ability of cancer cells to metastasize, and cause tumor cells to undergo suicide. Recent development of RNAi technology,

which uses a loss-of-function approach to block gene functions, ensures a new wave of hopes for gene therapy. Nonetheless, gene therapy is still experimental and is being studied in clinical trials for many different types of cancer. The mapping of genes responsible for human cancer is likely to provide new targets for gene therapy in the future. The preliminary results of gene therapy for cancer are encouraging, and as advancements are made in the understanding of the molecular biology of human cancer, the future of this rapidly developing field holds great potential for treating cancer.

It is noteworthy that the use of multiple therapeutic methods has proven more powerful than a single method. The use of chemotherapy after surgery to destroy the few remaining cancerous cells in the body is called *adjuvant* therapy. Adjuvant therapy was first tested and found to be effective in breast cancer. It was later adopted for use in other cancers. A major discovery in chemotherapy is the advantage of multiple chemotherapeutic agents (known as *combination* or *cocktail chemotherapy*) over single agents. Some types of fast-growing leukemias and lymphomas (tumors involving the cells of the bone marrow and lymph nodes) responded extremely well to combination chemotherapy, and clinical trials led to gradual improvement of the drug combinations used. Many of these tumors can be cured today by combination chemotherapy. As cancer cells carry multiple genetic defects, the use of combination chemotherapy, immunotherapy, and gene therapies may be more effective in treating cancers.

Stem Cell Research

Stem cell biology represents a cutting-edge scientific research field with potential clinical applications.¹⁶ It may have an enormous impact on human health by offering hope for curing human diseases such as diabetes mellitus, Parkinson's disease, neurologic degeneration, and congenital heart disease. Stem cells are endowed with two remarkable properties (Fig. 15-14). First, stem cells can proliferate in an undifferentiated but pluripotent state, and as a result can self-renew. Second, they have the ability to differentiate into many specialized cell types. There are two groups of stem cells: embryonic stem (ES) cells and adult stem cells. Human ES cells are derived from early preimplantation embryos called *blastocysts* (5 days postfertilization), and are capable of generating all differentiated cell types in the body. Adult stem cells are present in and can be isolated from adult tissues. They often are tissue specific and only can generate the cell types comprising a particular tissue in the body; however, in some cases they can transdifferentiate into cell types found in other tissues. Hematopoietic stem cells are adult stem cells. They reside in bone marrow and are capable of generating all cell types of the blood and immune system.

Fig. 15-14.

Stem cells. A stem cell is capable of self-renewal (unlimited cell cycle) and differentiation (becoming nondividing cells with specialized functions). Differentiating stem cells often undergo additional cell divisions before they become fully mature cells that carry out specific tissue functions.

Stem cells can be grown in culture and be induced to differentiate into a particular cell type, either *in vitro* or *in vivo*. With the recent and continually increasing improvement in culturing stem cells, scientists are beginning to understand the molecular mechanisms of stem cell self-renewal and differentiation in response to environmental cues. It is believed that discovery of the signals that control self-renewal vs. differentiation will be extremely important for the therapeutic use of stem cells in treating disease. It is possible that success in the study of the changes in signal transduction pathways in stem cells will lead to the development of therapies to specifically differentiate stem cells into a

particular cell type to replace diseased or damaged cells in the body. Recently, stem cell research has been transformed by the discovery from the Shinya Yamanaka group and the James Thomson group, who have found that a simple genetic manipulation can reprogram adult differentiated cells into pluripotent cells.¹⁷ This exciting discovery not only bypasses the ethical issues of using early embryos to generate ES cells, but also ensures a potentially limitless source of patient-specific stem cells for tissue engineering and transplantation medicine.

Personalized Genomic Medicine

Genes determine our susceptibility to diseases and direct our body's response to medicine. Because an individual's genes differ from those of another, the determination of each individual's genome has the potential to improve the predication, prevention, and treatment of disease. Sequencing of individual genomes holds the key to realize this revolution called *personalized genomic medicine*. Next generation sequencing such as 454 Life Sciences technology is promising to reduce the time and cost so that genome sequencing can be affordable in the health care system. The goal of personalized genomic medicine is to spot the gene variations in each individual and to attack the disease by choosing personalized treatments that work with the individual's genomic profile. Personalized genomic medicine will undoubtedly revolutionize the practice of modern medicine.

TECHNOLOGIES OF MOLECULAR AND CELL BIOLOGY

DNA Cloning

Since the advent of recombinant DNA technology three decades ago, hundreds of thousands of genes have been identified. Recombinant DNA technology is the technology that uses advanced enzymatic and microbiologic techniques to manipulate DNA.¹⁸ Pure pieces of any DNA can be inserted into bacteriophage DNA or other carrier DNA such as plasmids to produce recombinant DNA in bacteria. In this way, DNA can be reconstructed, amplified, and used to manipulate the functions of individual cells or even organisms. This technology, often referred to as *DNA cloning*, is the basis of all other DNA analysis methods. It is only with the awesome power of recombinant DNA technology that the completion of the Human Genome Project was possible. It also has led to the identification of the entire gene complements of organisms such as viruses, bacteria, worms, flies, and plants.

Molecular cloning refers to the process of cloning a DNA fragment of interest into a DNA vector that ultimately is delivered into bacterial or mammalian cells or tissues^{19,20} (Fig. 15-15). This represents a very basic technique that is widely used in almost all areas of biomedical research. DNA vectors often are called *plasmids*, which are extrachromosomal molecules of DNA that vary in size and can replicate and be transmitted from bacterial cell to cell. Plasmids can be propagated either in the cytoplasm, or after insertion, as part of the bacterial chromosome in *Escherichia coli*. The process of molecular cloning involves several steps of manipulation of DNA. First, the vector plasmid DNA is cleaved with a restriction enzyme to create compatible ends with the foreign DNA fragment to be cloned. The vector and the DNA fragment are then joined in vitro by a DNA ligase. Alternatively, DNA cloning can be simply done through the so-called *Gateway Technology* that allows for the rapid and efficient transfer of DNA fragments between different cloning vectors while maintaining reading frame and orientation, without the use of restriction endonucleases and DNA ligase. The technology, which is based on the site-specific recombination system of bacteriophage I, is simple, fast, robust and automatable, thus compatible for high-throughput DNA cloning.

Fig. 15-15.

Generation of recombinant DNA. The vector is a circular DNA molecule that is capable of replicating in *Escherichia coli* cells. Insert DNA (often your favorite gene) is ligated to the vector after ends of both DNA are properly treated with restriction enzymes. Ligated DNA (i.e., the recombinant plasmid DNA) is then transformed into *E. coli* cells, where it replicates to produce recombinant progenies. *E. coli* cells carrying the recombinant plasmid can be propagated to yield large quantities of plasmid DNA.

Finally, the ligation product or the Gateway reaction product is introduced into competent host bacteria; this procedure is called *transformation*, which can be done by either calcium/heat shock or electroporation. Precautions must be taken in every step of cloning to generate the desired DNA construct. The vector must be correctly prepared to maximize the creation of recombinants; for example, it must be enzymatically treated to prevent self-ligation. Host bacteria must be made sufficiently competent to permit the entry of recombinant plasmids into cells. The selection of desired recombinant plasmid-bearing *E. coli* normally is achieved by the property of drug resistance conferred by the plasmid vectors. The plasmids encoding markers provide specific resistance to (i.e., the ability to grow in the presence of) antibiotics such as ampicillin, kanamycin, and tetracycline. The foreign component in the plasmid vector can be a mammalian expression cassette, which can direct expression of foreign genes in mammalian cells. The resulting plasmid vector can be amplified in *E. coli* to prepare large quantities of DNA for its subsequent applications such as transfection, gene therapy, transgenics, and knockout mice.

Detection of Nucleic Acids and Proteins

SOUTHERN BLOT HYBRIDIZATION

Southern blotting refers to the technique of transferring DNA fragments from an electrophoresis gel to a membrane support, and the subsequent analysis of the fragments by hybridization with a radioactively labeled probe (Fig. 15-16).²¹ Southern blotting is named after E. M. Southern, who in 1975 first described the technique of DNA analysis. It enables reliable and efficient analysis of size-fractionated DNA fragments in an immobilized membrane support. Southern blotting is composed of several steps. It normally begins with the digestion of the DNA samples with appropriate restriction enzymes and the separation of DNA samples in an agarose gel with appropriate DNA size markers. The DNA gel is stained with ethidium bromide and photographed with a ruler laid alongside the gel so that band positions can later be identified on the membrane. The DNA gel then is treated so the DNA fragments are denatured (i.e., strand separation). The DNA then is transferred onto a nitrocellulose membrane by capillary diffusion or under electricity. After immobilization, the DNA can be subjected to hybridization analysis, enabling bands with sequence similarity to a radioactively labeled probe to be identified.

Fig. 15-16.

Southern blotting. Restriction enzymatic fragments of DNA are separated by agarose gel electrophoresis, transferred to a membrane filter, and then hybridized to a radioactive probe.

The development of Southern transfer and the associated hybridization techniques made it possible for the first time to obtain information about the physical organization of single and multicopy sequences in complex genomes. The later application of Southern blotting hybridization to the study of restriction fragment length polymorphisms opened up new possibilities such as genetic fingerprinting and prenatal diagnosis of genetic diseases.

NORTHERN BLOT HYBRIDIZATION

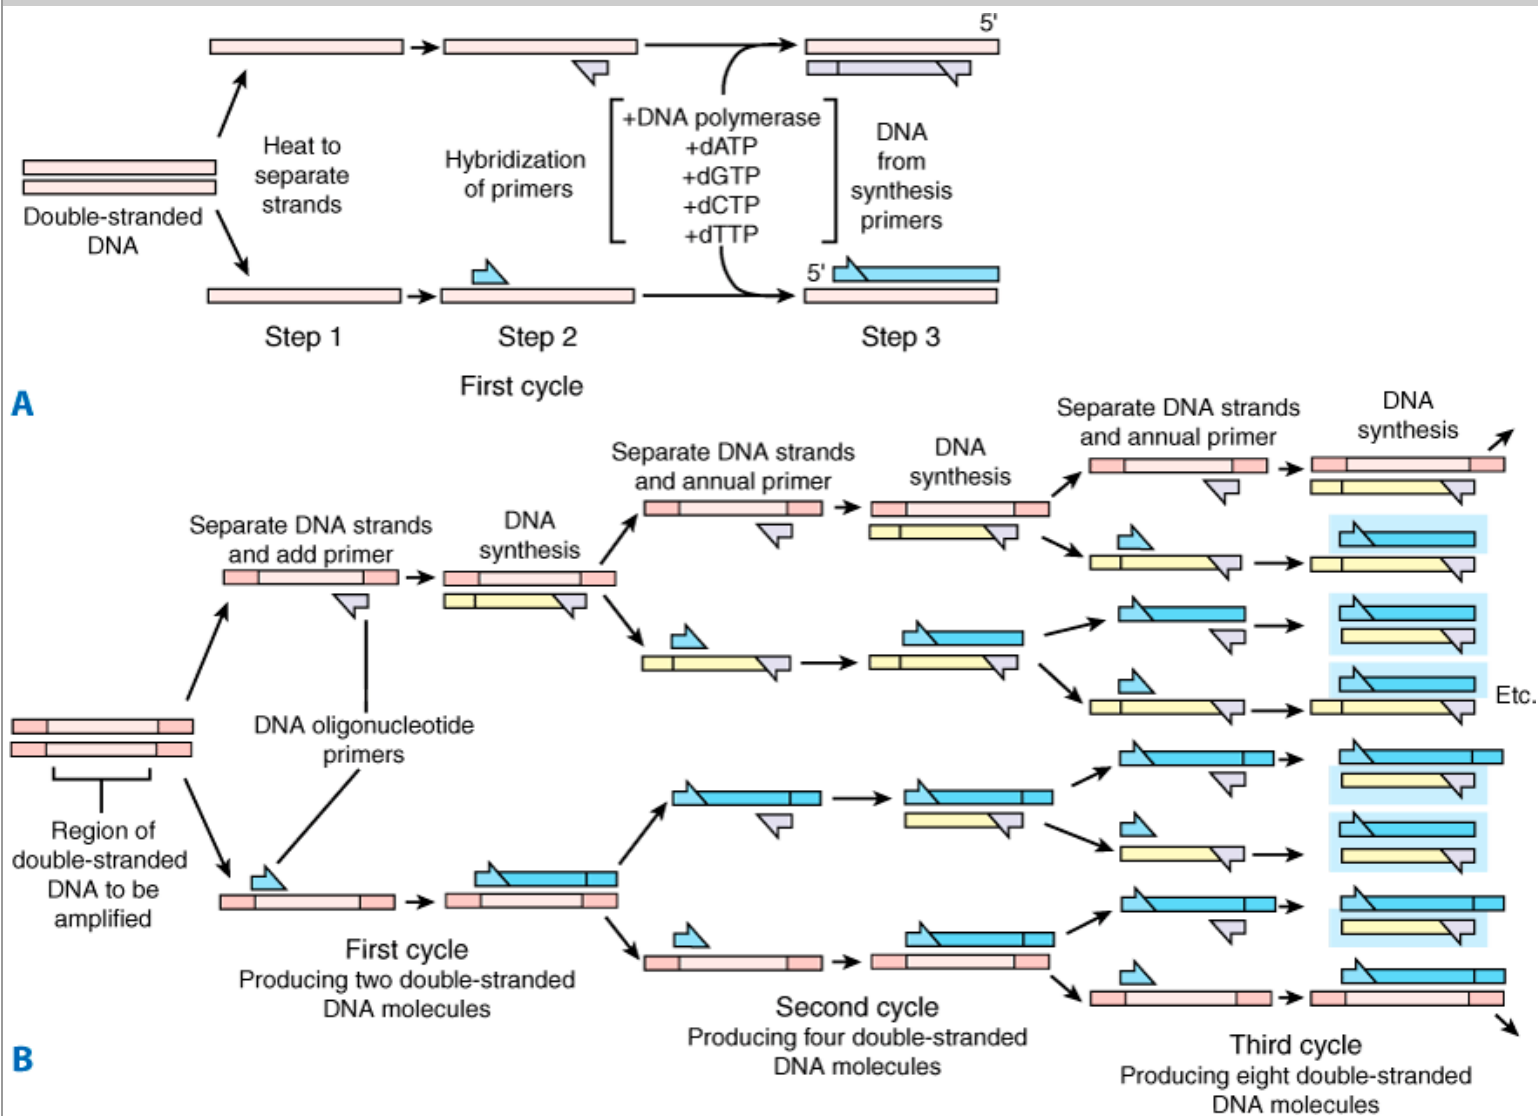

Northern blotting refers to the technique of size fractionation of RNA in a gel and the transferring of an RNA sample to a solid support (membrane) in such a manner that the relative positions of the RNA molecules are maintained. The resulting membrane then is hybridized with a labeled probe complementary to the mRNA of interest. Signals generated from detection of the membrane can be used to determine the size and abundance of the target RNA. In principle, Northern blot hybridization is similar to Southern blot hybridization (and hence its name), with the exception that RNA, not DNA, is on the membrane. Although reverse-transcriptase polymerase chain reaction has been used in many applications (described in Polymerase Chain Reaction below), Northern analysis is the only method that provides information regarding mRNA size and has remained a standard method for detection and quantitation of mRNA. The process of Northern hybridization involves several steps, as does Southern hybridization, including electrophoresis of RNA samples in an agarose-formaldehyde gel, transfer to a membrane support, and hybridization to a radioactively labeled DNA probe. Data from hybridization allow quantification of steady-state mRNA levels, and at the same time, provide information related to the presence, size, and integrity of discrete mRNA species. Thus, Northern blot analysis, also termed *RNA*

gel blot analysis, commonly is used in molecular biology studies relating to gene expression.

POLYMERASE CHAIN REACTION

PCR is an in vitro method for the polymerase-directed amplification of specific DNA sequences using two oligonucleotide primers that hybridize to opposite strands and flank the region of interest in the target DNA (Fig. 15-17).²² One cycle of PCR reaction involves template denaturation, primer annealing, and the extension of the annealed primers by DNA polymerase. Because the primer extension products synthesized in one cycle can serve as a template in the next, the number of target DNA copies nearly doubles at each cycle. Thus, a repeated series of cycles result in the exponential accumulation of a specific fragment in which the termini are sharply defined by the 5' ends of the primers. The introduction of the thermostable DNA polymerase (e.g., Taq polymerase) transforms the PCR into a simple and robust reaction. The reaction components (e.g., template, primers, Taq polymerase, 2'-deoxynucleoside 5'-triphosphates, and buffer) could all be assembled and the amplification reaction carried out by simply cycling the temperatures within the reaction tube. The specificity and yield in amplifying a particular DNA fragment by PCR reaction is affected by the proper setting of the reaction parameters (e.g., enzyme, primer, and Mg^{2+} concentration, as well as the temperature cycling profile). Modifying various PCR parameters to optimize the specificity of amplification yields more homogenous products, even in rare template reactions.

Fig. 15-17.

Amplification of DNA using the polymerase chain reaction technique. Knowledge of the DNA sequence to be amplified is used to design two synthetic DNA oligonucleotides, each complementary to the sequence on one strand of the DNA double helix at opposite ends of the region to

be amplified. These oligonucleotides serve as primers for in vitro DNA synthesis, which is performed by a DNA polymerase, and they determine the segment of the DNA that is amplified. **A.** PCR starts with a double-stranded DNA, and each cycle of the reaction begins with a brief heat treatment to separate the two strands (*Step 1*). After strand separation, cooling of the DNA in the presence of a large excess of the two primer DNA oligonucleotides allows these primers to hybridize to complementary sequences in the two DNA strands (*Step 2*). This mixture is then incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that DNA is synthesized, starting from the two primers (*Step 3*). The entire cycle is then begun again by a heat treatment to separate the newly synthesized DNA strands. **B.** As the procedure is performed over and over again, the newly synthesized fragments serve as templates in their turn, and, within a few cycles, the predominant DNA is identical to the sequence bracketed by and including the two primers in the original template. Of the DNA put into the original reaction, only the sequence bracketed by the two primers is amplified because there are no primers attached anywhere else. In the example illustrated in **B**, three cycles of reaction produce 16 DNA chains, eight of which (*boxed in brown*) are the same length as and correspond exactly to one or the other strand of the original bracketed sequence shown at the far left; the other strands contain extra DNA downstream of the original sequence, which is replicated in the first few cycles. After three more cycles, 240 of the 256 DNA chains correspond exactly to the original bracketed sequence, and after several more cycles, essentially all of the DNA strands have this unique length.

(From Alberts et al,¹ with permission.)

The emergence of the PCR technique has dramatically altered the approach to both fundamental and applied biologic problems. The capability of amplifying a specific DNA fragment from a gene or the whole genome greatly advances the study of the gene and its function. It is simple, yet robust, speedy, and most of all, flexible. As a recombinant DNA tool, it underlies almost all of molecular biology. This revolutionary technique enabled the modern methods for the isolation of genes, construction of a DNA vector, introduction of alterations into DNA, and quantitation of gene expression, making it a fundamental cornerstone of genetic and molecular analysis.

IMMUNOBLOTTING AND IMMUNOPRECIPITATION

Analyses of proteins are primarily carried out by antibody-directed immunologic techniques. For example, Western blotting, also called *immunoblotting*, is performed to detect protein levels in a population of cells or tissues, whereas immunoprecipitation is used to concentrate proteins from a larger pool. Using specific antibodies, microscopic analysis called *immunofluorescence* and *immunohistochemistry* is possible for the subcellular localization and expression of proteins in cells or tissues, respectively.

Immunoblotting refers to the process of identifying a protein from a mixture of proteins (Fig. 15-18). It consists of five steps: (a) sample preparation; (b) electrophoresis (separation of a protein mixture by sodium dodecyl sulfate-polyacrylamide gel electrophoresis); (c) transfer (the electrophoretic transfer of proteins from gel onto membrane support, (e.g., nitrocellulose, nylon, or polyvinylidene difluoride); (d) staining (the subsequent immunodetection of target proteins with specific antibody); and (e) development (colorimetric or chemiluminescent visualization of the antibody-recognized protein). Thus, immunoblotting combines the resolution of gel electrophoresis with the specificity of immunochemical detection. Immunoblotting is a powerful tool used to determine a number of important characteristics of proteins. For example, immunoblotting analysis will determine the presence and the quantity of a protein in a given cellular condition and its relative molecular weight. Immunoblotting also can be used to determine whether posttranslational modification such as phosphorylation has occurred on a protein. Importantly, through immunoblotting analysis, a comparison of the protein levels and modification states in normal vs. diseased tissues is possible.

Fig. 15-18.

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Immunoblotting. Proteins are prepared from cells or tissues, separated according to size by sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to a membrane filter. Detection of a protein of interest can be done by sequential incubation with a primary antibody directed against the protein, and then with an enzyme-conjugated secondary antibody that recognizes the primary antibody. Visualization of the protein is carried out by using colorimetric or luminescent substrates for the conjugated enzyme.

Immunoprecipitation, another widely used immunochemical technique, is a method that uses antibody to enrich a protein of interest and any other proteins that are associated with it (Fig. 15-19). The principle of the technique lies in the property of a strong and specific affinity between antibodies and their antigens to locate and pull down target proteins in solution. Once the antibody-antigen (target protein) complexes are formed in the solution, they are collected and purified using small agarose beads with covalently attached protein A or protein G. Both protein A and protein G specifically interact with the antibodies, thus forming a large immobilized complex of antibody-antigen bound to beads.

The purified protein can then be analyzed by a number of biochemical methods. When immunoprecipitation is combined with immunoblotting, it can be used for the sensitive detection of proteins in low concentrations, which would otherwise be difficult to detect. Moreover, combined immunoprecipitation and immunoblotting analysis is very efficient in analyzing the protein-protein interactions or determining the posttranslational modifications of proteins. In addition, immunoprecipitated proteins can be used as preparative steps for assays such as intrinsic or associated enzymatic activities. The success of immunoprecipitation is influenced by two major factors: (a) the abundance of the protein in the original preparation and (b) the specificity and affinity of the antibody for this protein.

Immunoprecipitation. Proteins prepared from cells or tissues can be enriched using an antibody directed against them. The antibody is first conjugated to agarose beads and then incubated with protein mixture. Owing to the specific high-affinity interaction between antibody and its antigen (the protein), the antigen-antibody complex can be collected on beads by centrifugation. The immunoprecipitated protein can then be analyzed by immunoblotting. Alternatively, if proteins are radiolabeled in cells or tissues, detection of immunoprecipitated proteins can be achieved by simple sodium dodecyl sulfate-polyacrylamide gel electrophoresis followed by autoradiography.

DNA MICROARRAY

Now that the human genome sequence is completed, the primary focus of biologists is rapidly shifting toward gaining an understanding of how genes function. One of the interesting findings about the human genome is that there are only approximately 25,000 to 30,000 protein-encoding genes. However, it is known that genes and their products function in a complicated and yet orchestrated fashion and that the surprisingly small number of genes from the genome sequence is sufficient to make a human being. Nonetheless, with the tens of thousands of genes present in the genome, traditional methods in molecular biology, which generally work on a one-gene-in-one-experiment basis, cannot generate the whole picture of genome function. In the past several years, a new technology called *DNA microarray* has attracted tremendous interest among biologists as well as clinicians. This technology promises to monitor the whole genome on a single chip so researchers can have a better picture of the interactions among thousands of genes simultaneously.

DNA microarray, also called *gene chip*, *DNA chip*, and *gene array*, refers to large sets of probes of known sequences orderly arranged on a small chip, enabling many hybridization reactions to be carried out in parallel in a small device (Fig. 15-20).²³ Like Southern and Northern hybridization, the underlying principle of this technology is the remarkable ability of nucleic acids to form a duplex between two strands with complementary base sequences. DNA microarray provides a medium for matching known and unknown DNA samples based on base-pairing rules, and automating the process of identifying the unknowns. Microarrays require specialized robotics and imaging equipment that spot the

samples on a glass or nylon substrate, carry out the hybridization, and analyze the data generated. DNA microarrays containing different sets of genes from a variety of organisms are now commercially available, allowing biologists to simply purchase the chips and perform hybridization and data collection. The massive scale of microarray experiments requires the aid of computers. They are used during the capturing of the image of the hybridized target, the conversion of the image into usable measures of the extent of hybridization, and the interpretation of the extent of hybridization into a meaningful measure of the amount of the complementary sequence in the target. Some data-analysis packages are available commercially or can be found in the core facility of certain institutions.

Fig. 15-20.

DNA microarrays. DNA microarrays, also referred to as *gene chips*, have arrayed oligonucleotides or complementary DNAs (cDNAs) corresponding to tens or hundreds of distinct genes. DNA microarray is used to comparatively analyze gene expression in different cells or tissues. Messenger RNAs (mRNAs) extracted from different sources are converted into cDNAs, which are then labeled with different fluorescent dyes. The two fluorescent cDNA probes are mixed and hybridized to the same DNA microarrays. The ratio of dark brown to light brown

fluorescence at each spot on the chip represents the relative expression of levels of that gene between two different cells. In the example shown in the figure, cDNA from cell #1 is labeled with dark brown fluorescence and the cell #2 light brown fluorescence. On the microarray, dark brown spots demonstrate that the gene in cell sample #1 is expressed at a higher level than the corresponding gene in cell sample #2. The light brown spots indicate that the gene in cell sample #1 also is expressed at a higher level than the corresponding gene in cell sample #2. Beige spots represent equal expression of the gene in both cell samples.

DNA microarray technology has produced many significant results in quite different areas of application. There are two major application forms for the technology: identification of sequence (gene/gene mutation) and determination of expression level (abundance) of genes. For example, analysis of genomic DNA detects amplifications and deletions found in human tumors. Differential gene expression analysis also has uncovered networks of genes differentially present in cancers that cannot be distinguished by conventional means. Significantly, recent advancements in next generation sequencing (e.g., Solexa and 454 technology) have demonstrated the precision and speed to analyze gene expression in any genome.

Cell Manipulations

CELL CULTURE

Cell culture has become one of the most powerful techniques, as cultured cells are being used in a diversity of biologic fields ranging from biochemistry to molecular and cellular biology.²⁴ Through their ability to be maintained *in vitro*, cells can be manipulated by the introduction of genes of interest (cell transfection) and be transferred into *in vivo* biologic receivers (cell transplantation) to study the biologic effect of the interested genes (Fig. 15-21). In general, cell culture procedures are simple and straightforward. In the laboratory, cells are cultured either as a monolayer (in which cells grow as one layer on culture dishes) or in suspension.

Fig. 15-21.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Cell culture and transfection. **A.** Primary cells can be isolated from tissues and cultured in medium for a limited period of time. After genetic manipulations to overcome the cell aging process, primary cells can be immortalized into cell lines for long-term culture. **B.** DNA can be introduced into cells to produce recombinant gene products or to analyze the biologic functions of the gene.

It is important to know the wealth of information concerning cell culturing before attempting the procedure. For example, conditions of culture will depend on the cell types to be cultured (e.g., origins of the cells such as epithelial or fibroblasts, or primary vs. immortalized/transformed

cells). It also is necessary to use special culture medium that has been used to establish the cell line (if it is a cell line), including the type and concentration of serum used to maintain the growth of cells in vitro. If primary cells are derived from human patients or animals, some commercial resources have a variety of culture media available for testing. Generally, cells are manipulated in a sterile hood and the working surfaces are wiped with 80% ethyl alcohol solution. Cultured cells are maintained in a humidified carbon dioxide incubator at 37°C (98.6°F), and need to be examined daily under an inverted microscope to check for possible contamination and confluency (the area cells occupy on the dish). As a general rule, cells should be fed with fresh medium every 2 to 3 days and split when they reach confluency. Depending upon the growth rate of cells, the actual time and number of plates required to split cells in two varies from cell line to cell line. Splitting a monolayer requires the detachment of cells from plates by using a trypsin treatment, of which concentration and time period vary depending on cell lines. If cultured cells grow continuously in suspension, they are split or subcultured by dilution.

Because cell lines may change their properties when cultured, it is not possible to maintain cell lines in culture indefinitely. Therefore, it is essential to store cells at various time passages for future use. The common procedure is to use cryopreservation. The solution for cryopreservation is fetal calf serum containing 10% dimethyl sulfoxide or glycerol, stored in liquid nitrogen [−196°C (−320.8°F)]. Cells can be stored for many years using this method.

CELL TRANSFECTION

Cells are cultured for two reasons: to maintain and to manipulate them (see Fig. 15-21). The transfer of foreign macromolecules, such as nucleic acid, into living cells provides an efficient method for studying a variety of cellular processes and functions at the molecular level. DNA transfection has become an important tool for studying the regulation and function of genes. The cDNA to be expressed should be in a plasmid vector, behind an appropriate promoter working in mammalian cells (e.g., the constitutively active cytomegalovirus promoter or inducible promoter). Depending on the cell type, many ways of introducing DNA into mammalian cells have been developed. Commonly used approaches include calcium phosphate, electroporation, liposome-mediated transfection, the nonliposomal formulation, and the use of viral vectors. These methods have shown variable success when attempting to transfect a wide variety of cells. Transfection can be performed in the presence or absence of serum. It is suggested to test the transfection efficiency of cell lines of interest by comparing transfection with several different approaches. For a detailed transfection protocol, it is best to follow the manufacturer's instructions for the particular reagent. General considerations for a successful transfection depend on several parameters, such as the quality and quantity of DNA and cell culture (type of cell and growth phase). To minimize variations in both of these in transfection experiments, it is best to use cells that are healthy, proliferate well, and are plated at a constant density. After DNA is introduced into the cells, it is normally maintained epitopically in cells and will be diluted while host cells undergo cell division. Therefore, functional assays should be performed 24 to 72 hours after transfection, also termed *transient transfection*. In many applications, it is important to study the long-term effects of DNA in cells by stable transfection. Stable cell clones can be selected for DNA integration into the host cell genome, when plasmids carry an antibiotic-resistant marker. In the presence of antibiotics, only those cells that continuously carry the antibiotic-resistant marker (after generations of cell division) can survive. One application of stable transfection is the generation of transgenic or knockout mouse models, in which the transgene has to be integrated in the mouse genome. Stable cells also can be transplanted into host organs.

Genetic Manipulations

Understanding how genes control the growth and differentiation of the mammalian organism has been the most challenging topic of modern research. It is essential for us to understand how genetic mutations and chemicals lead to the pathologic condition of human bodies. The knowledge and ability to change the genetic program will inevitably make a great impact on society and have far-reaching effects on how we think of ourselves.

The mouse has become firmly established as the primary experimental model for studying how genes control mammalian development. Genetically altered mice are powerful model systems in which to study the function and regulation of genes.²⁵ The gene function can be studied by creating mutant mice through homologous recombination (gene knockout). A gene of interest also can be introduced into the mouse (transgenic mouse) to study its effect on development or diseases. As mouse models do not precisely represent human biology, genetic manipulations of human somatic or ES cells provide a great means for the understanding of the molecular networks in human cells. In all cases, the gene to be manipulated must first be cloned. Gene cloning has been made easy by recombinant DNA technology and the availability of human and mouse genomes (see the Human Genome section). The following section briefly describes the technologies and the principles behind

them.

TRANSGENIC MICE

During the past 20 years, DNA cloning and other techniques have allowed the introduction of new genetic material into the mouse germline. As early as 1980, the first genetic material was successfully introduced into the mouse germline by using pronuclear microinjection of DNA (Fig. 15-22). These animals, called *transgenic*, contain foreign DNA within their genomes. In simple terms, a transgenic mouse is created by the microinjection of DNA into the one-celled mouse embryo, allowing the efficient introduction of cloned genes into the developing mouse somatic tissues, as well as into the germline.

Fig. 15-22.

Transgenic mouse technology. DNA is microinjected into a pronucleus of a fertilized egg, which is then transplanted into a foster mother. The microinjected egg develops offspring mice. Incorporation of the injected DNA into offspring is indicated by the different coat color of offspring mice.

Designs of a Transgene

The transgenic technique has proven to be extremely important for basic investigations of gene regulation, creation of animal models of human disease, and genetic engineering of livestock. The design of a transgene construct is a simple task. Like constructs used in cell transfection, a simple transgene construct consists of a protein-encoding gene and a promoter that precedes it. The most common applications for the use of transgenic mice are similar to those in the cell culture system: (a) to study the functions of proteins encoded by the transgene and (b) to analyze the tissue-specific and developmental-stage-specific activity of a gene promoter. Examples of the first application include overexpression of oncogenes, growth factors, hormones, and other key regulatory genes, as well as genes of viral origins. Overexpression of the transgene normally represents gain-of-function mutations. The tissue distribution or expression of a transgene is determined primarily by *cis*-acting promoter enhancer elements within or in the immediate vicinity of the genes themselves. Thus, controlled expression of the transgene can be made possible by using an inducible or tissue-specific promoter. Furthermore, transgenic mice carrying dominant negative mutations of a regulatory gene also have been generated. For example, a truncated growth factor receptor that can bind to the ligand, but loses its catalytic activity when expressed in mice, can block the growth factor binding to the endogenous protein. In this way, the transgenic mice exhibit a loss of function of phenotype, possibly resembling the knockout of the endogenous gene. The second application of the transgenic expression is to analyze the gene promoter of interest. The gene promoter of interest normally is fused to a reporter gene that encodes β -galactosidase (also called *LacZ*), luciferase, or green fluorescence protein. Chemical staining of *LacZ* activity or detection of chemiluminescence/fluorescence can easily visualize the expression of the reporter gene. The amount of the reporter gene activity represents the activity of the promoter, and thus, reporter activities are tightly correlated to expression of the gene in which the promoter is used to drive the reporter gene expression.

Production of Transgenic Mice

The success of generating transgenic mice is largely dependent upon the proper quality and concentration of the DNA supplied for

microinjection. For DNA to be microinjected into mouse embryos, it should be linearized by restriction digestion to increase the chance of proper transgene integration. Concentration of DNA should be accurately determined. Mice that develop from injected eggs often are termed *founder* mice.

Genotyping of Transgenic Mice

The screening of founder mice and the transgenic lines derived from the founders is accomplished by determining the integration of the injected gene into the genome. This normally is achieved by performing PCR or Southern blot analysis with a small amount of DNA extracted from the mouse tail. Once a given founder mouse is identified to be transgenic, it will be mated to begin establishing a transgenic line.

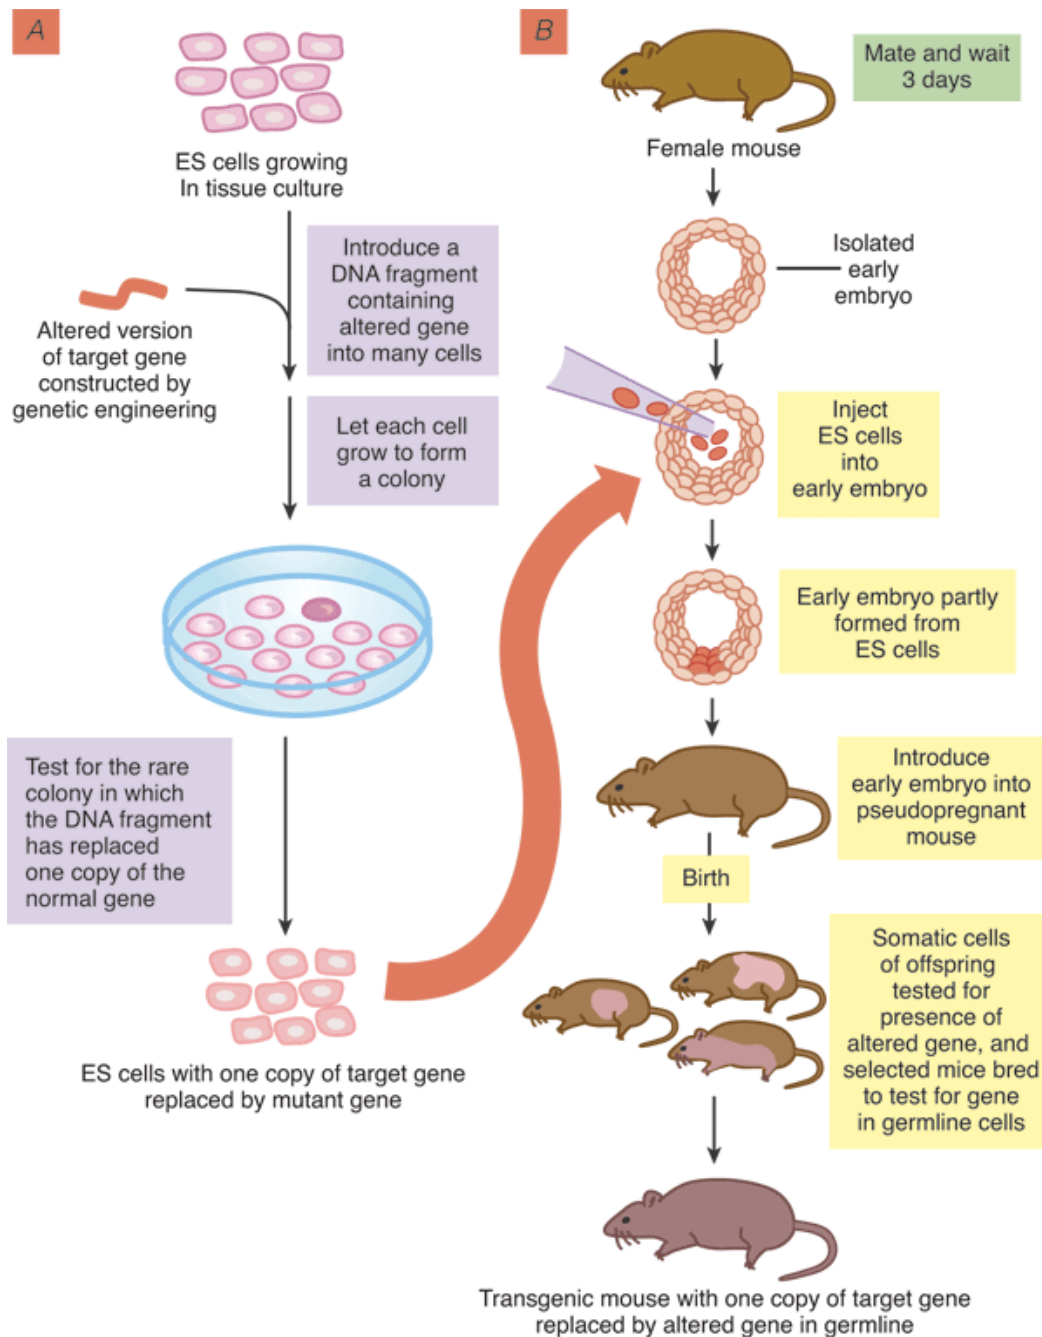

Analysis of Phenotype of Transgenic Mice

Phenotypes of transgenic mice are dictated by both the expression pattern and biologic functions of the transgene. Depending on the promoter and the transgene, phenotypes can be predictable or unpredictable. Elucidation of the functions of the transgene-encoded protein in vitro often offers some clue to what the protein might do in vivo. When a constitutively active promoter is used to drive the expression of transgenes, mice should express the gene in every tissue; however, this mouse model may not allow the identification and study of the earliest events in disease pathogenesis. Ideally, the use of tissue-specific or inducible promoter allows one to determine if the pathogenic protein leads to a reversible or irreversible disease process. For example, rat insulin promoter can target transgene expression exclusively in the α -cells of pancreatic islets. The phenotype of insulin promoter-mediated transgenic mice is projected to affect the function of human α -cells.

GENE KNOCKOUT IN MICE

The isolation and genetic manipulation of ES cells represents one of the most important milestones for modern genetic technologies. Several unique properties of these ES cells, such as the pluripotency to differentiate into different tissues in an embryo, make them an efficient vehicle for introducing genetic alterations into this species. Thus, this technology provides an important breakthrough, making it possible to genetically manipulate ES cells in a controlled way in the culture dish and then introduce the mutation into the germline (Fig. 15-23). This not only makes mouse genetics a powerful approach for addressing important gene functions but also identifies the mouse as a great system to model human disease.

Knockout mouse technology. Summary of the procedures used for making gene replacements in mice. In the first step (**A**), an altered version of the gene is introduced into cultured embryonic stem (ES) cells. Only a few rare ES cells will have their corresponding normal genes replaced by the altered gene through a homologous recombination event. Although the procedure is often laborious, these rare cells can be identified and cultured to produce many descendants, each of which carries an altered gene in place of one of its two normal corresponding genes. In the next step of the procedure (**B**), these altered ES cells are injected into a very early mouse embryo; the cells are incorporated into the growing embryo, and a mouse produced by such an embryo will contain some somatic cells that carry the altered gene. Some of these mice also will contain germline cells that contain the altered gene. When bred with a normal mouse, some of the progeny of these mice will contain the altered gene in all of their cells. If two such mice are in turn bred (not shown), some of the progeny will contain two altered genes (one on each chromosome) in all of their cells. If the original gene alteration completely inactivates the function of the gene, these mice are known as *knockout mice*. When such mice are missing genes that function during development, they often die with specific defects long before they reach adulthood. These defects are carefully analyzed to help decipher the normal function of the missing gene.

(From Alberts et al,¹ with permission.)

Targeting Vector

The basic concept in building a targeting vector to knock out a gene is to use two segments of homologous sequence to a gene of interest that

flank a part of the gene essential for functions (e.g., the coding region). In the target vector, a positive selectable marker (e.g., the *neo* gene) is placed between the homology arms. Upon the homologous recombination between the arms of the vector and the corresponding genomic regions of the gene of interest in ES cells, the positive selectable marker will replace the essential segment of the target gene, thus creating a null allele. In addition, a negative selectable marker also can be used alone or in combination with the positive selectable marker, but must be placed outside of the homologous arms to enrich for homologous recombination. To create a conditional knockout (i.e., gene knockout in a spatiotemporal fashion), site-specific recombinases such as the popular cre-loxP system are used. If the consensus loxP sequences that are recognized by cre recombinases are properly designed into targeting loci, controlled expression of the recombinase as a transgene can result in the site-specific recombination at the right time and in the right place (i.e., cell type or tissue). This method is markedly useful to prevent developmental compensations and to introduce null mutations in the adult mouse that would otherwise be lethal. Overall, this cre-loxP system allows for spatial and temporal control over transgene expression and takes advantage of inducers with minimal pleiotropic effects.

Introduction of the Targeting Vector into ES Cells

ES cell lines can be obtained from other investigators, commercial sources, or established from blastocyst-stage embryos. To maintain ES cells at their full developmental potential, optimal growth conditions should be provided in culture. If culture conditions are inappropriate or inadequate, ES cells may acquire genetic lesions or alter their gene expression patterns, and consequently decrease their pluripotency. Excellent protocols are available in public domains or in mouse facilities in most institutions.

To alter the genome of ES cells, the targeting vector DNA then is transfected into ES cells. Electroporation is the most widely used and the most efficient transfection method for ES cells. Similar procedures for stable cell transfection are used for selecting ES cells that carry the targeting vector. High-quality, targeting-vector DNA free of contaminating chemicals is first linearized and then electroporated into ES cells. Stable ES cells are selected in the presence of a positive selectable antibiotic drug. After a certain period of time and depending on the type of antibiotics, all sensitive cells die and the resistant cells grow into individual colonies of the appropriate size for subcloning by picking. It is extremely important to minimize the time during which ES cells are in culture between selection and injection into blastocysts. Before injecting the ES cells, DNA is prepared from ES colonies to screen for positive ES cells that exhibit the correct integration or homologous recombination of the targeting vector. Positive ES colonies are then expanded and used for creation of chimeras.

Creation of the Chimera

A chimeric organism is one in which cells originate from more than one embryo. Here, chimeric mice are denoted as those that contain some tissues from the ES cells with an altered genome. When these ES cells give rise to the lineage of the germ layer, the germ cells carrying the altered genome can be passed on to the offspring, thus creating the germline transmission from ES cells. There are two methods for introducing ES cells into preimplantation-stage embryos: injection and aggregation. The injection of embryonic cells directly into the cavity of blastocysts is one of the fundamental methods for generating chimeras, but aggregation chimeras also have become an important alternative for transmitting the ES cell genome into mice. The mixture of recognizable markers (e.g., coat color) that are specific for the donor mouse and ES cells can be used to identify chimeric mice. However, most experimenters probably use existing mouse core facilities already established in some institutions, or contract a commercial vendor for the creation of a chimera.

Genotyping and Phenotyping of Knockout Animals

The next step is to analyze whether germline transmission of targeted mutation occurs in mice. DNA from a small amount of tissue from offspring of the chimera is extracted and subjected to genomic PCR or Southern blot DNA hybridization. Positive mice (i.e., those with properly integrated targeting vector into the genome) will be used for the propagation of more knockout mice for phenotype analysis. When the knockout genes are crucial for early embryogenesis, mice often die in utero, an occurrence called *embryonic lethality*. When this happens, only the phenotype of the homozygous (both alleles ablated) knockout mouse embryos and the phenotype of the heterozygous (only one allele ablated) adult mice can be studied. Because most are interested in the phenotype of adult mice, in particular when using mice as disease models, it is recommended to create the conditional knockout using the cre-loxP system so that the gene of interest can be knocked out at will.

To date, more than 5000 genes have been disrupted by homologous recombination and transmitted through the germline. The phenotypic studies of these mice provide ample information on the functions of these genes in growth and differentiation of organisms, and during development of human diseases.

RNA INTERFERENCE

Although gene ablation in animal models provides an important means to understand the *in vivo* functions of genes of interest, animal models may not adequately represent human biology. Alternatively, gene targeting can be used to knock out genes in human cells, including human ES cells. A number of recent advances have made gene targeting in somatic cells as easy as in murine ES cells.²⁵ However, gene targeting (knocking out both alleles) in somatic cells is a time-consuming process.

Development of RNAi technology in the past few years has provided a more promising approach to understanding the biologic functions of human genes in human cells.²⁶ RNAi is an ancient natural mechanism by which small, double-stranded RNA (dsRNA) acts as a guide for an enzyme complex that destroys complementary RNA and downregulates gene expression in a sequence-specific manner. Although the mechanism by which dsRNA suppresses gene expression is not entirely understood, experimental data provide important insights. In nonmammalian systems such as *Drosophila*, it appears that longer dsRNA is processed into 21–23 nt dsRNA (called *small interfering RNA* or *siRNA*) by an enzyme called *Dicer* containing RNase III motifs. The siRNA apparently then acts as a guide sequence within a multicomponent nuclease complex to target complementary mRNA for degradation. Because long dsRNA induces a potent antiviral response pathway in mammalian cells, short siRNAs are used to perform gene silencing experiments in mammalian cells (Fig. 15-24).

Fig. 15-24.

RNA interference in mammalian cells. Small interfering RNA (siRNA) can be produced from a polymerase III–driven expression vector. Such a vector first synthesizes a 19–29 nt double-stranded (ds)RNA stem and a loop (labeled as *shRNA* in the figure), and then the RNase complex called *Dicer* processes the hairpin RNA into a small dsRNA (labeled as *siRNA* in the figure). siRNA can be chemically synthesized and directly introduced into the target cell. In the cell, through RNA-induced silencing complex (RISC), siRNA recognizes and degrades target messenger RNAs (mRNAs).

For siRNA studies in mammalian cells, researchers have used two 21-mer RNAs with 19 complementary nucleotides and 3' terminal noncomplementary dimers of thymidine or uridine. The antisense siRNA strand is fully complementary to the mRNA target sequence. Target sequences for an siRNA are identified visually or by software.

The target 19 nucleotides should be compared to an appropriate genome database to eliminate any sequences with significant homology to other genes. Those sequences that appear to be specific to the gene of interest are the potential siRNA target sites. A few of these target sites are selected for siRNA design. The antisense siRNA strand is the reverse complement of the target sequence. The sense strand of the siRNA is the same sequence as the target mRNA sequence. A deoxythymidine dimer is routinely incorporated at the 3' end of the sense strand siRNA, although it is unknown whether this noncomplementary dinucleotide is important for the activity of siRNAs.

There are two ways to introduce siRNA to knock down gene expression in human cells:

1. RNA transfection: siRNA can be made chemically or using an in vitro transcription method. Like DNA oligos, chemically synthesized siRNA oligos can be commercially ordered. However, synthetic siRNA is expensive and several siRNAs may have to be tried before a particular gene is successfully silenced. In vitro transcription provides a more economic approach. Both short and long RNA can be synthesized using bacteriophage RNA polymerase T7, T3, or SP6. In the case of long dsRNAs, RNase such as recombinant Dicers will be used to process the long dsRNA into a mixture of 21–23 nt siRNA. siRNA oligos or mixtures can be transfected into a few characterized cell lines such as HeLa (human cervical carcinoma) and 293T cells (human kidney carcinoma). Transfection of siRNA directly into primary cells may be difficult.

2. DNA transfection: Expression vectors for expressing siRNA have been made using RNA polymerase III promoters such as U6 and H1. These promoters precisely transcribe a hairpin structure of dsRNA, which will be processed into siRNA in the cell (see Fig. 15-24). Therefore, properly-designed DNA oligos corresponding to the desired siRNA will be inserted downstream of the U6 or H1 promoter. There are two advantages of the siRNA expression vectors over siRNA oligos. First, it is easier to transfect DNA into cells. Second, stable populations of cells can be generated that maintain the long-term silencing of target genes. Furthermore, the siRNA expression cassette can be incorporated into a retroviral or adenoviral vector to provide a wide spectrum of applications in gene therapy.

There has been a fast and fruitful development of RNAi tools for in vitro and in vivo use in mammals. These novel approaches, together with future developments, will be crucial to put RNAi technology to use for effective disease therapy or to exert the awesome power of mammalian genetics. Therefore, the applications of RNAi to human health are enormous. siRNA can be applied as a new tool for sequence-specific regulation of gene expression in functional genomics and biomedical studies. With the availability of the human genome sequences, RNAi approaches hold tremendous promise for unleashing the dormant potential of sequenced genomes.

Practical applications of RNAi will possibly result in new therapeutic interventions. In 2002, the concept of using siRNA in battling infectious diseases and carcinogenesis was proven effective. These include notable successes in blocking replication of viruses, such as HIV, hepatitis B virus, and hepatitis C virus, in cultured cells using siRNA targeted at the viral genome or the human gene encoding viral receptors. RNAi has been shown to antagonize the effects of hepatitis C virus in mouse models. In cancers, silencing of oncogenes such as *c-Myc* or *Ras* can slow down the proliferation rate of cancer cells. Finally, siRNA also has potential applications for some dominant genetic disorders.

The twenty-first century, already heralded as the "century of the gene," carries great promise for alleviating suffering from disease and improving human health. On the whole, completion of the human genome blueprint, the promise of gene therapy, and the existence of stem cells has captured the imagination of the public and the biomedical community for good reason. Aside from their potential in curing human diseases, these emerging technologies also have provoked many political, economic, religious, and ethical discussions. As more is discerned about the technologic advances, more attention must also be paid to concerns for their inherent risks and social implications. Surgeons must take the opportunity to collaborate with basic scientists to develop the field of personalized genomic surgery this century.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 16. The Skin and Subcutaneous Tissue >

KEY POINTS

1. The epidermis consists of five layers. The two most superficial layers (the stratum corneum and lucidum) contain nonviable keratinocytes.
2. Collagen III provides tensile strength to the dermis and epidermis.
3. Adult dermis contains a 4:1 ratio of type I:type III collagen.
4. Of the congenital skin disorders, only pseudoxanthoma elasticum and cutis laxa are responsive to surgical rejuvenation.
5. Hemangioma is the most common cutaneous lesion of infancy and a large majority spontaneously involute (resolve) past the first year of patient age.
6. Basal cell carcinoma (BCC) is the most common form of skin cancer and nodular BCC is the most frequent form of this tumor.
7. Breslow thickness is the most important prognostic variable predicting survival in those with cutaneous melanoma.

BACKGROUND

As the largest human organ, the skin is one of the most complex and physiologically underappreciated elements of our bodies. Beneath its uniform appearance, the skin demonstrates profound regional variation due to the highly structured organization of many different cell types and dermal elements. Although primarily valued as a protective barrier allowing interface with our surroundings, the structure and physiology of the skin is complex and fascinating. As an environmental buffer, the skin protects against a vast array of destructive forces: The structural integrity of the epidermis creates a semipermeable barrier to chemical absorption, prevents fluid loss, protects against penetration of solar radiation, rebuffs infectious agents, and dermal durability resists physical forces. In addition, the skin's ability to regulate body heat makes it the body's primary thermoregulatory organ. The relative ease of analyzing skin specimens has made the skin one of the best-studied tissues of the human body. Not only does this fascinating organ form the primary focus of the subspecialties of plastic surgery and dermatology, but it also has driven research in a broad number of fields, including immunology, transplantation, and wound healing.

ANATOMY AND PHYSIOLOGY OF THE SKIN

Anatomically, the skin may be divided into three layers: the epidermis, basement membrane, and dermis.^{1–3} With very little extracellular matrix (ECM), the epidermis is composed primarily of specialized cells that perform vital functions. Sandwiched between epidermal and dermal structures, the basement membrane anchors these layers together.^{1–3} This membrane fulfills many biologic functions, including tissue organization, growth factor reservoir, support of cell monolayers during tissue development, and semipermeable selective barrier. In addition to its role in providing soft-tissue durability, the dermis is

primarily composed of a dense ECM that provides support for a complex network of nerves, vasculature, and adnexal structures.^{3,4} The ECM is a collection of fibrous proteins and associated glycoproteins embedded in a hydrated ground substance of glycosaminoglycans and proteoglycans. These distinct molecules are organized into a highly ordered network that is closely associated with the cells that produce them. In addition to providing the architectural framework that imparts mechanical support and viscoelasticity, the ECM can regulate the neighboring cells, including their ability to migrate, proliferate, and survive injury.^{2,4,5}

The Epidermis

Composed primarily of keratinocytes, the epidermis is a dynamic, multilayered composite of maturing cells. From internal to external-most layer, the epidermis is composed of the (a) stratum germinatum, (b) stratum spinosum, (c) stratum granulosum, (d) stratum lucidum, and finally, (e) the stratum corneum. Basal cells are a mitotically active, single-cell layer of the least-differentiated keratinocytes at the base of epidermal structure.^{2,6} As basal cells multiply, they leave the basal lamina to begin their differentiation and upward migration. In the spinous layer, keratinocytes are linked together by tonofibrils and produce keratin. As these cells drift upward, they lose their mitotic ability. With entry into the granular layer, cells accumulate keratohyalin granules.^{1,4,6} In the horny layer, keratinocytes age, lose their intercellular connections, and shed. From basal layer exit to shedding, keratinocyte transit time approximates 40 to 56 days.^{2,3}

Melanocytes and other cellular components within the skin deter absorption of harmful radiation. Initially derived from precursor cells of the neural crest, melanocytes extend dendritic processes upward into epidermal tissues from their position beneath the basal cell layer.^{5,7} They number approximately one for every 35 keratinocytes, and produce melanin from tyrosine and cysteine. Once the pigment is packaged into melanosomes within the melanocyte cell body, these pigment molecules are transported into the epidermis via dendritic processes.^{6,7} As dendritic processes (apocoptation) are sheared off, melanin is transferred to keratinocytes via phagocytosis. Despite differences in skin tone, the density of melanocytes is constant among individuals. It is the rate of melanin production, transfer to keratinocytes, and melanosome degradation that determine the degree of skin pigmentation.^{5,6} Whereas people of North European ancestry have melanocytes that release relatively low amounts of melanin, those of African descent demonstrate the same overall quantity of melanocytes, but with much higher melanin production. Genetically activated factors as well as ultraviolet (UV) radiation, hormones such as estrogen, adrenocorticotrophic hormone, and melanocyte-stimulating hormone, increase melanin production.^{6,7}

Cutaneous melanocytes play a critical role in neutralizing the sun's harmful rays. UV-induced damage affects the function of tumor suppressor genes, directly causes cell death, and facilitates neoplastic transformation.²⁻⁵ Although a majority of solar radiation that reaches the Earth is UVA (315 to 400 nm), the majority of skin damage is caused by UVB (240 to 315 nm). UVB is the major factor in sunburn injury, and is a known risk factor in the development of melanoma. Although UVB causes considerable DNA damage in the skin, UVA has only recently been shown to damage DNA, proteins, and lipids.⁸⁻¹¹ In addition, UV-related damage can either be potentiated by or contribute to effects of other harmful agents such as ionizing radiation, viruses, or chemical carcinogens.³⁻⁶

As a durable barrier against external forces, the skin relies on a complex network of filaments to maintain cellular integrity. Intermediate filaments, called *keratins*, are found within the spindle layer and provide flexible scaffolding that enables the keratinocyte to resist external stress.^{4,6} Various keratins are expressed according to keratinocyte maturation phase, and mitotically active keratinocytes mainly express keratins 5 and 14.^{6,7} Point mutations affecting these genes may result in blistering diseases, such as epidermolysis bullosa, associated with spontaneous release of dermal-epidermal attachments.^{4,7}

In addition to its role in resisting radiation, toxin absorption, and deforming forces, the skin is a critically immunoreactive barrier.^{4,6} Following migration into epidermal structure from the bone marrow, Langerhans' cells act as the skin's macrophages. This specialized cell type expresses class II major histocompatibility antigens, and has antigen-presenting capabilities.^{4,7} In addition to initiating rejection of foreign bodies, Langerhans' cells play a crucial role in immunosurveillance against viral infections and neoplasms of the skin.^{2,7}

The Dermis

The dermis is mostly comprised of structural proteins, and to a smaller degree, cellular components.^{2,4–6} Collagen, the main functional protein within the dermis, constitutes 70% of dermal dry weight and is responsible for its remarkable tensile strength.^{4,5} Tropocollagen, a collagen precursor, consists of three polypeptide chains (hydroxyproline, hydroxylysine, and glycine) wrapped in a helix.^{2,6} These long molecules are then cross-linked to one another to form collagen fibers. Of the seven structurally distinct collagens, the skin primarily contains type I. Fetal dermis contains mostly type III (reticulin fibers) collagen, but this only remains in the basement membrane zone and perivascular regions during postnatal development.^{6,7} Elastic fibers are highly branched proteins capable of stretching to twice their resting length. In addition to resisting stretch forces, these fibers allow a return to baseline form after the skin responds to deforming stress.^{4,6} Ground substance, consisting of various polysaccharide–polypeptide (glycosaminoglycans) complexes, is an amorphous material that occupies the remaining spaces. These glycosaminoglycans, secreted by fibroblasts, can hold up to 1000 times their own volume in water and constitute most of dermal volume.^{6,7}

The blood supply to the dermis is based on an intricate network of blood vessels which provide vascular inflow to superficial structures, as well as regulate body temperature.^{3–7} This is achieved with the help of vertical vascular channels that interconnect two horizontal plexuses, one within the papillary dermis, and the other at the dermal–subcutaneous junction.^{4,6} Glomus bodies are tortuous arteriovenous shunts that allow a substantial increase in superficial blood flow when stimulated to open.^{3,5}

Cutaneous sensation is achieved via activation of a complicated plexus of dermal autonomic fibers synapsed to sweat glands, erector pili, and vasculature control points.^{6,7} These fibers also connect to corpuscular receptors that relay information from the skin back to the central nervous system. Meissner's, Ruffini's, and Pacini's corpuscles transmit information on local pressure, vibration, and touch.^{4,6} In addition, "unspecialized" free nerve endings report temperature, touch, pain, and itch sensations.^{4,6}

Cutaneous Adnexal Structures

The skin has three main adnexal structures: eccrine glands, pilosebaceous units, and apocrine glands.^{4–7} The sweat-producing eccrine glands are located over the entire body but are concentrated on the palms, soles, axillae, and forehead.^{3,4} Although pheromone-producing apocrine glands play a distinct role in lower mammalian life, these structures have not been shown to demonstrate significant activity in human populations.^{5,7} However, large populations of apocrine glands are primarily found in the human axillae and anogenital region. It is these structures that predispose both regions to suppurative hydroadenitis.^{4,6} Hair follicles are mitotically active germinal centers that produce hair, a cylinder of tightly packed cornified epithelial cells. Together with oil-secreting sebaceous glands, these two structures form a pilosebaceous unit.^{3,4,7} In addition to the production of hair, hair follicles perform several vital functions. The hair follicle contains a reservoir of pluripotential stem cells critical in epidermal reproductivity.^{2,7} These cells are capable of near limitless expansion to replace lost or injured cells, as well as restore epidermal continuity after wounding. For example, in skin graft harvest, residual hair follicles supply

new keratinocytes to regenerate the epidermis and restore skin integrity.^{3,5}

INJURIES TO THE SKIN AND SUBCUTANEOUS TISSUE

Each day, the skin and subcutaneous tissue face an endless supply of stimuli that threaten to break tissue integrity. Such lapses in continuity provide entry of microorganisms, allow injury to deeper tissue layers, and prompt local tissue inflammation. In addition to penetrating trauma, the environment offers a host of potentially injurious elements, such as caustic substances, extreme temperatures, prolonged or excessive pressure, and radiation.

Traumatic Injuries

Traumatic wounds may be caused by penetrating, blunt, and shear force, bite, and degloving injuries. Although clean lacerations may be closed primarily after irrigation, débridement, and careful evaluation, contaminated or infected wounds should be allowed to heal by secondary intention or delayed primary closure.^{8–10} Débridement of nonviable tissue and aggressive irrigation of the wound are principles guiding the management of more complex wounds. Tangential abrasions should be approached similarly to second-degree burns, and degloving injuries considered third-degree or full-thickness burns.^{8–10} Degloved skin may be partially salvaged by placing it back on the wound like a skin graft. In addition, replacement of clean, avulsed tissue can effectively provide wound coverage as a biologic dressing.^{8–10} As the injured tissues declare their viability throughout the post-injury period, necrotic debris is removed. Areas of uncovered wound bed undergo delayed primary closure, are allowed to granulate in, or undergo definitive reconstruction.^{8–10}

Bite wounds account for 4.5 million injuries each year, and prompt 2% of all emergency rooms visits.^{8–10} These small puncture wounds may initially seem innocuous, but the impregnation of oral bacteria into deep, contained tissue layers can lead to significant morbidity if unrecognized (Fig. 16-1). The most common infectious organisms found with human bites are *Viridans streptococci*, *Staphylococcus aureus*, *Eikenella corrodens*, *Haemophilus influenzae*, and beta-lactamase-producing bacteria.^{8–10} Dog bites account for the most frequent animal-related wound. Because the canine jaw can exert over 450 pounds of pressure per square inch,^{9,10} dog bites often add a crushing element in addition to penetrating injury as well as an avulsion element. Although the dog bite injury may contaminate tissues with both aerobic and anaerobic organisms, the most commonly cultured bacteria include *Pasteurella multocida*, *Staphylococcus* species, alpha-hemolytic streptococci, *E. corrodens*, *Actinomyces*, and *Fusobacterium*.^{8–10} The bite wound, whether from human or animal, is a contaminated wound and should not be closed primarily. Selected facial wounds may be closed primarily after very thorough cleansing and initiation of antibiotic therapy. Although there remains a potential risk of serious infection, this risk may be low enough on the face to weigh in favor of the improved long-term wound appearance after primary closure. The great majority of bite wounds should be approached via drainage, copious irrigation, débridement of necrotic material, antibiotic therapy, extremity immobilization, and elevation.^{8–10}

Digital infection following puncture or bite wounds often contain a variety of bacteria, and rapid spread of infection is possible in the absence of antibiotic therapy.

Exposure to Caustic Substances

Injuries secondary to caustic substance exposure may be categorized as resulting from either acidic or alkali solutions. The effect of acid exposure on the skin is determined by the concentration, duration of contact, amount, and penetrability.^{11–13} Deep tissue *coagulative* injury may result, damaging nerves, blood vessels, tendons, and bone.^{12–15} The initial treatment should include copious skin irrigation for at least 30 minutes with either saline or water.^{11–15} This dilutes active acid solution and helps return the skin to normal pH. Injuries associated with hydrofluoric acid present an additional treatment challenge. Fluoride ions continue to injure underlying tissue until they are neutralized with calcium, and absorb the body's calcium supply, which may prompt cardiac arrhythmia.^{12,14,15} Topical quaternary ammonium compounds are widely used, and topical calcium carbonate gel also effectively detoxifies fluoride ions.^{14,15}

Alkaline agents often used as household cleaning agents are responsible for more than 15,000 skin burns in the United States annually.^{12,13} After penetrating the skin, alkaline substances cause fat saponification that facilitates tissue penetration and increases tissue damage. In addition, the *liquefactive* injury produced by alkali burns provides a longer, more sustained period of injury.^{12,13} Immediate irrigation of the affected area with continuous water flow should be maintained for at least 2 hours, or until symptomatic relief is achieved.

Intravenous fluid (IVF) extravasation—leakage of injectable fluids into interstitial space—is considered a chemical burn (Fig. 16-2). In contrast to many cutaneous injuries, this type of insult occurs from underneath the skin surface and is actually a

deep injury. Extravasation produces injury via chemical toxicity, osmotic toxicity, or from pressure effects in a closed environment.^{12,13} This displacement may be the result of IV catheter movement or increased vascular permeability. The most common substances associated with these injuries are cationic solutions (e.g., potassium ion, calcium ion, bicarbonate), osmotically active chemicals (e.g., total parenteral nutrition or hypertonic dextrose solutions), and antibiotics or cytotoxic drugs.^{12,13} The dorsum of the hand is the most common site of extravasation in the adult, which may result in extensor tendon exposure.

Fig. 16-2.

Infiltration of IV fluid may produce significant soft-tissue injury. However, a great majority of these wounds respond well to conservative management, including frequent dressing change and continued wound care.

Patients undergoing chemotherapy have a 4.7% risk for developing extravasation, and children present an incidence as high as 58%.^{16,17} Newborn babies are at particular risk due to the fragility and small caliber of their veins, their poor ability to verbalize pain, and the frequent use of pressurized IVF pumps used in their care. The most common IVF extravasations causing necrosis in the infant are high-concentration dextrose solutions, calcium, bicarbonate, and parenteral nutrition.^{16,17} In the adult population, commonly extravasated drugs are chemotherapeutic agents, such as doxorubicin (Adriamycin) and paclitaxel.¹⁸ The direct toxic effects of doxorubicin causes cellular death that is perpetuated by release of doxorubicin-DNA complexes from dead cells. This cellular death prevents release of cytokines and growth factors, which may ultimately result in wound healing failure.¹⁸ Following extravasation, edema, erythema, and induration usually are present. Injury to underlying nerves, muscles, tendons, and blood vessels must be taken into account. Although a majority of such injuries are

successfully managed through a conservative approach, many treatment options are available.^{16–18} In the severe infusion injury, vigorous liposuction with a small cannula may be used to introduce saline flush into the injured area. The flush is then allowed to egress via the small liposuction wounds.^{16–18} Although patients more than 24 hours after extravasation injury have shown no benefit from flush-out, this technique has proved useful in the acute setting. Surgery should be limited to patients with necrotic tissue, pain, or damage of underlying structures.^{16–18}

Hyper- and Hypothermic Injury

Skin exposed to temperature extremes is at significant risk of hypo- or hyperthermic injury. Depending upon the temperature, period, and method of exposure, hyperthermic burns may cause varying degrees of tissue injury affecting the skin at different levels of depth.¹⁹ The central area of injury, the zone of coagulation, is exposed to the most direct heat transfer and typically becomes necrotic.^{20,21} Surrounding the zone of coagulation is the zone of stasis, which has marginal tissue perfusion and questionable viability. The outermost area, the zone of hyperemia, is most similar to uninjured tissue and demonstrates increased blood flow due to the body's response to injury.^{20,21} A more detailed discussion of burn wounds may be found in Chap. 8. Hypothermic injury (frostbite) results in the acute freezing of tissues and is the product of two factors: (a) duration of exposure, and (b) the temperature gradient at the skin surface.^{22,23} Severe hypothermia primarily exerts its damaging effect by causing direct cellular injury to blood vessel walls and microvascular thrombosis. In addition, the skin's tensile strength decreases by 20% in a cold environment [12°C, (53.6°F)].^{22,23} The treatment protocol for frostbite includes rapid rewarming, close observation, elevation and splinting, daily hydrotherapy, and serial débridements.^{22,23}

Pressure Injury

Prolonged, excessive pressure often results in pressure ulcer formation. As pressure is applied to overlying tissues, cutaneous vascular flow is decreased, rendering local tissues functionally ischemic.^{23–25} As little as 1 hour of 60 mmHg pressure produces histologically identifiable venous thrombosis, muscle degeneration, and tissue necrosis.^{23–25} Although normal arteriole, capillary, and venule pressures are 32, 20, and 12 mmHg, respectively, sitting can produce pressures as high 300 mmHg at the ischial tuberosities.^{23–25} Healthy individuals regularly shift their body weight, even while asleep. However, sacral pressure can build to 150 mmHg when lying on a standard hospital mattress.^{24,25} Patients unable to sense pain or shift their body weight, such as paraplegics or bedridden individuals, may develop prolonged elevated tissue pressures and local necrosis. Because muscle tissue is more sensitive to ischemia than skin, necrosis usually extends to a deeper area than that apparent on superficial inspection.^{24,25} The elements of pressure sore treatment include relief of pressure, wound care, and systemic enhancement, such as optimization of nutrition. Air flotation mattresses and gel seat cushions redistribute pressure, decrease the incidence of pressure ulcers, and are cost-effective in the care of patients at high risk.^{24,25} In addition, many institutions provide nutritional support services to facilitate proper dietary intake. Surgical management should include débridement of all necrotic tissue followed by thorough irrigation. Shallow ulcers may be allowed to close by secondary intention, but deeper wounds with involvement of the underlying bone require surgical débridement and coverage.^{24,25}

Radiation Exposure

Radiation injuries are frequently produced by a wide range of environmental elements, such as solar (UV) exposure, iatrogenic management, and industrial/occupational applications.^{26,27} Solar or UV radiation is the most common form of radiation exposure. The UV spectrum is divided into UVA (400 to 315 nm), UVB (315 to 290 nm), and UVC (290 to 200

nm).^{27–29} With regard to skin damage and development of skin cancers, significant wavelengths are in the UV spectrum. The ozone layer absorbs UVC wavelengths below 290 nm, allowing only UVA and UVB to reach the earth.^{50,52} UVB is responsible for the acute sunburns and for the chronic skin damage leading to malignant degeneration, although it makes up less than 5% of the solar UV radiation that hits the earth.^{27–29}

Ionizing radiation effectively blocks mitosis in rapidly dividing cell types,^{26,28,29} and has become a mainstay in the treatment of various malignancies. The extent of cellular damage is dependent on radiation dose, exposure period, and the cell type being treated.^{27–29} Acute radiation changes include erythema and basal epithelial cellular death in the area of direct application. With cellular repair, permanent hyperpigmentation is observed in healing areas. Four to 6 months following radiation application, chronic radiation changes are characterized by a loss of capillaries via thrombosis and fibrinoid necrosis of vessel walls.^{27,29} Progressive fibrosis and hypovascularity may eventually lead to ulceration when poor vascular inflow results in poor tissue perfusion that progresses as the skin ages.^{27–29}

INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

Heralded by erythema, warmth, tenderness, and edema, cellulitis is a superficial, spreading infection of the skin and subcutaneous tissue. The most common organisms associated with cellulitis are group A streptococci and *S. aureus*.³⁰ Unless associated with significant patient morbidities, uncomplicated cellulitis usually can be managed with oral antibiotics on an outpatient basis.

Folliculitis, Furuncles, and Carbuncles

Folliculitis is an infection of the hair follicle. The causative organism is usually *Staphylococcus*, but gram-negative organisms may cause follicular inflammation as well. A furuncle (boil) begins as folliculitis, but may eventually progress to form a fluctuant nodule.^{30,31} Whereas folliculitis usually resolves with adequate hygiene, soaking the furuncle in warm water hastens liquefaction and hastens spontaneous rupture. More involved, deep-seated infections that result in multiple draining cutaneous sinuses are called carbuncles. Along with furuncles, these lesions often require incision and drainage before healing can be initiated.^{30,31}

Necrotizing Soft-Tissue Infections

Although many soft-tissue infections remain localized, some result in rapid, necrotizing spread and septic shock. The most common sites are the external genitalia, perineum, or abdominal wall (*Fournier gangrene*).^{30–32} Currently, classification of these infections is based on (a) the tissue plane affected and extent of invasion, (b) the anatomic site, and (c) the causative pathogen(s).^{30–32} Deep soft-tissue infections are classified as either necrotizing fasciitis or necrotizing myositis. Necrotizing fasciitis represents a rapid, extensive infection of the fascia deep to the adipose tissue. Necrotizing myositis primarily involves the muscles but typically spreads to adjacent soft tissues.^{30–32} The most common organisms isolated from patients presenting with necrotizing soft-tissue infections include the gram-positive organisms: group A streptococci, enterococci, coagulase-negative staphylococci, *S. aureus*, *S. epidermidis*, and *Clostridium* species.^{30–32} Gram-negative species frequently associated with necrotizing infections include *Escherichia coli*, *Enterobacter*, *Pseudomonas* species, *Proteus* species, *Serratia* species, and bacteroides.^{30–32} Polymicrobial infections tend to be more common than single organism disease in these cases.^{31,32}

Clinical risk factors for necrotizing soft-tissue infection include diabetes mellitus, malnutrition, obesity, chronic alcoholism, peripheral vascular disease, chronic lymphocytic leukemia, steroid use, renal failure, cirrhosis, and autoimmune deficiency

syndrome.^{30–32} Appropriate management starts with prompt recognition, broad-spectrum IV antibiotics, aggressive surgical débridement, and intensive care unit support.^{30–32} Débridement must be extensive, including all skin, subcutaneous tissue, and muscle, until there is no further evidence of infected tissue. Initial resection is followed by frequent returns to the operating room for additional débridement as required.^{31,32} In addition, aggressive fluid replacement is typically needed to offset acute renal failure from ongoing sepsis.^{31,32}

Hidradenitis Suppurativa

Hidradenitis suppurativa is a defect of the terminal follicular epithelium.^{33,34} Because the follicular defect results in apocrine gland blockage, obstructed infection leads to abscess formation throughout affected axillary, inguinal, and perianal regions. Following spontaneous rupture of these localized collections, foul-smelling sinuses form and repeated infections create a wide area of inflamed, painful tissue.^{33,34} Treatment of acute infections includes application of warm compresses, antibiotics, and open drainage. In cases of chronic hidradenitis, wide excision is required and closure may be achieved via skin graft or local flap placement.^{33,34}

Actinomycosis

Actinomycosis is a granulomatous suppurative bacterial disease caused by *Actinomyces*. In addition to *Nocardia*, *Actinomadura*, and *Streptomyces*, *Actinomyces* infections may produce deep cutaneous infections that present as nodules and spread to form draining tracts within surrounding soft tissue.^{35,36} Forty to 60% of the actinomycotic infections occur within the face or head.^{35,36} Actinomycotic infection usually results following tooth extraction, odontogenic infection, or facial trauma.^{35,36} Accurate diagnosis depends on careful histologic analysis, and the presence of sulfur granules within purulent specimen is pathognomonic.³⁵ Penicillin and sulfonamides are typically effective against these infections. However, areas of deep-seated infection, abscess, or chronic scarring may require surgical therapy.^{35,36}

VIRAL INFECTIONS OF THE SKIN AND SUBCUTANEOUS TISSUE

Human Papillomavirus

Warts are epidermal growths resulting from human papillomavirus (HPV) infection. Different morphologic types have a tendency to occur at different areas of the body. The common wart (verruca vulgaris) is found on the fingers and toes and is rough and bulbous (Fig. 16-3). Plantar warts (verruca plantaris) occur on the soles and palms, and may resemble a common callus. Flat warts (verruca plana) are slightly raised and flat. This particular subtype tends to appear on the face, legs, and hands.^{37–39} Venereal warts (condylomata acuminata) grow in the moist areas around the vulva, anus, and scrotum. Histologic examination demonstrates hyperkeratosis (hypertrophy of the horny layer), acanthosis (hypertrophy of the spinous layer), and papillomatosis.^{37–39} A multitude of various therapies have been created to eradicate the papillomatous growth. Warts may be removed via application of chemicals, such as formalin, podophyllum, and phenol-nitric acid.^{37–39} Curettage with electrodesiccation also can be used for scattered lesions. Treatment of extensive areas of skin requires surgical excision under general anesthesia.^{37–39} Because of the infectious etiology, recurrences are common, and repeated excisions are often necessary. Some warts (especially HPV types 5, 8, and 10) are associated with squamous cell cancers, therefore lesions that grow rapidly, atypically, or ulcerate should be biopsied.^{38,39}

Fig. 16-3.

The common wart, caused by cutaneous infection with human papillomavirus, may affect all areas covered by epidermal tissues.

Condylomata acuminata is one of the most common sexually transmitted diseases, and largely results from HPV types 6 and 11 (Fig. 16-4).³⁷⁻³⁹ Extensive growths, facilitated by concomitant HIV infection, are often multiple and can grow large in size (Buschke-Löwenstein tumor). In addition to local destruction or excision, adjuvant therapy with interferon, isotretinoin, or autologous tumor vaccine decreases recurrence rates.^{38,39} Immune response modifiers, such as imiquimod, may also optimize long-term eradication of HPV-induced anogenital lesions.³⁷⁻³⁹ Because larger lesions have a significant risk of malignant transformation, close observation of lesion return or atypical presentation should be advised.

Human papillomavirus affecting digital and genitourinary sites often proves most problematic for the patient.

Human Immunodeficiency Virus

Patients with HIV commonly display a variety of skin manifestations. As a result of intrinsic wound-healing deficiencies and much lower resilience, these patients frequently develop chronic wounds.^{40–42} In addition, the risk of postoperative soft-tissue complications directly increases with disease progression. The cause for delayed wound healing is unknown but is thought to be secondary to: (a) decreasing T-cell CD4⁺ count, (b) opportunistic infection, (c) low serum albumin, and (d) poor nutrition.^{40–42} Overall, these effects are thought to result in poor collagen cross-linking and deposition producing a profound compromise in wound healing.^{40–42}

INFLAMMATORY DISEASES OF THE SKIN AND SUBCUTANEOUS SOFT TISSUE

Pyoderma Gangrenosum

Pyoderma gangrenosum is a relatively uncommon destructive cutaneous lesion. Clinically, a rapidly enlarging, necrotic lesion with undermined border and surrounding erythema characterize this disease.^{43–45} Linked to underlying systemic disease in 50% of cases, these lesions are commonly associated with inflammatory bowel disease, rheumatoid arthritis, hematologic malignancy, and monoclonal immunoglobulin A gammopathy.^{43–45} Recognition of the underlying disease is of paramount importance. Management of pyoderma gangrenosum ulcerations without correction of underlying systemic disorders is fraught with complication. A majority of patients receive systemic steroids or cyclosporine.^{43–45} Although medical management alone may slowly result in wound healing, many physicians advocate chemotherapy with aggressive wound care and skin graft coverage.^{43–45}

Staphylococcal Scalded Skin Syndrome and Toxic Epidermal Necrolysis

Staphylococcal scalded skin syndrome (SSSS) and toxic epidermal necrolysis (TEN) create a similar clinical picture including

skin erythema, bullae formation, and wide areas of tissue loss (Fig. 16-5).^{46,47} SSSS is caused by an exotoxin produced during staphylococcal infection of the nasopharynx or middle ear.^{46,47} TEN is an immune response to certain drugs such as sulfonamides, phenytoin, barbiturates, and tetracycline.^{46,47} Diagnosis is made via skin biopsy. Histologic analysis of SSSS reveals a cleavage plane in the granular layer of the epidermis.^{46,47} In contrast, TEN results in structural defects at the dermoepidermal junction and is similar to a second-degree burn.^{46,47} Treatment involves fluid and electrolyte replacement, as well as wound care similar to burn therapy. Whereas those with more than 30% of total body surface area involvement are classified as TEN, patients with less than 10% of epidermal detachment are categorized as Stevens-Johnson syndrome.^{46,47} In Stevens-Johnson syndrome, respiratory and alimentary tract epithelial sloughing may result in intestinal malabsorption and pulmonary failure. Patients with significant soft-tissue loss should be treated in burn units with specially trained staff and critical equipment.^{46,47} Although corticosteroid therapy has not been efficacious, temporary coverage via cadaveric, porcine skin, or semisynthetic biologic dressings (Biobrane) allows the underlying epidermis to regenerate spontaneously.^{46,47}

Fig. 16-5.

Staphylococcal scalded skin syndrome is associated with retained foreign objects colonized with toxin-secreting staphylococcus strains.

BENIGN TUMORS OF THE SKIN AND SUBCUTANEOUS TISSUE

Cysts (Epidermal, Dermoid, Trichilemmal)

Cutaneous cysts are categorized as either epidermal, dermoid, or trichilemmal.^{48,49} Although surgeons often refer to cutaneous cysts as sebaceous cysts because they appear to contain sebum, this is a misnomer and the substance is actually keratin.^{48,49} Epidermal cysts are the most common type of cutaneous cyst, and may present as a single, firm nodule anywhere on the body. Dermoid cysts are congenital lesions that result when epithelium is trapped during fetal midline

closure.^{48,49} Although the eyebrow is the most frequent site of presentation, dermoid cysts are common anywhere from the nasal tip to the forehead.^{48,49} Trichilemmal (pillar) cysts, the second most common cutaneous cyst, occur more often on the scalp of females.^{48,49} When ruptured, these cysts have an intense, characteristic odor.

On clinical examination, it is difficult to distinguish one type of cyst from another: Each cyst presents as a subcutaneous, thin-walled nodule containing a white, creamy material.^{48,49} Histologic examination reveals several key features. Cyst walls consist of an epidermal layer oriented with the basal layer superficial, and the more mature layers deep (i.e., with the epidermis growing into the center of the cyst).^{48,49} The desquamated cells (keratin) collect in the center to form the cyst. Epidermal cysts have a mature epidermis complete with granular layer.^{48,49} Dermoid cysts demonstrate squamous epithelium, eccrine glands, and pilosebaceous units. In addition, these particular cysts may develop bone, tooth, or nerve tissue on occasion.^{48,49} Trichilemmal cyst walls do not contain a granular layer; however, these cysts contain a distinctive outer layer resembling the root sheath of a hair follicle (trichilemmoma).⁴⁸⁻⁵⁰ Each of these cysts typically remain unnoticed and asymptomatic until they rupture, cause local inflammation, or become infected. Once infected, these cysts behave similar to abscesses, and incision and drainage is recommended. After resolution of inflammation, the cyst wall must be removed in its entirety or the cyst will recur.⁴⁸⁻⁵⁰

Keratoses (Seborrheic, Solar)

Seborrheic keratoses arise in sun-exposed areas of the body such as the face, forearms, and back of the hands.⁵¹⁻⁵³ Most notable in the older age groups, lesions appear light brown or yellow and have a velvety, greasy texture. Seborrheic keratoses are considered premalignant lesions, and squamous cell carcinoma (SCC) may develop over time.^{52,53} Interestingly, sudden eruptions of multiple lesions may be associated with internal malignancies.^{50,52} However, seborrheic keratoses are rarely mistaken for other lesions, so biopsy and treatment are seldom required.^{50,52} Histologically, these lesions contain atypical-appearing keratinocytes and evidence of dermal solar damage.^{50,52} Although malignancies that do develop rarely metastasize, lesion destruction is the treatment of choice. Treatments often include application of topical 5-fluorouracil, surgical excision, electrodesiccation, and dermabrasion.^{50,52}

Nevi (Acquired and Congenital)

Depending on the location of nevus cells, acquired melanocytic nevi are classified as junctional, compound, or dermal.⁵⁴⁻⁵⁷ This classification does not represent different types of nevi, but rather different stages in nevus maturation. Initially, nevus cells accumulate in the epidermis (junctional).⁵⁵⁻⁵⁷ As they mature, nevus cells migrate partially into the dermis (compound) and finally rest completely within dermal tissues (dermal). Eventually most lesions undergo involution. Congenital nevi are relatively rare, and may be found in less than 1% of neonates.^{54,56,57} These lesions are larger and often contain hair. Histologically, congenital and acquired nevi appear similar. Giant congenital lesions (giant hairy nevi) most often occur in a swim trunk distribution, chest, or back (Fig. 16-6).⁵⁴⁻⁵⁷ Not only are these lesions cosmetically unpleasant, but congenital nevi may develop into malignant melanoma in 1 to 5% of cases.⁵⁴⁻⁵⁷ Total excision of the nevus is the treatment of choice; however, the lesion is often so large that inadequate tissue for wound closure precludes complete resection. Instead, serial excisions with local tissue expansion/advancement are frequently required over several years.⁵⁴⁻⁵⁷

Fig. 16-6.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Although the giant nevus may be aesthetically concerning, these lesions present a roughly 5% risk of malignant transformation over one's lifetime.

Vascular Tumors of the Skin and Subcutaneous Tissue

Hemangiomas are benign vascular neoplasms that present soon after birth (Fig. 16-7). They initially undergo rapid cellular proliferation over the first year of life, then undergo slow involution throughout childhood.⁵⁸⁻⁶⁰ Histologically, hemangiomas are composed of mitotically active endothelial cells surrounding several, confluent blood-filled spaces. Although these lesions may enlarge significantly in the first year of life, approximately 90% involute over time.⁵⁸⁻⁶⁰ Acute treatment is limited to hemangiomas that interfere with function, such as airway, vision, and feeding. In addition, lesions resulting in systemic problems, such as thrombocytopenia or high-output cardiac failure, should prompt resection. The growth of rapidly enlarging lesions also can be halted with systemic prednisone or interferon alpha-2a treatment use.⁵⁸⁻⁶⁰ In the absence of acute surgical indications or significant patient/parent concern, many lesions are allowed to spontaneously involute. However, hemangiomas that remain into adolescence or involute to leave an unsightly telangiectasia typically require surgical excision for optimal resolution.⁵⁸⁻⁶⁰

Fig. 16-7.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Hemangiomas most often present at approximately 2 to 4 weeks after birth, rapidly proliferate during infancy, reach a plateau phase, then involute over several years. Unless the hemangiomatous mass obstructs the airway, visual axis, or imposes psychological harm to a preschool age child, these tumors typically are allowed to spontaneously involute.

In contrast to neoplasms, vascular malformations are a result of structural abnormalities formed during fetal development.^{61,62} Unlike hemangiomas, vascular malformations grow in proportion to the body and never involute. Histologically, they contain enlarged vascular spaces lined by nonproliferating endothelium.^{61,62} Arteriovenous malformations are high-flow lesions that often present as subcutaneous masses associated with locally elevated temperature, dermal stain, thrill, and bruit. In addition, overlying ischemic ulcers, adjacent bone destruction, or local hypertrophy may occur.^{61,62} Very large malformations may cause cardiac enlargement and congestive heart failure. Complications of arteriovenous malformations, such as pain, hemorrhage, ulceration, cardiac effects, or local tissue destruction, should prompt attempts at lesion destruction.^{61,62} Therapy consists of surgical resection. Even when complete lesion resection is not possible, significant debulking may greatly diminish symptomatology. In addition, angiography with selective embolization just before surgery greatly facilitates operative removal.^{61,62}

The capillary malformation, or port-wine stain, is a flat, dull-red lesion often located on the trigeminal (cranial nerve V) distribution on the face, trunk, or extremities (Fig. 16-8).^{61,62} Presentation within the V1 or V2 facial regions should prompt concern of a possible link to more systemic syndromes such as Sturge-Weber syndrome (leptomeningeal angiomatosis, epilepsy, and glaucoma).^{61,62} Histologically, these nevi are composed of ectatic capillaries lined by mature endothelium. Unsightly lesions may be treated with pulsed dye laser, covered with cosmetics, or surgically excised.^{61,62}

Fig. 16-8.

A capillary hemangioma (also known as a *port-wine stain*) present upon the midface may signify Churg-Strauss syndrome, and computed tomography of the brain is appropriate to rule out intracranial berry aneurysms.

Glomus tumor is an uncommon, benign neoplasm of the extremity. Representing less than 1.5% of all benign, soft-tissue extremity tumors, these lesions arise from dermal neuromyoarterial apparatus (glomus bodies).^{63,64} Glomus tumor more commonly affects the hand, and presentation within the subungual region of the toe is rare. Diagnosis of these lesions is traditionally delayed, and atypical presentation on the foot or toes often leads to even greater diagnostic challenges. In addition to the severe pain, point tenderness and cold sensitivity are associated with these lesions and subungual glomus tumors typically appear as blue, subungual discolorations of 1 to 2 mm. Tumor excision is the treatment of choice.^{63,64}

Soft-Tissue Tumors (Acrochordons, Dermatofibromas, Lipomas)

Lipomas are the most common subcutaneous neoplasm.⁶⁴ Although they are found most frequently on the trunk, these lesions may appear anywhere. Typically soft and fleshy on palpation, lipomas may grow to a large size and become substantially deforming. Histologic examination reveals a lobulated tumor composed of normal fat cells.⁶⁴ Although fears of malignant degeneration have prompted resection in the past, no report of such malignancy has been substantiated. To date, the lipoma is widely viewed as benign with essentially no risk of malignant devolvment.⁶⁴ Although observation is an option, surgical excision is required for tumor removal. Acrochordons (skin tags) are fleshy, pedunculated masses located on the preauricular areas, axillae, trunk, and eyelids.^{65–67} They are composed of hyperplastic epidermis over a fibrous connective

tissue stalk. These lesions are usually small, and are frequently treated via "tying off" or with resection in the clinic.^{65–67} Dermatofibromas are solitary, soft-tissue nodules usually approximating 1 to 2 cm in diameter, and are found primarily on the legs and flanks. Histologically, these lesions are composed of unencapsulated connective tissue whorls containing fibroblasts.^{65–67} Although a majority of dermatofibromas can be diagnosed clinically, atypical presentation or course should prompt excisional biopsy to assess for malignancy. Although these tumors may be managed conservatively, operative removal is the treatment of choice.^{66–68}

Neural Tumors (Neurofibromas, Neurilemmomas, Granular Cell Tumors)

Benign, cutaneous neural tumors such as neurofibromas, neurilemmomas, and granular cell tumors primarily arise from the nerve sheath.^{65,68} Neurofibromas can be sporadic and solitary. However, a majority are associated with café au lait spots, Lisch nodules, and an autosomal dominant inheritance (von Recklinghausen's disease).^{65,66} These lesions are firm, discrete nodules attached to a nerve. Histologically, proliferation of perineurial and endoneurial fibroblasts with Schwann cells embedded in collagen are noted. In contrast to direct nerve attachment as seen with neurofibromas, neurilemmomas are solitary tumors arising from cells of the peripheral nerve sheath.^{65,66} These lesions are discrete nodules that may induce local or radiating pain along the distribution of the nerve. Microscopically, the tumor contains Schwann cells with nuclei packed in palisading rows. Surgical resection is the management option of choice. Granular cell tumors are usually solitary lesions of the skin or, more commonly, the tongue.^{65,66} They consist of granular cells derived from Schwann cells that often infiltrate the surrounding striated muscle. Based on the severity of symptomatology, operative resection is the primary therapy of choice.^{65–68}

MALIGNANT TUMORS OF THE SKIN

Although malignancies arising from cells of the dermis or adnexal structures are relatively uncommon, the skin is frequently subject to epidermal tumors, such as basal cell carcinoma (BCC), SCC, and melanoma.^{69–72} Each of these tumors has received exhaustive study, and several key factors associated with their development have been identified. Perhaps of greatest significance is that increased exposure to UV radiation is associated with an increased development of all skin cancer.^{69–72} Clinical studies reveal that persons with outdoor occupations are at greater risk, as are those with fair complexions and people living in regions receiving higher per capita sunlight. In addition, albino individuals of dark-skinned races are prone to develop cutaneous neoplasms that are typically rare in nonalbino members of the same group. This observation suggests that melanin, and its ability to limit UV radiation tissue penetration, plays a large role in carcinogenesis protection.^{69–72}

Skin cancer development also has been strongly linked to chemical carcinogens such as tar, arsenic, and nitrogen mustard. Radiation therapy directed at skin lesions increases the risk for local BCC and SCC.^{69–72} As an ongoing area of intense research interest, certain subtypes of HPV have been linked to SCC.^{69–72} Additionally, chronically irritated or nonhealing areas such as burn scars, sites of repeated bullous skin sloughing, and decubitus ulcers present an elevated risk of developing SCC.^{69–72} Systemic immunologic dysfunction is also related to an increase in cutaneous malignancies. Immunosuppressed patients receiving chemotherapy, those with advanced HIV/AIDS, and immunosuppressed transplant recipients have an increased incidence of BCC, SCC, and melanoma.^{69–72}

Basal Cell Carcinoma

Arising from the basal layer of the epidermis, BCC is the most common type of skin cancer. Based on gross and histologic

morphology, BCC has been divided into several subtypes: nodular, superficial spreading, micronodular, infiltrative, pigmented, and morpheaform.^{69–72}

Nodulocystic or noduloulcerative type accounts for 70% of BCC tumors. Waxy and frequently cream colored, these lesions present with rolled, pearly borders surrounding a central ulcer. Although superficial basal cell tumors commonly occur on the trunk and form a red, scaling lesion, pigmented BCC lesions are tan to black in color. Morpheaform BCC often appears as a flat, plaque-like lesion.^{69–72} This particular variant is considered relatively aggressive and should prompt early excision. A rare form of BCC is the basosquamous type, which contains elements of both basal cell and squamous cell cancer. These lesions may metastasize similar to SCC, and should be treated aggressively.^{69–72}

BCCs are slow growing, and metastasis is extremely rare.^{69–72} Due to this slow developmental progression, patients often neglect these lesions for years and presentation with extensive local tissue destruction is common. The majority of small (less than 2 mm), nodular lesions may be treated via curettage, electrodesiccation, or laser vaporization.^{69–72}

Although effective, these techniques destroy any potential tissue sample for confirmatory pathology diagnosis and tumor margin analysis. Surgical excision may be used to both effect complete tumor removal as well as allow proper laboratory evaluation. Basal cell tumors located at areas of great aesthetic value, such as the cheek, nose, or lip, may be best approached with Mohs' surgery.^{69–72} Typically completed by specialized dermatology surgeons, Mohs' surgery uses minimal tissue resection and immediate microscopic analysis to confirm appropriate resection. Large tumors, those that invade surrounding structures, and aggressive histologic types (morpheaform, infiltrative, and basosquamous) are best treated by surgical excision with 0.5-cm to 1-cm margins.^{69–72}

Squamous Cell Carcinoma

SCCs arise from epidermal keratinocytes (Fig. 16-9). While less common than BCC, SCC is more devastating due to an increased invasiveness and tendency to metastasize.^{69–72} Before local invasion, in situ SCC lesions are termed *Bowen's disease*. In situ SCC tumors specific to the penis are referred to as *erythroplasia of Queyrat*.^{67,68} Following tissue invasion, tumor thickness correlates well with malignant behavior. Tumor recurrence is more prevalent once SCC tumors grow more than 4 mm in thickness, and lesions that metastasize are typically at least 10 mm in diameter.^{69–72} Tumor location is also of great prognostic importance. Although SCC tumors in areas with cumulative solar damage are less aggressive, and respond well to local excision, lesions arising in burn scars (Marjolin's ulcer), areas of chronic osteomyelitis, and areas of previous injury metastasize early.^{69–72}

Although basal cell carcinoma is the most common tumor involving the head and neck, squamous cell carcinoma (pictured here) occurs with high frequency on the nose, ears, and lower lip.

Although small lesions can be treated with curettage and electrodesiccation, most surgeons recommend surgical excision. Lesions should be excised with a 1-cm margin, and histologic confirmation of tumor-free borders is mandatory.^{69–72} Tumors within areas of great aesthetic value, such as the cheek, nose, or lip, may be best approached with Mohs' surgery. This precise, specialized surgical technique uses minimal tissue resection and immediate microscopic analysis to confirm appropriate resection yet limit removal of valuable anatomy. The need for lymph node (LN) dissection in the setting of SCC remains a topic of debate. Regional LN excision is indicated for clinically palpable nodes.^{69–72} However, SCC lesions arising in chronic wounds are more aggressive and regional lymph node metastases are observed more frequently. In this instance, lymphadenectomy before development of palpable nodes (prophylactic LN dissection) is indicated. Metastatic disease is a poor prognostic sign, and only 13% of patients typically survive 10 years.^{69–72}

Mohs' Surgery for Squamous and Basal Cell Carcinomas

Basal and squamous cell lesions often present on sun-exposed portions of the body such as the head and face. Unfortunately, these areas are of great aesthetic value and significant tissue loss may significantly alter facial symmetry, contour, and continuity. Developed in 1936, Mohs' technique uses serial excision in small increments coupled with immediate microscopic analysis to ensure tumor removal, yet limit resection of aesthetically valuable tissue.^{70–72} One distinct advantage of Mohs' technique is that all specimen margins are evaluated. In contrast, traditional histologic examination surveys selected portions on surgical margin. The major benefit of Mohs' technique is the ability to remove a tumor with

minimal sacrifice of uninvolved tissue.⁷⁰⁻⁷² Although this procedure is of particular value when managing tumors of the eyelid, nose, or cheek, one major drawback is procedure length. Total lesion excision may require multiple attempts at resection, and many procedures may be carried out over several days. Recurrence and metastases rates are comparable to those of wide local excision.⁷⁰⁻⁷²

Malignant Melanoma

The increasing rate of melanoma diagnoses is the highest of any cancer in the United States. The age-adjusted incidence of invasive melanoma in the United States increased from approximately 4 to 18 per 100,000 white males between 1973 and 1998.⁷³ With this increasing prevalence, it is critical that physicians recognize and appropriately manage these lesions early.

The pathogenesis of melanoma is complex and remains poorly understood to date. Melanoma may arise from transformed melanocytes anywhere that these cells have migrated during normal embryogenesis (Fig. 16-10).⁷³⁻⁷⁶ Although nevi (freckles) are benign melanocytic neoplasms found on the skin of many people, dysplastic nevi contain a histologically identifiable focus of atypical melanocytes. These lesions are thought to represent an intermediate stage between benign nevus and true malignant melanoma.⁷³⁻⁷⁶ Studies demonstrate increased relative risk of melanoma development based on increasing numbers of dysplastic nevi found on the patient. In addition, a strong genetic component has been described.⁷³⁻⁷⁶ Up to 14% of malignant melanomas occur in a familial pattern, and family members of those with either dysplastic nevi or melanoma are at increased risk for tumor development.⁷³⁻⁷⁶

Following malignant transformation, invasive melanoma cells replicate, penetrate surrounding epidermal layers, and migrate to more distant tissues.

Once the melanocyte has transformed into the malignant phenotype, tumor growth occurs radially in the epidermal plane.^{73–76} Even though microinvasion of the dermis may have occurred, metastases do not occur until these melanocytes form dermal nests. During the subsequent vertical growth phase, cells develop different cell-surface antigens and their malignant behavior becomes much more aggressive.^{73–76} Study of these cell populations in culture medium demonstrates substantially lengthened cellular life span and increased malignant growth despite significantly poor nutrient medium.^{73–76}

Although the eye and anus are notable sites, over 90% of melanomas are found on the skin (Fig. 16-11).^{73–76} In addition, 4% of tumors are discovered as metastases without any identifiable primary site. Suspicious features suggestive of melanoma include any pigmented lesion with an irregular border, darkening coloration, ulceration, and raised surface.^{73–76} Although many benign lesions may fit these descriptors, it is perhaps most critical to note recent changes in nevus appearance that may denote malignant transformation. In addition, approximately 5 to 10% of melanomas are nonpigmented.^{73–76}

Lateral view of a subungual melanoma demonstrating apparent proximal digital extension.

In order of decreasing frequency, the four types of melanoma are superficial spreading, nodular, lentigo maligna, and acral lentiginous.^{73–76} The most common type, superficial spreading, accounts for up to 70% of melanomas. These lesions occur anywhere on the skin except the hands and feet. They are typically flat and measure 1 to 2 cm in diameter at diagnosis.^{73–76} Before vertical extension, a prolonged radial growth phase is characteristic of these lesions. Typically of darker coloration and often raised, the nodular type accounts for 15 to 30% of melanomas.^{73–76} These lesions are noted for their lack of radial growth; hence, all nodular melanomas are in the vertical growth phase at diagnosis. Although considered a more aggressive lesion, the prognosis for patients with nodular-type melanomas is similar to that for a patient with a superficial spreading

lesion of the same depth. Lentigo maligna accounts for 4 to 15% of melanomas, and occurs most frequently on the neck, face, and hands of the elderly.^{73–76} Although they tend to be quite large at diagnosis, these lesions have the best prognosis because invasive growth occurs late. Less than 5% of lentigo maligna are estimated to evolve into melanoma.^{74,75} Acral lentiginous melanoma is the least common subtype, and constitutes only 2 to 8% of melanomas in white populations. Although acral lentiginous melanoma among dark-skinned people is relatively rare, this type accounts for 29 to 72% of all melanomas in dark-skinned people (African Americans, Asians, and Hispanics).^{74,75} Acral lentiginous melanoma most frequently is encountered on the palms, soles, and subungual regions. Most common on the great toe or thumb, subungual lesions appear as blue-black discolorations of the posterior nail fold. The additional presence of pigmentation in the proximal or lateral nail folds (Hutchinson's sign) is diagnostic of subungual melanoma.^{73–76}

Several clinical features of melanoma have been identified as significant prognostic indicators. Independent of histologic type and depth of invasion, those with lesions of the extremities have a better prognosis than patients with melanomas of the head, neck, or trunk (10-year survival rate of 82% for localized disease of the extremity compared to a 68% survival rate with a lesion of the face).^{73–76} Lesion ulceration carries a worse prognosis. The 10-year survival rate for patients with local disease (stage I) and an ulcerated melanoma was 50% compared to 78% for the same stage lesion without ulceration.^{73–76} Early studies identified that the incidence of ulceration increases with increasing thickness, from 12.5% in melanomas less than 0.75 mm to 72.5% in melanomas greater than 4.0 mm.^{74,76} Recent evidence suggests that tumors ulcerate as the result of increased angiogenesis.^{73–76} Gender is also a substantial prognostic indicator. Numerous studies demonstrate that females have an improved survival compared to males.^{74,75} Women tend to acquire melanomas in more favorable anatomic sites, and these lesions are less likely to contain ulceration. After correcting for thickness, age, and location, females continue to have a higher survival rate than men (10-year survival rate of 80% for women vs. 61% for men with stage I disease).^{74–76} In general, there is no significant difference between different histologic tumor types in terms of prognosis, when matched for tumor thickness, gender, age, or other. Nodular melanomas have the same prognosis as superficial spreading types when lesions are matched for depth of invasion. Lentigo maligna types, however, have a better prognosis even after correcting for thickness, and acral lentiginous lesions have a worse prognosis. Even though the various types of melanoma have similar prognoses when controlled for the other prognostic factors, acral lentiginous melanoma has a shorter interval to recurrence.^{74–76}

The most current staging system, from the American Joint Committee on Cancer (AJCC), contains the best method of interpreting clinical information in regard to prognosis of this disease (Fig. 16-12).^{74–76} Historically, the vertical thickness of the primary tumor (Breslow thickness) and the anatomic depth of invasion (Clark level) have represented the dominant factors in the T classification. The T classification of lesions comes from the original observation by Clark that prognosis is directly related to the level of invasion of the skin by the melanoma. Whereas Clark used the histologic level [I, superficial to basement membrane (in situ); II, papillary dermis; III, papillary/reticular dermal junction; IV, reticular dermis; and V, subcutaneous fat], Breslow modified the approach to obtain a more reproducible measure of invasion by the use of an ocular micrometer. The lesions were measured from the granular layer of the epidermis or the base of the ulcer to the greatest depth of the tumor (I, 0.75 mm or less; II, 0.76 to 1.5 mm; III, 1.51 to 4.0 mm; IV, 4.0 mm or more).^{74–76} These levels of invasion have been subsequently modified and incorporated in the AJCC staging system. The new staging system has largely replaced the Clark level with another histologic feature, ulceration, based on analysis of large databases available to the AJCC Melanoma Committee.^{75,76}

Although Breslow's thickness has traditionally been used to anticipate clinical outcomes based on the depth of melanoma invasion, more recent staging criteria advanced by the American Joint Committee on Cancer (AJCC) are today's standard of care.

Evidence of tumor in regional LNs is a poor prognostic sign associated with a precipitous drop in survival at 15-year follow-up.⁷⁷⁻⁸¹ Based on the tumor, node, and metastasis tumor staging system, this finding advances any classification from stage I or II to stage III. Identification of distant metastasis is the worst prognostic sign and is classified as stage IV disease. Although occasional survival for several years has been noted, median survival ranges from 2 to 7 months depending on the number and site of metastases.⁷⁷⁻⁸¹

Diagnosis of melanoma typically requires excisional biopsy (Fig. 16-13). A 1-mm margin of normal skin is taken if the wound can be closed primarily.⁷³⁻⁷⁶ If removal of the entire lesion creates too large a defect, then an incisional biopsy of a representative part is recommended. Biopsy incisions should be made with the expectation that a subsequent wide excision of the biopsy site may be done.

Fig. 16-13.

The diagnosis of melanoma should be made via excisional biopsy. Based on tumor depth, appropriate margins may be planned. Indications for lymph node evaluation continue to advance as our understanding of tumor behavior improves and outcome data become available. LAD = lymphadenopathy.

With diagnosis made, treatment of melanoma may range from simple excision to more complex lymphadenectomy or immunotherapy (see Fig. 16-13). Regardless of tumor depth or extension, surgical excision is the management of choice. Lesions 1 mm or less in thickness can be treated with a 1-cm margin.⁷³⁻⁷⁶ For lesions 1 mm to 4 mm thick, a 2-cm margin is recommended. Lesions of greater than 4 mm may be treated with 3-cm margins.⁷³⁻⁷⁶ The surrounding tissue should be removed down to the fascia to remove all lymphatic channels. If the deep fascia is not involved by the tumor, removing it does not affect recurrence or survival rates, so the fascia is left intact.⁷³⁻⁷⁶

Treatment of regional LNs that do not obviously contain tumor in patients without evidence of metastasis is an area of continued debate. In patients with thin lesions (less than 1 mm), the tumor cells are still localized in the surrounding tissue, and the cure rate is excellent with wide excision of the primary lesion; therefore treatment of regional LNs is not beneficial (Fig. 16-14).⁷³⁻⁷⁶ With lesions deeper than 4 mm, it is highly likely that the tumor cells already have spread to the regional LNs and distant sites. Removal of the melanomatous LNs has no effect on survival.⁷³⁻⁷⁶ Most of these patients die of metastatic disease before developing problems in regional nodes.

Melanoma treatment algorithm. The algorithmic approach to melanoma has taken many forms throughout the last several decades. However, as our diagnostic technology, therapeutic approaches, and ability to assess outcome improves, the current algorithm incorporates these advances. ELND = elective lymph node dissection; IFN-a2b = interferon alfa-2b; LAD = lymphadenopathy; LN = lymph node; SLND = sentinel lymph node dissection.

In patients with intermediate-thickness tumors (T2 and T3, 1 to 4.0 mm) and no clinical evidence of nodal or metastatic disease, the use of prophylactic dissection (elective LN dissection on clinically negative nodes) is controversial. To date, no prospective, randomized studies have demonstrated that elective LN dissection improves survival in patients with intermediate-thickness melanomas. However, 25 to 50% of LN specimens contain micrometastases in these cases and recurrence may be decreased with LN dissection.^{77–81}

Sentinel lymphadenectomy for malignant melanoma is gaining acceptance (Fig. 16-15). The sentinel node may be preoperatively located with the use of a gamma camera, which identifies the radioisotope injected into the primary lesion.^{77–81} Whereas preoperative identification may provide the surgeon greater reliability in localizing the LN, intraoperative mapping with 1% isosulfan blue dye injection may be equally effective.^{77–81} Both techniques identify the lymphatic drainage from the primary lesion, and determine the first (sentinel) LN draining the tumor area.^{77–81} If micrometastasis is identified in the removed node by frozen-section examination, a complete LN dissection is performed.^{77–81} This method may be used to identify patients who would benefit from LN dissection, while sparing others an unnecessary operation.

Intraoperative view of sentinel lymph node identification during distal melanoma excision.

All microscopically or clinically positive LNs should be removed by regional nodal dissection.⁷⁷⁻⁸¹ When groin LNs are removed, the deep (iliac) nodes must be removed along with the superficial (inguinal) nodes, or disease will recur in that region. For axillary dissections, the nodes medial to the pectoralis minor muscle also must be resected.⁷⁷⁻⁸¹ For lesions on the face, anterior scalp, and ear, a superficial parotidectomy to remove parotid nodes and a modified neck dissection is recommended.⁷⁷⁻⁸¹

Once melanoma has spread to a distant site, median survival is 7 to 8 months and the 5-year survival rate is less than 5%.⁷⁷⁻⁸¹ Solitary lesions in the brain, GI tract, or skin that are symptomatic should be excised when possible. Although cure is extremely rare, the degree of palliation can be high and asymptomatic survival prolonged.⁷⁷⁻⁸¹ A decision to operate on metastatic lesions must be made after careful deliberation with the patient and the treating oncologist.

Locally recurrent, lymphatic-invading, or tumors unamenable to surgical excision present a significant management challenge. In-transit disease (local disease in lymphatics) develops in 5 to 8% of melanoma patients with a high-risk primary melanoma (>1.5 mm).⁷⁷⁻⁸¹ Hyperthermic regional perfusion with a chemotherapeutic agent (e.g., melphalan) is presently the treatment of choice. The goal of regional perfusion therapy is to increase the dosage of the chemotherapeutic agent to maximize tumor response while limiting systemic toxic effects.⁷⁷⁻⁸¹ Melphalan generally is heated to an elevated temperature [up to 41.5°C, (106.7°F)] and perfused for 60 to 90 minutes. Although difficult to perform and associated with complications (neutropenia, amputation, death), it does produce a high response rate (greater than 50%).^{74,77-79} The introduction of tumor necrosis factor alpha or interferon- γ with melphalan results in the regression of more than 90% of cutaneous in-transit metastases.⁷⁵⁻⁷⁷

Although initially thought to be ineffective in the treatment of melanoma, the use of radiation therapy, regional and systemic chemotherapy, and immunotherapy are all under investigation. High-dose-per-fraction radiation produces a better response

rate than low-dose large-fraction therapy. As the treatment of choice for patients with symptomatic multiple brain metastases, radiation therapy produced measurable improvement in tumor size, symptomatology, or performance status in 70% of treated patients.^{79–81}

Another promising area of nonsurgical melanoma treatment is the use of immunologic manipulation. Interferon alfa-2b is the only Food and Drug Administration–approved adjuvant treatment for AJCC stages IIB/III melanoma.^{80,81} In these patients, both the relapse-free interval and overall survival were improved with use of INF- α .^{80,81} Side effects were common and frequently severe; the majority of the patients required modification of the initial dosage and 24% discontinued treatment.^{80,81} Immunotherapy also continues to be a field of great promise. Vaccines have been developed with the hope of stimulating the body's own immune system against the tumor. Melanoma cells contain a number of distinctly different cell-surface antigens, and monoclonal antibodies have been raised against these antigens.^{80,81} These antibodies have been used alone or linked to a radioisotope or cytotoxic agent in an effort to selectively kill tumor cells. All treatments are currently investigational. One defined-antigen vaccine has entered clinical testing; the ganglioside G_{M2}. Gangliosides are carbohydrate antigens found on the surface of melanomas as well as many other tumors.^{80,81}

ADDITIONAL MALIGNANCIES OF THE SKIN

Merkel Cell Carcinoma (Primary Neuroendocrine Carcinoma of the Skin)

Once thought to be a variant of SCC, Merkel cell carcinomas are actually of neuroepithelial differentiation.^{82,83} These tumors are associated with a synchronous or metasynchronous SCC 25% of the time. Due to their aggressive nature, wide local resection with 3-cm margins is recommended.^{82,83} Local recurrence rates are high, and distant metastases occur in one third of patients. Prophylactic regional LN dissection and adjuvant radiation therapy are recommended. Overall, the prognosis is worse than for malignant melanoma.^{82,83}

Kaposi's Sarcoma

Kaposi's sarcoma (KS) appears as rubbery bluish nodules that occur primarily on the extremities but may appear anywhere on the skin and viscera. These lesions are usually multifocal rather than metastatic.^{84–88} Histologically, the lesions are composed of capillaries lined by atypical endothelial cells. Early lesions may resemble hemangiomas, while older lesions contain more spindle cells and resemble sarcomas.^{84–86} Classically, KS is seen in people of Eastern Europe or sub-Saharan Africa. The lesions are locally aggressive but undergo periods of remission. A different variety of KS has been described for people with AIDS or with immunosuppression from chemotherapy.^{84–86} For reasons not yet understood, AIDS-related KS occurs primarily in male homosexuals and not in IV drug abusers or hemophiliacs. In this form of the disease, the lesions spread rapidly to the nodes, and the GI and respiratory tract often are involved.^{84–86} Development of AIDS-related KS is associated with concurrent infection with a herpes-like virus.^{84–86} Treatment for all types of KS consists of radiation to the lesions. Combination chemotherapy is effective in controlling the disease, although most patients develop an opportunistic infection during or shortly after treatment. Surgical treatment is reserved for lesions that interfere with vital functions, such as bowel obstruction or airway compromise.^{84–86}

Extramammary Paget's Disease

This tumor is histologically similar to the mammary type. It is a cutaneous lesion that appears as a pruritic red patch that does not resolve.⁸⁵ Biopsy demonstrates classic Paget's cells. Paget's disease is thought to be a cutaneous extension of an underlying adenocarcinoma, although an associated tumor cannot always be demonstrated.⁸⁵

Angiosarcoma

Angiosarcomas may arise spontaneously, mostly on the scalp, face, and neck. They usually appear as a bruise that spontaneously bleeds or enlarges without trauma.^{87,88} Tumors also may arise in areas of prior radiation therapy or in the setting of chronic lymphedema of the arm, such as after mastectomy (Stewart-Treves syndrome).^{87,88} The angiosarcomas that arise in these areas of chronic change occur decades later. The tumors consist of anaplastic endothelial cells surrounding vascular channels. Although total excision of early lesions can provide occasional cure, the prognosis usually is poor, with 5-year survival rates of less than 20%. Chemotherapy and radiation therapy are used for palliation.^{87,88}

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) accounts for 1 to 2% of all soft-tissue sarcomas, occurs most frequently in persons aged 20 to 50 years, and is more common in males.^{88,89} The most common presenting location is on the trunk (50 to 60%), although the proximal extremities (20 to 30% of cases), as well as head and neck also are frequently affected (10 to 15%).^{88,89} DFSP often appears as a pink, nodular lesion that may ulcerate and become infected. Histologically, the lesions contain atypical spindle cells, probably of fibroblast origin, located around a core of collagen tissue. Despite what appears to be complete lesion excision, local recurrence remains frequent and mortality associated with metastasis relatively high.^{88,89} To date, the minimum resection margin needed to achieve local control remains undefined. Local recurrence rates of up to 50% have been reported after simple excision, and wide local excision with 3-cm margins is linked to a 20% recurrence rate. Most authorities seem to advocate a three-dimensional margin of 2 to 3 cm with resection of skin, subcutaneous tissue, and the underlying investing fascia.^{88,89} The periosteum and a portion of the bone may also need to be resected to achieve negative deep surgical margins. In addition to achieving wide macroscopic resection, conformation of negative microscopic margins is especially critical. DFSP is considered to be a radiosensitive tumor, and radiotherapy following wide local excision has reached local control rates approximating 95% at 10 years.^{88,89} Continued study of chemotherapy efficacy on DFSP also has produced optimistic results. Imatinib, a selective inhibitor of platelet-derived growth factor (PDGF) β -chain alpha and PDGF receptor beta protein-tyrosine kinase activity, alters the biologic effects of deregulated PDGF receptor signaling. Clinical trials have shown activity against localized and metastatic DFSP containing the t(17:22) translocation, suggesting that targeting the PDGF receptors may become a new therapeutic option for DFSP. Phase II clinical trials are underway.^{88,89}

Fibrosarcoma

Fibrosarcomas are hard, irregular masses found in the subcutaneous fat.^{88,89} The fibroblasts appear markedly anaplastic with disorganized growth. If they are not excised completely, metastases usually develop. The 5-year survival rate after excision is approximately 60%.^{88,89}

Liposarcoma

Liposarcomas arise in the deep muscle planes, and, rarely, from the subcutaneous tissue.^{88,89} They occur most commonly on the thigh. An enlarging lipoma should be excised and inspected to distinguish it from a liposarcoma. Wide excision is the treatment of choice, with radiation therapy reserved for metastatic disease.^{88,89}

SYNDROMIC SKIN MALIGNANCIES

Several genetic syndromes are associated with an increased incidence of skin malignancy. Although many are related to development of a specific lesion, others appear to produce a more generic prevalence for neoplastic formation. Based on

their respective genetic defects, syndromes associated with BCC, SCC, and melanoma have all been identified and well described. Diseases linked with BCC include the basal cell nevus (Gorlin's) syndrome and nevus sebaceus of Jadassohn.^{90–92} Basal cell nevus syndrome is an autosomal dominant disorder characterized by the growth of hundreds of BCCs during young adulthood. Palmar and plantar pits are a common physical finding and represent foci of neoplasms.^{90–92} Treatment is limited to excision of only aggressive and symptomatic lesions. Nevus sebaceus of Jadassohn is a lesion containing several cutaneous tissue elements that develops during childhood.^{90–92} This lesion is associated with a variety of neoplasms of the epidermis, but most commonly BCC. Diseases associated with SCC may have a causative role in the development of carcinoma. Skin diseases that cause chronic wounds, such as epidermolysis bullosus and lupus erythematosus, are associated with a high incidence of SCC.^{90–92} Epidermodysplasia verruciformis is a rare autosomal recessive disease associated with infection with HPV. Large verrucous lesions develop early in life and often progress to invasive SCC in middle age.^{90–92} Xeroderma pigmentosum is an autosomal recessive disease associated with a defect in cellular repair of DNA damage. The inability of the skin to correct DNA damage from UV radiation leaves these patients prone to cutaneous malignancies.^{90–92} SCCs are most frequent, but BCCs, melanomas, and even acute leukemias are seen. Dysplastic nevi are considered precursors to melanoma. Familial dysplastic nevus syndrome is an autosomal dominant disorder.^{90–92} Patients develop multiple dysplastic nevi, and longitudinal studies have demonstrated an almost 100% incidence of melanoma. Gene mapping of the defects found in familial dysplastic nevus syndrome has identified several candidate "melanoma" genes.^{90–94} It remains to be determined whether these germline mutations also are found in sporadic cases of melanoma. Much like other familial malignancy syndromes, genetic analysis of the hereditary defect may shed much needed light on the molecular mechanisms that lead to malignant transformation. Much like familial polyposis coli and the association with colon cancer, familial dysplastic nevus syndrome is treated by close surveillance and frequent biopsy of all suspicious lesions. Similarly, the development of colon cancer can be arrested with total proctocolectomy; unfortunately, a similar solution is not possible in patients with familial dysplastic nevi.^{90–94}

FUTURE DEVELOPMENTS IN SKIN SURGERY

The last decade has seen unprecedented advances in our understanding of the skin and its pathology as well as our ability to protect and replace it. Autologous skin grafts remain the best method to cover skin defects, but donor-site problems and limited availability of autologous skin remain problematic.^{95–98} Tissue expansion with subcutaneous balloon implants produces new epidermis, and mobilization achieved via expansion remains a highly effective approach to wound coverage.^{95–98} Still, optimal wound coverage lies in the development of engineered skin replacements. Current research is directed at identifying different materials and cells that can be used to replace both epidermis and dermis.

Several dermal replacements based on synthetic materials or cadaveric sources are in clinical use (Fig. 16-16). A bovine-collagen and shark-proteoglycan-based dermis (Integra) has been used primarily in burn patients for more than a decade.^{95–98} This prosthetic dermis, available in ready-to-use form, can cover large surface areas. Vascularization of this dermis takes 2 to 3 weeks, and final epidermal coverage of the wound requires a thin skin graft.^{95–98} The final result is functionally and aesthetically good, but the high cost has been problematic. Cadaveric dermis, with all of the cellular elements removed, is not antigenic and is not rejected by the recipient patient.^{95–98} This human dermal matrix is commercially-available (AlloDerm) and functions much like Integra, with similar limitations of engraftment and high cost. Both forms of dermal replacements are more frequently used in delayed reconstruction of burn patients than in the acute setting.^{95–98}

The most recent generation of dermal matrix replacement tissues includes both cadaveric and xenographic materials. AlloDerm (pictured here) may be placed over various deeper tissues to provide a dermal scaffold onto which autologous skin may be grafted.

Another issue confounding surgeons is the lack of means to quickly provide numerous autologous skin cells for permanent skin replacement. The expansion of epidermis by the growth and maturation of keratinocytes in culture is readily performed.⁹⁵⁻⁹⁸ A small skin biopsy specimen can produce enough autologous epithelium to cover the entire body surface. However, on the body, the cultured epidermis often blisters and sloughs as a consequence of slow restoration of the basement membrane. Improving the durability of these cells may one day negate autologous skin grafting technique or the requirement for cadaveric soft tissues. In addition, as more is learned about the protein factors that control wound healing and tissue growth, the replacement for damaged skin will eventually come from complete organogenesis of tissue.⁹⁵⁻⁹⁸ Characterization of these growth factors on a structural and functional level is progressing rapidly. Factors have been isolated that cause specific mesenchymal cells to proliferate, migrate, and organize into structures such as capillaries or even rudimentary organoid tissue.⁹⁵⁻⁹⁸

CONCLUSION

Anatomically, the epidermal, basement membrane, and dermal layers of the skin each play a vital role in maintaining dermal/epidermal integrity. Multiple, complex mechanisms within these soft tissues protect us from injury as well as relay external information along a vast neural network. In addition to penetrating trauma, the environment offers a host of potentially injurious elements such as caustic substances, extreme temperatures, prolonged or excessive pressure, and radiation. Infections ranging from simple bacterial to necrotizing, life-threatening disease may also affect the skin and subcutaneous tissues. Perhaps of greatest public concern, a multitude of benign and malignant tumors threaten to disrupt, disfigure, and invade normal skin structure. Although the risks associated with many of these lesions are great, a broad variety of medical and surgical management options currently exist. Although contemporary medicine may not have an optimal answer for each threat the skin may face, continued research, advances in our understanding, and technical improvements in the field promise to enhance our ability to replace and protect the skin well into the future.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 17. The Breast >

KEY POINTS

1. The breast receives its principal blood supply from perforating branches of the internal mammary artery, lateral branches of the posterior intercostal arteries, and branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery.
2. The axillary lymph nodes usually receive >75% of the lymph drainage from the breast, and the rest flows through the lymph vessels that accompany the perforating branches of the internal mammary artery and enters the parasternal (internal mammary) group of lymph nodes.
3. Breast development and function are initiated by a variety of hormonal stimuli, with the major trophic effects being modulated by estrogen, progesterone, and prolactin.
4. Benign breast disorders and diseases are related to the normal processes of reproductive life and to involution, and there is a spectrum of breast conditions that ranges from normal to disorder to disease (aberrations of normal development and involution classification).
5. To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories. This risk score is then compared with an adjusted population risk of breast cancer to determine the woman's individual risk. This model is not appropriate for use in women with a known *BRCA1* or *BRCA2* mutation or women with lobular or ductal carcinoma in situ.
6. Routine use of screening mammography in women ≥ 50 years of age reduces mortality from breast cancer by 33%.
7. Core-needle biopsy is the preferred method for diagnosis of palpable or nonpalpable breast abnormalities.
8. When a diagnosis of breast cancer is made, the surgeon should determine the clinical stage, histologic characteristics, and appropriate biomarker levels before initiating local therapy.
9. Sentinel node dissection is the preferred method for staging of the regional lymph nodes in women with clinically node-negative invasive breast cancer.
10. Local-regional and systemic therapy decisions for an individual patient with breast cancer are best made using a multidisciplinary treatment approach.

A BRIEF HISTORY OF BREAST CANCER THERAPY

Breast cancer, with its uncertain cause, has captured the attention of surgeons throughout the ages. Despite centuries of theoretical meandering and scientific inquiry, breast cancer remains one of the most dreaded of human diseases.^{1–12} The story of efforts to cope with breast cancer is complex, and there is no successful conclusion as in diseases for which cause and cure are known. However, progress has been made in lessening the horrors that formerly devastated the body and psyche. Currently, 50% of American women will consult a surgeon regarding breast disease, 25% will undergo breast biopsy, and 12% will develop

some variant of breast cancer.

The Smith Surgical Papyrus (3000–2500 B.C.) is the earliest known document to refer to breast cancer. The cancer was in a man, but the description encompassed most of the common clinical features. In reference to this cancer, the author concluded, "There is no treatment."¹ There were few other historical references to breast cancer until the first century. In *De Medicina*, Celsus commented on the value of operations for early breast cancer: "None of these may be removed but the cacoethes (early cancer), the rest are irritated by every method of cure. The more violent the operations are, the more angry they grow."² In the second century, Galen inscribed his classical clinical observation: "We have often seen in the breast a tumor exactly resembling the animal the crab. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab's legs. We have often cured this disease in its early stages, but after it has reached a large size, no one has cured it. In all operations we attempt to excise the tumor in a circle where it borders on the healthy tissue."³

The galenic system of medicine ascribed cancers to an excess of black bile and concluded that excision of a local bodily outbreak could not cure the systemic imbalance. Theories espoused by Galen dominated medicine until the Renaissance. The majority of respected surgeons considered operative intervention to be a futile and ill-advised endeavor. However, beginning with Morgagni, surgical resections were more frequently undertaken, including some early attempts at mastectomy and axillary dissection. Le Dran repudiated Galen's humoral theory in the eighteenth century and stated that breast cancer was a local disease that spread by way of lymph vessels to axillary lymph nodes. When operating on a woman with breast cancer, he routinely removed any enlarged axillary lymph nodes.⁵

In the nineteenth century, Moore, of the Middlesex Hospital, London, emphasized complete resection of the breast for cancer and stated that palpable axillary lymph nodes also should be removed.¹¹ In a presentation before the British Medical Association in 1877, Banks supported Moore's concepts and advocated the resection of axillary lymph nodes even when palpable lymphadenopathy was not evident, recognizing that occult involvement of axillary lymph nodes was frequently present. In 1894, Halsted and Meyer reported their operations for treatment of breast cancer.⁴ By demonstrating superior local-regional control rates after radical resection, these surgeons established radical mastectomy as state-of-the-art treatment for that era. Both Halsted and Meyer advocated complete dissection of axillary lymph node levels I to III. Both routinely resected the long thoracic nerve and the thoracodorsal neurovascular bundle with the axillary contents.

In 1943, Haagensen and Stout described the grave signs of breast cancer, which included (a) edema of the skin of the breast, (b) skin ulceration, (c) chest wall fixation, (d) an axillary lymph node >2.5 cm in diameter, and (e) fixed axillary lymph nodes. Women with two or more signs had a 42% local recurrence rate and only a 2% 5-year disease-free survival rate.⁶ Based on these findings, they declared that women with grave signs were beyond cure by radical surgery. Approximately 25% of women were excluded from surgery based on these criteria of inoperability. Today, with comprehensive mammography screening, only 10% of women are found to have such advanced breast cancers. In 1948, Patey and Dyson of the Middlesex Hospital, London, advocated a modified radical mastectomy for the management of advanced operable breast cancer, explaining, "Until an effective general agent for treatment of carcinoma of the breast is developed, a high proportion of these cases are doomed to die."¹² Their technique included removal of the breast and axillary lymph nodes with preservation of the pectoralis major muscle. They showed that removal of the pectoralis minor muscle allowed access to and clearance of axillary lymph node levels I to III. Subsequently, Madden advocated a modified radical mastectomy that preserved both the pectoralis major and pectoralis minor muscles, even though this approach prevented complete dissection of the apical (level III) axillary lymph nodes.⁷

In the 1970s, there was a transition from the Halsted radical mastectomy to the modified radical mastectomy as the surgical procedure most frequently used by American surgeons to treat breast cancer. This transition acknowledged that (a) extirpation of

the pectoralis major muscle was not essential for local-regional control in stage I and stage II breast cancer, and (b) neither the modified radical mastectomy nor the Halsted radical mastectomy consistently achieved local-regional control of stage III breast cancer. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial conducted by Fisher and colleagues compared local and regional treatments of breast cancer. Life table estimates were obtained for 1665 women enrolled and followed for a mean of 120 months (Fig. 17-1). This study randomly divided clinically node-negative women into three treatment groups: (a) Halsted radical mastectomy; (b) total mastectomy plus radiation therapy; and (c) total mastectomy alone. Clinically node-positive women were treated with Halsted radical mastectomy or total mastectomy plus radiation therapy. This trial accrued patients between 1971 and 1974, an era that predated widespread availability of effective systemic therapy for breast cancer. Outcomes from this trial therefore reflect survival associated with local-regional therapy only. There were no differences in survival between the three groups of node-negative women or between the two groups of node-positive women (see Fig. 17-1A). Correspondingly, there were no differences in survival during the first and second 5-year follow-up periods (see Fig. 17-1B and 17-1C). These overall survival equivalence patterns have persisted at 25 years of follow-up.¹³

Results of the National Surgical Adjuvant Breast and Bowel Project B-04 trial. Disease-free survival for women treated by radical mastectomy (orange circles), total mastectomy plus radiation (x's), or total mastectomy alone (blue circles).

(Reproduced with permission from Fisher B, et al: Ten-year results of a randomized clinical trial comparing radical mastectomy and total mastectomy with or without radiation. *N Engl J Med* 312:674, 1985. Copyright © Massachusetts Medical Society. All rights reserved.)

Other prospective clinical trials that compared the Halsted radical mastectomy to the modified radical mastectomy were the Manchester trial, reported by Turner and colleagues, and the University of Alabama trial, reported by Maddox and colleagues.^{8,9} In both studies, the type of surgical procedure did not influence recurrence rates for patients with stage I and stage II breast cancer. The criterion for accrual to the Alabama Breast Cancer Project (1975 to 1978) was a T1 to T3 breast cancer with no apparent distant metastases. Patients received a radical or a modified radical mastectomy. Node-positive patients received adjuvant cyclophosphamide (Cytoxan), methotrexate, and 5-fluorouracil chemotherapy or adjuvant melphalan. After a median follow-up period of 15 years, neither type of surgery nor type of chemotherapy was shown to affect local-regional, disease-free,

or overall survival.⁸ Since the 1970s, considerable progress has been made in the integration of surgery, radiation therapy, and chemotherapy to control local-regional disease, enhance survival, and increase the possibility of breast conservation. Local-regional control is achieved for nearly 80% of women with advanced breast cancers.

EMBRYOLOGY AND FUNCTIONAL ANATOMY OF THE BREAST

Embryology

At the fifth or sixth week of fetal development, two ventral bands of thickened ectoderm (mammary ridges, milk lines) are evident in the embryo.¹⁴ In most mammals, paired breasts develop along these ridges, which extend from the base of the forelimb (future axilla) to the region of the hind limb (inguinal area). These ridges are not prominent in the human embryo and disappear after a short time, except for small portions that may persist in the pectoral region. Accessory breasts (*polymastia*) or accessory nipples (*polythelia*) may occur along the milk line (Fig. 17-2) when normal regression fails. Each breast develops when an ingrowth of ectoderm forms a primary tissue bud in the mesenchyme. The primary bud, in turn, initiates the development of 15 to 20 secondary buds. Epithelial cords develop from the secondary buds and extend into the surrounding mesenchyme. Major (lactiferous) ducts develop, which open into a shallow mammary pit. During infancy, a proliferation of mesenchyme transforms the mammary pit into a nipple. If there is failure of a pit to elevate above skin level, an inverted nipple results. This congenital malformation occurs in 4% of infants. At birth, the breasts are identical in males and females, demonstrating only the presence of major ducts. Enlargement of the breast may be evident and a secretion, referred to as *witch's milk*, may be produced. These transitory events occur in response to maternal hormones that cross the placenta.

The mammary milk line.

The breast remains undeveloped in the female until puberty, when it enlarges in response to ovarian estrogen and progesterone, which initiate proliferation of the epithelial and connective tissue elements. However, the breasts remain incompletely developed until pregnancy occurs. Absence of the breast (*amastia*) is rare and results from an arrest in mammary ridge development that occurs during the sixth fetal week. Poland's syndrome consists of hypoplasia or complete absence of the breast, costal cartilage and rib defects, hypoplasia of the subcutaneous tissues of the chest wall, and brachysyndactyly. Breast hypoplasia also may be iatrogenically induced before puberty by trauma, infection, or radiation therapy. *Symmastia* is a rare anomaly recognized as webbing between the breasts across the midline. Accessory nipples (polythelia) occur in <1% of infants and may be associated with abnormalities of the urinary tract (renal agenesis and cancer), abnormalities of the cardiovascular system (conduction disturbances, hypertension, congenital heart anomalies), and other conditions (pyloric stenosis, epilepsy, ear abnormalities, arthrogryposis). Supernumerary breasts may occur in any configuration along the mammary milk line but most frequently occur between the normal nipple location and the symphysis pubis. Turner's syndrome (ovarian agenesis and dysgenesis) and Fleischer's syndrome (displacement of the nipples and bilateral renal hypoplasia) may have polymastia as a component. Accessory axillary breast tissue is uncommon and usually is bilateral.

Functional Anatomy

The breast is composed of 15 to 20 lobes (Fig. 17-3), which are each composed of several lobules.¹⁵ Fibrous bands of connective tissue travel through the breast (Cooper's suspensory ligaments), insert perpendicularly into the dermis, and provide structural support. The mature female breast extends from the level of the second or third rib to the inframammary fold at the sixth or seventh rib. It extends transversely from the lateral border of the sternum to the anterior axillary line. The deep or posterior surface of the breast rests on the fascia of the pectoralis major, serratus anterior, and external oblique abdominal muscles, and the upper extent of the rectus sheath. The retromammary bursa may be identified on the posterior aspect of the breast between the investing fascia of the breast and the fascia of the pectoralis major muscles. The axillary tail of Spence extends laterally across the anterior axillary fold. The upper outer quadrant of the breast contains a greater volume of tissue than do the other quadrants. The breast has a protuberant conical form. The base of the cone is roughly circular, measuring 10 to 12 cm in diameter. Considerable variations in the size, contour, and density of the breast are evident among individuals. The nulliparous breast has a hemispheric configuration with distinct flattening above the nipple. With the hormonal stimulation that accompanies pregnancy and lactation, the breast becomes larger and increases in volume and density, whereas with senescence, it assumes a flattened, flaccid, and more pendulous configuration with decreased volume.

(Reproduced with permission from Romrell et al,¹⁵ p 20. Copyright Elsevier.)

NIPPLE-AREOLA COMPLEX

The epidermis of the nipple-areola complex is pigmented and is variably corrugated. During puberty, the pigment becomes darker and the nipple assumes an elevated configuration. During pregnancy, the areola enlarges and pigmentation is further enhanced. The areola contains sebaceous glands, sweat glands, and accessory glands, which produce small elevations on the surface of the areola (Montgomery's tubercles). Smooth muscle bundle fibers, which lie circumferentially in the dense connective tissue and longitudinally along the major ducts, extend upward into the nipple, where they are responsible for the nipple erection that occurs with various sensory stimuli. The dermal papilla at the tip of the nipple contains numerous sensory nerve endings and Meissner's corpuscles. This rich sensory innervation is of functional importance, because the sucking of the infant initiates a chain of neurohumoral events that results in milk letdown.

INACTIVE AND ACTIVE BREAST

Each lobe of the breast terminates in a major (lactiferous) duct (2 to 4 mm in diameter), which opens through a constricted orifice (0.4 to 0.7 mm in diameter) into the ampulla of the nipple (see Fig. 17-3). Immediately below the nipple-areola complex, each major duct has a dilated portion (lactiferous sinus), which is lined with stratified squamous epithelium. Major ducts are lined with two layers of cuboidal cells, whereas minor ducts are lined with a single layer of columnar or cuboidal cells. Myoepithelial cells of ectodermal origin reside between the epithelial cells in the basal lamina and contain myofibrils. In the inactive breast, the epithelium is sparse and consists primarily of ductal epithelium (Fig. 17-4). In the early phase of the menstrual cycle, minor ducts are cord-like with small lumina. With estrogen stimulation at the time of ovulation, alveolar epithelium increases in height, duct lumina become more prominent, and some secretions accumulate. When the hormonal stimulation decreases, the alveolar epithelium regresses.

Inactive human breast (x160). The epithelium (*Ep*), which is primarily ductal, is embedded in loose connective tissue [*CT(L)*]. Dense connective tissue [*CT(D)*] surrounds the lobule.

(Reproduced with permission from Romrell et al,¹⁵ p 22. Copyright Elsevier.)

With pregnancy, the breast undergoes proliferative and developmental maturation. As the breast enlarges in response to hormonal stimulation, lymphocytes, plasma cells, and eosinophils accumulate within the connective tissues. The minor ducts branch and alveoli develop. Development of the alveoli is asymmetric, and variations in the degree of development may occur within a single lobule (Fig. 17-5). With parturition, enlargement of the breasts occurs via hypertrophy of alveolar epithelium and accumulation of secretory products in the lumina of the minor ducts. Alveolar epithelium contains abundant endoplasmic reticulum, large mitochondria, Golgi complexes, and dense lysosomes. Two distinct substances are produced by the alveolar epithelium: (a) the protein component of milk, which is synthesized in the endoplasmic reticulum (merocrine secretion); and (b) the lipid component of milk (apocrine secretion), which forms as free lipid droplets in the cytoplasm. Milk released in the first few days after parturition is called *colostrum* and has low lipid content but contains considerable quantities of antibodies. The lymphocytes and plasma cells that accumulate within the connective tissues of the breast are the source of the antibody component. With subsequent reduction in the number of these cells, the production of colostrum decreases and lipid-rich milk is released.

BLOOD SUPPLY, INNERVATION, AND LYMPHATICS

The breast receives its principal blood supply from (a) perforating branches of the internal mammary artery; (b) lateral branches of the posterior intercostal arteries; and (c) branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery (Fig. 17-6). The second, third, and fourth anterior intercostal perforators and branches of the internal mammary artery arborize in the breast as the medial mammary arteries. The lateral thoracic artery gives off branches to the serratus anterior, pectoralis major and pectoralis minor, and subscapularis muscles. It also gives rise to lateral mammary branches. The veins of the breast and chest wall follow the course of the arteries, with venous drainage being toward the axilla. The three principal groups of veins are (a) perforating branches of the internal thoracic vein, (b) perforating branches of the posterior intercostal veins, and (c) tributaries of the axillary vein. Batson's vertebral venous plexus, which invests the vertebrae and extends from the base of the skull to the sacrum, may provide a route for breast cancer metastases to the vertebrae, skull, pelvic bones, and central nervous system. Lymph vessels generally parallel the course of blood vessels.

Arterial supply to the breast, axilla, and chest wall.

(Reproduced with permission from Romrell et al,¹⁵ p 28. Copyright Elsevier.)

Lateral cutaneous branches of the third through sixth intercostal nerves provide sensory innervation of the breast (lateral mammary branches) and of the anterolateral chest wall. These branches exit the intercostal spaces between slips of the serratus anterior muscle. Cutaneous branches that arise from the cervical plexus, specifically the anterior branches of the supraclavicular nerve, supply a limited area of skin over the upper portion of the breast. The intercostobrachial nerve is the lateral cutaneous branch of the second intercostal nerve and may be visualized during surgical dissection of the axilla. Resection of the intercostobrachial nerve causes loss of sensation over the medial aspect of the upper arm.

The boundaries for lymph drainage of the axilla are not well demarcated, and there is considerable variation in the position of the axillary lymph nodes. The six axillary lymph node groups recognized by surgeons (Figs. 17-7 and 17-8) are (a) the axillary vein group (lateral), which consists of four to six lymph nodes that lie medial or posterior to the vein and receive most of the lymph drainage from the upper extremity; (b) the external mammary group (anterior or pectoral group), which consists of five or six lymph nodes that lie along the lower border of the pectoralis minor muscle contiguous with the lateral thoracic vessels and receive most of the lymph drainage from the lateral aspect of the breast; (c) the scapular group (posterior or subscapular), which consists of five to seven lymph nodes that lie along the posterior wall of the axilla at the lateral border of the scapula contiguous with the subscapular vessels and receive lymph drainage principally from the lower posterior neck, the posterior trunk, and the posterior shoulder; (d) the central group, which consists of three or four sets of lymph nodes that are embedded in the fat of the axilla lying immediately posterior to the pectoralis minor muscle and receive lymph drainage both from the axillary vein, external mammary, and scapular groups of lymph nodes, and directly from the breast; (e) the subclavicular group (apical), which consists of six to twelve sets of lymph nodes that lie posterior and superior to the upper border of the pectoralis minor muscle and receive lymph drainage from all of the other groups of axillary lymph nodes; and (f) the interpectoral group (Rotter's nodes), which consists of one to four lymph nodes that are interposed between the pectoralis major and pectoralis minor muscles and receive lymph drainage directly from the breast. The lymph fluid that passes through the interpectoral group

of lymph nodes passes directly into the central and subclavicular groups.

Axillary lymph node groups. Level I includes lymph nodes located lateral to the pectoralis minor muscle (PM); level II includes lymph nodes located deep to the PM; and level III includes lymph nodes located medial to the PM. *Arrows* indicate the direction of lymph flow. The axillary vein with its major tributaries and the supraclavicular lymph node group are also illustrated.

(Reproduced with permission from Romrell et al,¹⁵ p 32. Copyright Elsevier.)

As indicated in Fig. 17-8, the lymph node groups are assigned levels according to their anatomic relationship to the pectoralis minor muscle. Lymph nodes located lateral to or below the lower border of the pectoralis minor muscle are referred to as *level I lymph nodes*, which include the axillary vein, external mammary, and scapular groups. Lymph nodes located superficial or deep to the pectoralis minor muscle are referred to as *level II lymph nodes*, which include the central and interpectoral groups. Lymph nodes located medial to or above the upper border of the pectoralis minor muscle are referred to as *level III lymph nodes*, which consist of the subclavicular group. The plexus of lymph vessels in the breast arises in the interlobular connective tissue and in the walls of the lactiferous ducts and communicates with the subareolar plexus of lymph vessels. Efferent lymph vessels from the breast pass around the lateral edge of the pectoralis major muscle and pierce the clavipectoral fascia, ending in the external mammary (anterior, pectoral) group of lymph nodes. Some lymph vessels may travel directly to the subscapular (posterior, scapular) group of lymph nodes. From the upper part of the breast, a few lymph vessels pass directly to the subclavicular (apical) group of lymph nodes. The axillary lymph nodes usually receive >75% of the lymph drainage from the breast. The rest is derived primarily from the medial aspect of the breast, flows through the lymph vessels that accompany the perforating branches of the internal mammary artery, and enters the parasternal (internal mammary) group of lymph nodes.

PHYSIOLOGY OF THE BREAST

Breast Development and Function

Breast development and function are initiated by a variety of hormonal stimuli, including estrogen, progesterone, prolactin,

oxytocin, thyroid hormone, cortisol, and growth hormone.^{16,17} Estrogen, progesterone, and prolactin especially have profound trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development, whereas progesterone is responsible for differentiation of epithelium and for lobular development. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and the postpartum period. It upregulates hormone receptors and stimulates epithelial development. Figure 17-9 depicts the secretion of neurotrophic hormones from the hypothalamus, which is responsible for regulation of the secretion of the hormones that affect the breast tissues. The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) regulate the release of estrogen and progesterone from the ovaries. In turn, the release of LH and FSH from the basophilic cells of the anterior pituitary is regulated by the secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Positive and negative feedback effects of circulating estrogen and progesterone regulate the secretion of LH, FSH, and GnRH. These hormones are responsible for the development, function, and maintenance of breast tissues (Fig. 17-10). In the female neonate, circulating estrogen and progesterone levels decrease after birth and remain low throughout childhood because of the sensitivity of the hypothalamic-pituitary axis to negative feedback from these hormones. With the onset of puberty, there is a decrease in the sensitivity of the hypothalamic-pituitary axis to negative feedback and an increase in its sensitivity to positive feedback from estrogen. These physiologic events initiate an increase in GnRH, FSH, and LH secretion and ultimately an increase in estrogen and progesterone secretion by the ovaries, which leads to establishment of the menstrual cycle. At the beginning of the menstrual cycle, there is an increase in the size and density of the breasts, which is followed by engorgement of the breast tissues and epithelial proliferation. With the onset of menstruation, the breast engorgement subsides and epithelial proliferation decreases.

The breast at different physiologic stages. The central column contains three-dimensional depictions of microscopic structures.
A. Adolescence. **B.** Pregnancy. **C.** Lactation. **D.** Senescence.

Pregnancy, Lactation, and Senescence

A dramatic increase in circulating ovarian and placental estrogens and progestins is evident during pregnancy, which initiates striking alterations in the form and substance of the breast (see Fig. 17-10B).^{16–18} The breast enlarges as the ductal and lobular epithelium proliferates, the areolar skin darkens, and the accessory areolar glands (Montgomery's glands) become prominent. In the first and second trimesters, the minor ducts branch and develop. During the third trimester, fat droplets accumulate in the

alveolar epithelium and colostrum fills the alveolar and ductal spaces. In late pregnancy, prolactin stimulates the synthesis of milk fats and proteins.

After delivery of the placenta, circulating progesterone and estrogen levels decrease, which permits full expression of the lactogenic action of prolactin. Milk production and release are controlled by neural reflex arcs that originate in nerve endings of the nipple-areola complex. Maintenance of lactation requires regular stimulation of these neural reflexes, which results in prolactin secretion and milk letdown. Oxytocin release results from the auditory, visual, and olfactory stimuli associated with nursing. Oxytocin initiates contraction of the myoepithelial cells, which results in compression of alveoli and expulsion of milk into the lactiferous sinuses. After weaning of the infant, prolactin and oxytocin release decreases. Dormant milk causes increased pressure within the ducts and alveoli, which results in atrophy of the epithelium (Fig. 17-10C). With menopause there is a decrease in the secretion of estrogen and progesterone by the ovaries and involution of the ducts and alveoli of the breast. The surrounding fibrous connective tissue increases in density, and breast tissues are replaced by adipose tissues (Fig. 17-10D).

Gynecomastia

Gynecomastia refers to an enlarged breast in the male.¹⁹ Physiologic gynecomastia usually occurs during three phases of life: the neonatal period, adolescence, and senescence. Common to each of these phases is an excess of circulating estrogens in relation to circulating testosterone. Neonatal gynecomastia is caused by the action of placental estrogens on neonatal breast tissues, whereas in adolescence, there is an excess of estradiol relative to testosterone, and with senescence, the circulating testosterone level falls, which results in relative hyperestrinism. In gynecomastia, the ductal structures of the male breast enlarge, elongate, and branch with a concomitant increase in epithelium. During puberty, the condition often is unilateral and typically occurs between ages 12 and 15 years. In contrast, senescent gynecomastia is usually bilateral. In the nonobese male, breast tissue measuring at least 2 cm in diameter must be present before a diagnosis of gynecomastia may be made. Mammography and ultrasonography are used to differentiate breast tissues. Dominant masses or areas of firmness, irregularity, and asymmetry suggest the possibility of a breast cancer, particularly in the older male. Gynecomastia generally does not predispose the male breast to cancer. However, the hypoandrogenic state of Klinefelter's syndrome (XXY), in which gynecomastia is usually evident, is associated with an increased risk of breast cancer. Table 17-1 presents a clinical classification of gynecomastia.

Table 17-1 Clinical Classification of Gynecomastia	
Grade I	Mild breast enlargement without skin redundancy
Grade IIa	Moderate breast enlargement without skin redundancy
Grade IIb	Moderate breast enlargement with skin redundancy
Grade III	Marked breast enlargement with skin redundancy and ptosis, which simulates a female breast

Source: Modified with permission from Simon BE: Classification and surgical correction of gynecomastia. *Plas Reconstr Surg* 51:48, 1973, Wolters Kluwer Health.

Table 17-2 identifies the pathophysiologic mechanisms that may initiate gynecomastia. Estrogen excess results from an increase in the secretion of estradiol by the testicles or by nontesticular tumors, nutritional alterations such as protein and fat deprivation, endocrine disorders (hyperthyroidism, hypothyroidism), and hepatic disease (nonalcoholic and alcoholic cirrhosis). Refeeding gynecomastia is related to the resumption of pituitary gonadotropin secretion after pituitary shutdown. Androgen deficiency may initiate gynecomastia. Concurrently occurring with decreased circulating testosterone levels is an elevated level of circulating testosterone-binding globulin, which results in a reduction of free testosterone. This senescent gynecomastia usually occurs in men aged 50 to 70 years. Klinefelter's syndrome (XXY) is manifested by gynecomastia, hypergonadotropic hypogonadism, and

azoospermia. Primary testicular failure also may be caused by adrenocorticotrophic hormone deficiency, hereditary defects of androgen synthesis, and congenital anorchia (eunuchoidal males). Secondary testicular failure may result from trauma, orchitis, and cryptorchidism. Renal failure, regardless of cause, also may initiate gynecomastia. Drugs with estrogenic activity (digitalis, estrogens, anabolic steroids, marijuana) or drugs that enhance estrogen synthesis (human chorionic gonadotropin) may cause gynecomastia. Drugs that inhibit the action or synthesis of testosterone (cimetidine, ketoconazole, phenytoin, spironolactone, antineoplastic agents, diazepam) also have been implicated. Drugs such as reserpine, theophylline, verapamil, tricyclic antidepressants, and furosemide induce gynecomastia through idiopathic mechanisms. When gynecomastia is caused by androgen deficiency, then testosterone administration may cause regression. When it is caused by medications, then these are discontinued if possible. When endocrine defects are responsible, then these receive specific therapy. When gynecomastia is progressive and does not respond to other treatments, surgical therapy is considered. Attempts to reverse gynecomastia with danazol have been successful, but the androgenic side effects of the drug are considerable.

Table 17-2 Pathophysiologic Mechanisms of Gynecomastia	
I. Estrogen excess states

IV. Systemic diseases with idiopathic mechanisms

INFECTIOUS AND INFLAMMATORY DISORDERS OF THE BREAST

Except during the postpartum period, infections of the breast are rare and are classified as intrinsic (secondary to abnormalities in the breast) or extrinsic (secondary to an infection in an adjacent structure, e.g., skin, thoracic cavity).

Bacterial Infection

Staphylococcus aureus and *Streptococcus* species are the organisms most frequently recovered from nipple discharge from an infected breast.¹⁶ Breast abscesses are typically seen in staphylococcal infections and present with point tenderness, erythema, and hyperthermia. These abscesses are related to lactation and occur within the first few weeks of breastfeeding. Figure 17-11 depicts the progression of a staphylococcal infection, which may result in subcutaneous, subareolar, interlobular (periductal), and retromammary abscesses (unicentric or multicentric), necessitating operative drainage of fluctuant areas. Preoperative ultrasonography is effective in delineating the required extent of the drainage procedure, which is best accomplished via circumareolar incisions or incisions paralleling Langer's lines. Although staphylococcal infections tend to be more localized and may be situated deep in the breast tissues, streptococcal infections usually present with diffuse superficial involvement. They are treated with local wound care, including application of warm compresses, and the administration of IV antibiotics (penicillins or cephalosporins). Breast infections may be chronic, possibly with recurrent abscess formation. In this situation, cultures are performed to identify acid-fast bacilli, anaerobic and aerobic bacteria, and fungi. Uncommon organisms may be encountered, and long-term antibiotic therapy may be required.

Breast abscesses. Sagittal view of the breast with sites of potential abscess formation. Deep abscesses may be multilocular and may communicate with subcutaneous or subareolar sites. *Insert* depicts drainage of a multilocular breast abscess through circumareolar incisions and other incisions that parallel Langer's lines.

Biopsy of the abscess cavity wall is generally recommended at the time of incision and drainage to rule out underlying or coexisting breast cancer with necrotic tumor.

Hospital-acquired puerperal infections of the breast are much less common nowadays, but nursing women who present with milk stasis or noninfectious inflammation may still develop this problem. Epidemic puerperal mastitis is initiated by highly virulent strains of methicillin-resistant *S. aureus* that are transmitted via the suckling neonate and may result in substantial morbidity and occasional mortality. Purulent fluid may be expressed from the nipple. In this circumstance, breastfeeding is stopped, antibiotics are started, and surgical therapy is initiated. *Nonepidemic (sporadic) puerperal mastitis* refers to involvement of the interlobular connective tissue of the breast by an infectious process. The patient develops nipple fissuring and milk stasis, which initiate a retrograde bacterial infection. Emptying of the breast using breast suction pumps shortens the duration of symptoms and reduces the incidence of recurrences. The addition of antibiotic therapy results in a satisfactory outcome in >95% of cases.

Zuska's disease, also called *recurrent periductal mastitis*, is a condition of recurrent retroareolar infections and abscesses.^{21,22} This syndrome is managed symptomatically, by antibiotics coupled with incision and drainage as necessary. Attempts to obtain durable long-term control by wide débridement of chronically infected tissue and/or terminal duct resection are frequently frustrated by postoperative infections. Smoking has been implicated as a risk factor for this condition.

Mycotic Infections

Fungal infections of the breast are rare and usually involve blastomycosis or sporotrichosis.²⁰ Intraoral fungi that are inoculated into the breast tissue by the suckling infant initiate these infections, which present as mammary abscesses in close proximity to the nipple-areola complex. Pus mixed with blood may be expressed from sinus tracts. Antifungal agents can be administered for the treatment of systemic (noncutaneous) infections. This therapy generally eliminates the necessity of surgical intervention, but occasionally drainage of an abscess, or even partial mastectomy, may be necessary to eradicate a persistent fungal infection.

Candida albicans affecting the skin of the breast presents as erythematous, scaly lesions of the inframammary or axillary folds. Scrapings from the lesions demonstrate fungal elements (filaments and budding cells). Therapy involves the removal of predisposing factors such as maceration and the topical application of nystatin.

Hidradenitis Suppurativa

Hidradenitis suppurativa of the nipple-areola complex or axilla is a chronic inflammatory condition that originates within the accessory areolar glands of Montgomery or within the axillary sebaceous glands.²⁰ Women with chronic acne are predisposed to developing hidradenitis. When located in and about the nipple-areola complex, this disease may mimic other chronic inflammatory states, Paget's disease of the nipple, or invasive breast cancer. Involvement of the axillary skin is often multifocal and contiguous. Antibiotic therapy with incision and drainage of fluctuant areas is appropriate treatment. Excision of the involved areas may be required. Large areas of skin loss may necessitate coverage with advancement flaps or split-thickness skin grafts.

Mondor's Disease

Mondor's disease is a variant of thrombophlebitis that involves the superficial veins of the anterior chest wall and breast.²³ In 1939, Mondor described the condition as "string phlebitis," a thrombosed vein presenting as a tender, cord-like structure.²⁴ Frequently involved veins include the lateral thoracic vein, the thoracoepigastric vein, and, less commonly, the superficial epigastric vein. Typically, a woman presents with acute pain in the lateral aspect of the breast or the anterior chest wall. A tender, firm cord is found to follow the distribution of one of the major superficial veins. Rarely, the presentation is bilateral, and most women have no evidence of thrombophlebitis in other anatomic sites. This benign, self-limited disorder is not indicative of a cancer. When the diagnosis is uncertain, or when a mass is present near the tender cord, biopsy is indicated. Therapy for Mondor's disease includes the liberal use of anti-inflammatory medications and application of warm compresses along the symptomatic vein. Restriction of motion of the ipsilateral extremity and shoulder as well as brassiere support of the breast are important. The process usually resolves within 4 to 6 weeks. When symptoms persist or are refractory to therapy, excision of the involved vein segment is appropriate.

COMMON BENIGN DISORDERS AND DISEASES OF THE BREAST

Benign breast disorders and diseases encompass a wide range of clinical and pathologic entities. Surgeons require an in-depth understanding of benign breast disorders and diseases so that clear explanations may be given to affected women, appropriate treatment instituted, and unnecessary long-term follow up avoided.

Aberrations of Normal Development and Involution

The basic principles underlying the aberrations of normal development and involution (ANDI) classification of benign breast conditions are the following: (a) benign breast disorders and diseases are related to the normal processes of reproductive life and to involution; (b) there is a spectrum of breast conditions that ranges from normal to disorder to disease; and (c) the ANDI classification encompasses all aspects of the breast condition, including pathogenesis and the degree of abnormality.²⁵ The horizontal component of Table 17-3 defines ANDI along a spectrum from normal, to mild abnormality (disorder), to severe abnormality (disease). The vertical component indicates the period during which the condition develops.

Table 17-3 ANDI Classification of Benign Breast Disorders			
	Normal	Disorder	Disease
Early reproductive years (age 15–25 y)	Lobular development	Fibroadenoma	Giant fibroadenoma

	Stromal development	Adolescent hypertrophy	Gigantomastia
	Nipple eversion	Nipple inversion	Subareolar abscess
			Mammary duct fistula
Later reproductive years (age 25–40 y)	Cyclical changes of menstruation	Cyclical mastalgia	Incapacitating mastalgia
		Nodularity	
	Epithelial hyperplasia of pregnancy	Bloody nipple discharge	
Involution (age 35–55 y)	Lobular involution	Macrocysts	—
		Sclerosing lesions	
	Duct involution		
	Dilatation	Duct ectasia	Periductal mastitis
	Sclerosis	Nipple retraction	—
	Epithelial turnover	Epithelial hyperplasia	Epithelial hyperplasia with atypia

ANDI = aberrations of normal development and involution.

EARLY REPRODUCTIVE YEARS

Fibroadenomas are seen predominantly in younger women aged 15 to 25 years (Fig. 17-12).²⁶ Fibroadenomas usually grow to 1 or 2 cm in diameter and then are stable but may grow to a larger size. Small fibroadenomas (\leq 1 cm in size) are considered normal, whereas larger fibroadenomas (\leq 3 cm) are disorders and giant fibroadenomas (>3 cm) are disease. Similarly, multiple fibroadenomas (more than five lesions in one breast) are very uncommon and are considered disease. The precise etiology of adolescent breast hypertrophy is unknown. A spectrum of changes from limited to massive stromal hyperplasia (gigantomastia) is seen. Nipple inversion is a disorder of development of the major ducts, which prevents normal protrusion of the nipple. Mammary duct fistulas arise when nipple inversion predisposes to major duct obstruction, leading to recurrent subareolar abscess and mammary duct fistula.

LATER REPRODUCTIVE YEARS

Cyclical mastalgia and nodularity usually are associated with premenstrual enlargement of the breast and are regarded as normal. Cyclical pronounced mastalgia and severe painful nodularity are viewed differently than are physiologic discomfort and lumpiness. Painful nodularity that persists for >1 week of the menstrual cycle is considered a disorder. In epithelial hyperplasia of pregnancy, papillary projections sometimes give rise to bilateral bloody nipple discharge.

INVOLUTION

Involution of lobular epithelium is dependent on the specialized stroma around it. However, an integrated involution of breast stroma and epithelium is not always seen, and disorders of the process are common. When the stroma involutes too quickly, alveoli remain and form microcysts, which are precursors of macrocysts. Macrocysts are common, are often subclinical, and do not require specific treatment. Sclerosing adenosis is considered a disorder of both the proliferative and the involutional phases of the breast cycle. Duct ectasia (dilated ducts) and periductal mastitis are other important components of the ANDI classification. Periductal fibrosis is a sequela of periductal mastitis and may result in nipple retraction. Sixty percent of women ≥ 70 years of age exhibit some degree of epithelial hyperplasia (Fig. 17-13). Atypical proliferative diseases include ductal and lobular hyperplasia, both of which display some features of carcinoma in situ. Women with atypical ductal or lobular hyperplasia have a fourfold increase in breast cancer risk (Table 17-4).

Table 17-4 Cancer Risk Associated with Benign Breast Disorders and In Situ Carcinoma of the Breast

Abnormality	Relative Risk
Nonproliferative lesions of the breast	No increased risk
Sclerosing adenosis	No increased risk

Intraductal papilloma	No increased risk
Florid hyperplasia	1.5 to 2-fold
Atypical lobular hyperplasia	4-fold
Atypical ductal hyperplasia	4-fold
Ductal involvement by cells of atypical ductal hyperplasia	7-fold
Lobular carcinoma in situ	10-fold
Ductal carcinoma in situ	10-fold

Pathology of Nonproliferative Disorders

Of paramount importance for the optimal management of benign breast disorders and diseases is the histologic differentiation of benign, atypical, and malignant changes.^{27,28} Determining the clinical significance of these changes is a problem that is compounded by inconsistent nomenclature. The classification system originally developed by Page separates the various types of benign breast disorders and diseases into three clinically relevant groups: nonproliferative disorders, proliferative disorders without atypia, and proliferative disorders with atypia (Table 17-5). Nonproliferative disorders of the breast account for 70% of benign breast conditions and carry no increased risk for the development of breast cancer. This category includes cysts, duct ectasia, periductal mastitis, calcifications, fibroadenomas, and related disorders.

Table 17-5 Classification of Benign Breast Disorders
Nonproliferative disorders of the breast
Cysts and apocrine metaplasia
Duct ectasia
Mild ductal epithelial hyperplasia
Calcifications
Fibroadenoma and related lesions
Proliferative breast disorders without atypia
Sclerosing adenosis
Radial and complex sclerosing lesions
Ductal epithelial hyperplasia
Intraductal papillomas
Atypical proliferative lesions
Atypical lobular hyperplasia
Atypical ductal hyperplasia

Breast macrocysts are an involutional disorder, have a high frequency of occurrence, and are often multiple. Duct ectasia is a clinical syndrome characterized by dilated subareolar ducts that are palpable and often associated with thick nipple discharge. Haagensen regarded duct ectasia as a primary event that led to stagnation of secretions, epithelial ulceration, and leakage of duct secretions (containing chemically irritating fatty acids) into periductal tissue.³⁰ This sequence was thought to produce a local inflammatory process with periductal fibrosis and subsequent nipple retraction. An alternative theory considers periductal mastitis

to be the primary process, which leads to weakening of the ducts and secondary dilatation. It is possible that both processes occur and together explain the wide spectrum of problems seen, which include nipple discharge, nipple retraction, inflammatory masses, and abscesses.

Calcium deposits are frequently encountered in the breast. Most are benign and are caused by cellular secretions and debris or by trauma and inflammation. Calcifications that are associated with cancer include microcalcifications, which vary in shape and density and are <0.5 mm in size, and fine, linear calcifications, which may show branching. Fibroadenomas have abundant stroma with histologically normal cellular elements. They show hormonal dependence similar to that of normal breast lobules in that they lactate during pregnancy and involute in the postmenopausal period. Adenomas of the breast are well circumscribed and are composed of benign epithelium with sparse stroma, which is the histologic feature that differentiates them from fibroadenomas. They may be divided into tubular adenomas and lactating adenomas. Tubular adenomas are seen in young nonpregnant women, whereas lactating adenomas are seen during pregnancy or during the postpartum period. Hamartomas are discrete breast tumors that are usually 2 to 4 cm in diameter, firm, and sharply circumscribed. Adenolipomas consist of sharply circumscribed nodules of fatty tissue that contain normal breast lobules and ducts.

FIBROCYSTIC DISEASE

The term *fibrocystic disease* is nonspecific. Too frequently, it is used as a diagnostic term to describe symptoms, to rationalize the need for breast biopsy, and to explain biopsy results. Synonyms include fibrocystic changes, cystic mastopathy, chronic cystic disease, chronic cystic mastitis, Schimmelbusch's disease, mazoplasia, Cooper's disease, Reclus' disease, and fibroadenomatosis. *Fibrocystic disease* refers to a spectrum of histopathologic changes that are best diagnosed and treated specifically.

Pathology of Proliferative Disorders Without Atypia

Proliferative breast disorders without atypia include sclerosing adenosis, radial scars, complex sclerosing lesions, ductal epithelial hyperplasia, and intraductal papillomas.^{27,28} Sclerosing adenosis is prevalent during the childbearing and perimenopausal years and has no malignant potential. Histologic changes are both proliferative (ductal proliferation) and involutional (stromal fibrosis, epithelial regression). Sclerosing adenosis is characterized by distorted breast lobules and usually occurs in the context of multiple microcysts, but occasionally presents as a palpable mass. Benign calcifications are often associated with this disorder. Central sclerosis and varying degrees of epithelial proliferation, apocrine metaplasia, and papilloma formation characterize radial scars and complex sclerosing lesions of the breast. Lesions up to 1 cm in diameter are called *radial scars*, whereas larger lesions are called *complex sclerosing lesions*. Radial scars originate at sites of terminal duct branching where the characteristic histologic changes radiate from a central area of fibrosis. All of the histologic features of a radial scar are seen in the larger complex sclerosing lesions, but there is a greater disturbance of structure with papilloma formation, apocrine metaplasia, and occasionally sclerosing adenosis.

Mild ductal hyperplasia is characterized by the presence of three or four cell layers above the basement membrane. Moderate ductal hyperplasia is characterized by the presence of five or more cell layers above the basement membrane. Florid ductal epithelial hyperplasia occupies at least 70% of a minor duct lumen. It is found in >20% of breast tissue specimens, is either solid or papillary, and is associated with an increased cancer risk (see Table 17-4). Intraductal papillomas arise in the major ducts, usually in premenopausal women. They generally are <0.5 cm in diameter but may be as large as 5 cm. A common presenting symptom is nipple discharge, which may be serous or bloody. Grossly, intraductal papillomas are pinkish tan, friable, and usually attached to the wall of the involved duct by a stalk. They rarely undergo malignant transformation, and their presence does not increase a woman's risk of developing breast cancer (unless accompanied by atypia). However, multiple intraductal papillomas, which occur in younger women and are less frequently associated with nipple discharge, are susceptible to malignant

transformation.

Pathology of Atypical Proliferative Diseases

The atypical proliferative diseases have some of the features of carcinoma in situ but either lack a major defining feature of carcinoma in situ or have the features in less than fully developed form.³⁰ In 1978, Haagensen and colleagues described lobular neoplasia, a spectrum of disorders ranging from atypical lobular hyperplasia to lobular carcinoma in situ (LCIS).³¹

Treatment of Selected Benign Breast Disorders and Diseases

CYSTS

Because needle biopsy of breast masses may produce artifacts that make mammography assessment more difficult, many radiologists prefer to image breast masses before performing needle biopsy.^{32,33} In practice, however, the first investigation of palpable breast masses is frequently needle biopsy, which allows for the early diagnosis of cysts. A 21-gauge needle attached to a 10-mL syringe is placed directly into the mass, which is fixed by fingers of the nondominant hand. The volume of a typical cyst is 5 to 10 mL but it may be 75 mL or more. If the fluid that is aspirated is not bloodstained, then the cyst is aspirated to dryness, the needle is removed, and the fluid is discarded, because cytologic examination of such fluid is not cost effective. After aspiration, the breast is carefully palpated to exclude a residual mass. If one exists, ultrasound examination is performed to exclude a persistent cyst, which is reaspirated if present. If the mass is solid, a tissue specimen is obtained. When cystic fluid is bloodstained, 2 mL of fluid is taken for cytologic examination. The mass is then imaged with ultrasound and any solid area on the cyst wall is sampled by needle biopsy. The presence of blood is usually obvious, but in cysts with dark fluid, an occult blood test or microscopic examination will eliminate any doubt. The two cardinal rules of safe cyst aspiration are that (a) the mass must disappear completely after aspiration, and (b) the fluid must not be bloodstained. If either of these conditions is not met, then ultrasound with needle biopsy or pneumocystography can be performed. A simple cyst is rarely of concern, but a complex cyst may be the result of an underlying malignancy. A pneumocystogram is obtained by injecting air into the cyst and then obtaining a repeat mammogram. When this technique is used, the wall of the cyst cavity can be more carefully assessed for any irregularities.

FIBROADENOMAS

Removal of all fibroadenomas has been advocated irrespective of patient age or other considerations, and solitary fibroadenomas in young women are frequently removed to alleviate patient concern. Yet most fibroadenomas are self-limiting and many go undiagnosed, so a more conservative approach is reasonable. Careful ultrasound examination with core-needle biopsy will provide for an accurate diagnosis. Ultrasonography may reveal specific features that are pathognomonic for fibroadenoma. In this situation a core-needle biopsy may not be necessary. Subsequently, the patient is counseled concerning the ultrasound and biopsy results, and excision of the fibroadenoma may be avoided. Cryoablation is an approved treatment for fibroadenomas of the breast. With short-term follow-up a significant percentage of fibroadenomas will decrease in size and will no longer be palpable.³⁴ However, many will remain palpable, especially those larger than 2 cm. Therefore, women should be counseled that the options for treatment include surgical removal, cryoablation, or observation.

SCLEROSING DISORDERS

The clinical significance of sclerosing adenosis lies in its mimicry of cancer. It may be confused with cancer on physical examination, by mammography, and at gross pathologic examination. Excisional biopsy and histologic examination are frequently necessary to exclude the diagnosis of cancer. The diagnostic work-up for radial scars and complex sclerosing lesions frequently involves stereoscopic biopsy. It usually is not possible to differentiate these lesions with certainty from cancer by mammographic

features, so biopsy is recommended. The mammographic appearance of a radial scar or sclerosing adenosis (mass density with spiculated margins) will usually lead to an assessment that the results of a core-needle biopsy showing benign disease are discordant with the radiographic findings. Breast radiologists will therefore often forego image-guided needle biopsy of a lesion suspicious for radial scar and refer the case directly to a surgeon for wire localized excisional biopsy.

PERIDUCTAL MASTITIS

Painful and tender masses behind the nipple-areola complex are aspirated with a 21-gauge needle attached to a 10-mL syringe. Any fluid obtained is submitted for cytologic examination and for culture using a transport medium appropriate for the detection of anaerobic organisms. In the absence of pus, women are started on a combination of metronidazole and dicloxacillin while awaiting the results of culture. Antibiotics are then continued based on sensitivity tests. Many cases respond satisfactorily, but when considerable purulent material is present, surgical treatment is recommended. Unlike puerperal abscesses, a subareolar abscess is usually unilocular and often is associated with a single duct system. Preoperative ultrasound will accurately delineate its extent. The surgeon may either undertake simple drainage with a view toward formal surgery, should the problem recur, or proceed with definitive surgery. In a woman of childbearing age, simple drainage is preferred, but if there is an anaerobic infection, recurrent infection frequently develops. Recurrent abscess with fistula is a difficult problem and may be treated by fistulectomy or by major duct excision, depending on the circumstances (Table 17-6). When a localized periareolar abscess recurs at the previous site and a fistula is present, the preferred operation is fistulectomy, which has minimal complications and a high degree of success. However, when subareolar sepsis is diffuse rather than localized to one segment or when more than one fistula is present, total duct excision is the most expeditious approach. The first circumstance is seen in young women with squamous metaplasia of a single duct, whereas the latter circumstance is seen in older women with multiple ectatic ducts. Age is not always a reliable guide, however, and fistula excision is the preferred initial procedure for localized sepsis irrespective of age. Antibiotic therapy is useful for recurrent infection after fistula excision, and a 2- to 4-week course is recommended before total duct excision.

Table 17-6 Treatment of Recurrent Subareolar Sepsis	
Suitable for Fistulectomy	Suitable for Total Duct Excision
Small abscess localized to one segment	Large abscess affecting >50% of the areolar circumference
Recurrence involving the same segment	Recurrence involving a different segment
Mild or no nipple inversion	Marked nipple inversion
Patient unconcerned about nipple inversion	Patient requests correction of nipple inversion
Younger patient	Older patient
No discharge from other ducts	Purulent discharge from other ducts
No prior fistulectomy	Recurrence after fistulectomy

NIPPLE INVERSION

More women request correction of congenital nipple inversion than request correction for the nipple inversion that occurs secondary to duct ectasia. Although the results are usually satisfactory, women seeking correction for cosmetic reasons should always be made aware of the surgical complications of altered nipple sensation, nipple necrosis, and postoperative fibrosis with nipple retraction. Because nipple inversion is a result of shortening of the subareolar ducts, a complete division of these ducts is

necessary for permanent correction of the disorder.

RISK FACTORS FOR BREAST CANCER

Hormonal and Nonhormonal Risk Factors

Increased exposure to estrogen is associated with an increased risk for developing breast cancer, whereas reducing exposure is thought to be protective.^{35–41} Correspondingly, factors that increase the number of menstrual cycles, such as early menarche, nulliparity, and late menopause, are associated with increased risk. Moderate levels of exercise and a longer lactation period, factors that decrease the total number of menstrual cycles, are protective. The terminal differentiation of breast epithelium associated with a full-term pregnancy is also protective, so older age at first live birth is associated with an increased risk of breast cancer. Finally, there is an association between obesity and increased breast cancer risk. Because the major source of estrogen in postmenopausal women is the conversion of androstenedione to estrone by adipose tissue, obesity is associated with a long-term increase in estrogen exposure.

Nonhormonal risk factors include radiation exposure. Young women who receive mantle radiation therapy for Hodgkin's lymphoma have a breast cancer risk that is 75 times greater than that of age-matched control subjects. Survivors of the atomic bomb blasts in Japan during World War II have a very high incidence of breast cancer, likely because of somatic mutations induced by the radiation exposure. In both circumstances, radiation exposure during adolescence, a period of active breast development, magnifies the deleterious effect. Studies also suggest that the risk of breast cancer increases as the amount of alcohol a woman consumes increases. Alcohol consumption is known to increase serum levels of estradiol. Finally, evidence suggests that long-term consumption of foods with a high fat content contributes to an increased risk of breast cancer by increasing serum estrogen levels.

Risk Assessment Models

The average lifetime risk of breast cancer for newborn U.S. females is 12%.^{42,43} The longer a woman lives without cancer, the lower her risk of developing breast cancer. Thus, a woman aged 50 years has an 11% lifetime risk of developing breast cancer, and a woman aged 70 years has a 7% lifetime risk of developing breast cancer. Because risk factors for breast cancer interact, evaluating the risk conferred by combinations of risk factors is difficult. Two risk assessment models are currently used to predict the risk of breast cancer. From the Breast Cancer Detection Demonstration Project, a mammography screening program conducted in the 1970s, Gail and colleagues developed the most frequently used model, which incorporates age at menarche, the number of breast biopsies, age at first live birth, and the number of first-degree relatives with breast cancer. It predicts the cumulative risk of breast cancer according to decade of life. To calculate breast cancer risk using the Gail model, a woman's risk factors are translated into an overall risk score by multiplying her relative risks from several categories (Table 17-7). This risk score is then compared to an adjusted population risk of breast cancer to determine a woman's individual risk. A software program incorporating the Gail model is available from the National Cancer Institute at <http://bcra.nci.nih.gov/brc>. This model was recently modified to more accurately assess risk in African American women.^{45,46}

Table 17-7 Relative Risk Estimates for the Gail Model	
Variable	Relative Risk
Age at menarche (years)	
≥14	1.00
12–13	1.10
<12	1.21

Number of biopsies/history of benign breast disease, age <50 y	
0	1.00
1	1.70
≥2	2.88
Number of biopsies/history of benign breast disease, age ≥50 y	
0	1.02
1	1.27
≥2	1.62
Age at first live birth (years)	
<20 y	
Number of first-degree relatives with history of breast cancer	
0	1.00
1	2.61
≥2	6.80
20–24 y	
Number of first-degree relatives with history of breast cancer	
0	1.24
1	2.68
≥2	5.78
25–29 y

Claus and colleagues, using data from the Cancer and Steroid Hormone Study, a case-control study of breast cancer, developed the other frequently used risk assessment model, which is based on assumptions about the prevalence of high-penetrance breast cancer susceptibility genes.⁴⁷ Compared with the Gail model, the Claus model incorporates more information about family history but excludes other risk factors. The Claus model provides individual estimates of breast cancer risk according to decade of life based on presence of first- and second-degree relatives with breast cancer and their age at diagnosis. Risk factors that are less consistently associated with breast cancer (diet, use of oral contraceptives, lactation) or are rare in the general population (radiation exposure) are not included in either the Gail or Claus risk assessment model. Other models have been proposed that account for mammographic breast density in assessing breast cancer risk.^{48,49} None of these models accounts for the risk associated with mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2*.

Risk Management

Several important medical decisions may be affected by a woman's underlying risk of developing breast cancer.^{50–58} These decisions include when to use postmenopausal hormone replacement therapy, at what age to begin mammography screening, when to use tamoxifen to prevent breast cancer, and when to perform prophylactic mastectomy to prevent breast cancer. Postmenopausal hormone replacement therapy was widely prescribed in the 1980s and 1990s because of its effectiveness in controlling the symptoms of estrogen deficiency; namely, vasomotor symptoms such as hot flashes, night sweats and their associated sleep deprivation, osteoporosis, and cognitive changes. Furthermore, these hormone supplements were thought to reduce coronary artery disease as well. Use of combined estrogen and progesterone became standard for women who had not undergone hysterectomy, because unopposed estrogen increases the risk of uterine cancer. Concerns of prolonging a woman's lifetime exposure to estrogen, coupled with conflicting data regarding the impact of these hormones on cardiovascular health, motivated the implementation of large-scale phase III clinical trials to definitively evaluate the risks vs. benefits of postmenopausal hormone replacement therapy. The Women's Health Initiative was therefore designed by the National Institutes of Health as a series of clinical trials to study the effects of diet, nutritional supplements, and hormones on the risk of cancer, cardiovascular disease, and bone health in postmenopausal women. Findings from primary studies of postmenopausal hormone replacement therapy were released in 2002, demonstrating conclusively that breast cancer risk is threefold to fourfold higher after >4 years of use and there is no significant reduction in coronary artery or cerebrovascular risks.

Routine use of screening mammography in women ≥ 50 years of age reduces mortality from breast cancer by 33%. This reduction comes without substantial risks and at an acceptable economic cost. However, the use of screening mammography in women <50 years of age is more controversial for several reasons: (a) breast density is greater and screening mammography is less likely to detect early breast cancer; (b) screening mammography results in more false-positive test findings, which results in unnecessary biopsies; and (c) younger women are less likely to have breast cancer, so fewer young women will benefit from screening. On a population basis, however, the benefits of screening mammography in women between the ages of 40 and 49 years still appear to outweigh the risks. Targeting mammography to women at higher risk of breast cancer may also improve the balance of risks and benefits. In one study of women aged 40 to 49 years, an abnormal mammography finding was three times more likely to be cancer in a woman with a family history of breast cancer than in a woman without such a history. Furthermore, as noted previously in the section Risk Assessment Models, mounting data regarding mammographic breast density demonstrate an independent correlation with breast cancer risk. Incorporation of breast density measurements into breast cancer risk assessment models appears to be a promising strategy for increasing the accuracy of these tools. Unfortunately, widespread application of these modified models is hampered by inconsistencies in the reporting of mammographic density. Current recommendations are that women undergo baseline mammography at age 35 and then have annual mammographic screening beginning at age 40.

Tamoxifen, a selective estrogen receptor modulator, was the first drug shown to reduce the incidence of breast cancer in healthy women. The Breast Cancer Prevention Trial (NSABP P-01) randomly assigned >13,000 women with a 5-year Gail relative risk of breast cancer of 1.70 or higher to receive tamoxifen or placebo. After a mean follow-up period of 4 years, the incidence of breast cancer was reduced by 49% in the group receiving tamoxifen.⁵⁰ Tamoxifen therapy currently is recommended only for women who have a Gail relative risk of 1.70 or higher. In addition, deep vein thrombosis occurs 1.6 times as often, pulmonary emboli 3.0 times as often, and endometrial cancer 2.5 times as often in women taking tamoxifen. The increased risk for endometrial cancer is restricted to early-stage cancers in postmenopausal women. Cataract surgery is required almost twice as often among women taking tamoxifen. Gail and colleagues subsequently developed a model that accounts for underlying risk of breast cancer as well as comorbidities to determine the net risk-benefit ratio of tamoxifen use for chemoprevention.⁵⁹ Most recently, the NSABP completed its second chemoprevention trial, designed to compare tamoxifen and raloxifene for breast cancer

risk reduction in high-risk postmenopausal women. Raloxifene, another selective estrogen receptor modulator, was selected for the experimental arm in this follow-up prevention trial because its use in managing postmenopausal osteoporosis suggested that it might be even more effective at breast cancer risk reduction, but without the adverse effects of tamoxifen on the uterus. The P-2 trial, the Study of Tamoxifen and Raloxifene (known as the *STAR trial*), randomly assigned 19,000 postmenopausal women at high-risk for breast cancer to receive either tamoxifen or raloxifene. At a median follow-up of 5 years, the two agents were found to be nearly identical in their ability to reduce breast cancer risk, but raloxifene was associated with a more favorable adverse event profile.⁶⁰ Of note, both drugs reduce the risk of developing breast cancer by approximately 50%. Although tamoxifen has been shown to reduce the incidence of LCIS and ductal carcinoma in situ (DCIS), raloxifene did not have an effect on the frequency of these diagnoses.

A retrospective study of women at high risk for breast cancer found that prophylactic mastectomy reduced their risk by >90%.⁵² However, the effects of prophylactic mastectomy on the long-term quality of life are poorly quantified. A study involving women who were carriers of a breast cancer susceptibility gene (BRCA) mutation found that the benefit of prophylactic mastectomy differed substantially according to the breast cancer risk conferred by the mutations. For women with an estimated lifetime risk of 40%, prophylactic mastectomy added almost 3 years of life, whereas for women with an estimated lifetime risk of 85%, prophylactic mastectomy added >5 years of life.⁵⁶

BRCA Mutations

BRCA1

Five to 10% of breast cancers are caused by inheritance of germline mutations such as *BRCA1* and *BRCA2*, which are inherited in an autosomal dominant fashion with varying penetrance (Table 17-8).^{61–67} *BRCA1* is located on chromosome arm 17q, spans a genomic region of approximately 100 kilobases (kb) of DNA, and contains 22 coding exons. The full-length messenger RNA is 7.8 kb and encodes a protein of 1863 amino acids. Both *BRCA1* and *BRCA2* function as tumor-suppressor genes, and for each gene, loss of both alleles is required for the initiation of cancer. Data accumulated since the isolation of the *BRCA1* gene suggest a role in transcription, cell-cycle control, and DNA damage repair pathways. More than 500 sequence variations in *BRCA1* have been identified. It now is known that germline mutations in *BRCA1* represent a predisposing genetic factor in as many as 45% of hereditary breast cancers and in at least 80% of hereditary ovarian cancers. Female mutation carriers have up to a 90% lifetime risk for developing breast cancer and up to a 40% lifetime risk for developing ovarian cancer. Breast cancer susceptibility in these families appears as an autosomal dominant trait with high penetrance. Approximately 50% of children of carriers inherit the trait. In general, *BRCA1*-associated breast cancers are invasive ductal carcinomas, are poorly differentiated, and are hormone receptor negative. *BRCA1*-associated breast cancers have a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases; a higher prevalence of bilateral breast cancer; and the presence of associated cancers in some affected individuals, specifically ovarian cancer and possibly colon and prostate cancers.

Table 17-8 Incidence of Sporadic, Familial, and Hereditary Breast Cancer	
Sporadic breast cancer	65–75%
Familial breast cancer	20–30%
Hereditary breast cancer	5–10%
<i>BRCA1</i> ^a	45%
<i>BRCA2</i>	35%
p53 ^a (Li-Fraumeni syndrome)	1%
STK11/LKB1a (Peutz-Jeghers syndrome)	<1%

PTENa (Cowden disease)	<1%
MSH2/MLH1a (Muir-Torre syndrome)	<1%
ATMa (Ataxia-telangiectasia)	<1%
Unknown	20%

^a Affected gene.

Source: Adapted from Martin.⁵⁴

Several founder mutations have been identified in *BRCA1*. The two most common mutations are 185delAG and 5382insC, which account for 10% of all the mutations seen in *BRCA1*. These two mutations occur at a 10-fold higher frequency in the Ashkenazi Jewish population than in non-Jewish whites. The carrier frequency of the 185delAG mutation in the Ashkenazi Jewish population is 1% and, along with the 5382insC mutation, accounts for almost all *BRCA1* mutations in this population. Analysis of germline mutations in Jewish and non-Jewish women with early-onset breast cancer indicates that 20% of Jewish women who develop breast cancer before age 40 years carry the 185delAG mutation.

BRCA2

BRCA2 is located on chromosome arm 13q and spans a genomic region of approximately 70 kb of DNA. The 11.2-kb coding region contains 26 coding exons.^{61–67} It encodes a protein of 3418 amino acids. The *BRCA2* gene bears no homology to any previously described gene, and the protein contains no previously defined functional domains. The biologic function of *BRCA2* is not well defined, but like *BRCA1*, it is postulated to play a role in DNA damage response pathways. *BRCA2* messenger RNA also is expressed at high levels in the late G₁ and S phases of the cell cycle. The kinetics of *BRCA2* protein regulation in the cell cycle is similar to that of *BRCA1* protein, which suggests that these genes are coregulated. The mutational spectrum of *BRCA2* is not as well established as that of *BRCA1*. To date, >250 mutations have been found. The breast cancer risk for *BRCA2* mutation carriers is close to 85%, and the lifetime ovarian cancer risk, while lower than for *BRCA1*, is still estimated to be close to 20%. Breast cancer susceptibility in *BRCA2* families is an autosomal dominant trait and has a high penetrance. Approximately 50% of children of carriers inherit the trait. Unlike male carriers of *BRCA1* mutations, men with germline mutations in *BRCA2* have an estimated breast cancer risk of 6%, which represents a 100-fold increase over the risk in the general male population. *BRCA2*-associated breast cancers are invasive ductal carcinomas, which are more likely to be well differentiated and to express hormone receptors than are *BRCA1*-associated breast cancers. *BRCA2*-associated breast cancer has a number of distinguishing clinical features, such as an early age of onset compared with sporadic cases, a higher prevalence of bilateral breast cancer, and the presence of associated cancers in some affected individuals, specifically ovarian, colon, prostate, pancreatic, gallbladder, bile duct, and stomach cancers, as well as melanoma. A number of founder mutations have been identified in *BRCA2*. The 6174delT mutation is found in Ashkenazi Jews with a prevalence of 1.2%. Another *BRCA2* founder mutation, 999del5, is observed in Icelandic and Finnish populations.

IDENTIFICATION OF BRCA MUTATION CARRIERS

Identifying hereditary risk for breast cancer is a four-step process that includes (a) obtaining a complete, multigenerational family history, (b) assessing the appropriateness of genetic testing for a particular patient, (c) counseling the patient, and (d) interpreting the results of testing.⁶⁸ Genetic testing should not be offered in isolation, but only in conjunction with patient education and counseling, including referral to a genetic counselor. Initial determinations include whether the individual is an appropriate candidate for genetic testing and whether genetic testing will be informative for personal and clinical decision making. A thorough and accurate family history is essential to this process, and the maternal and paternal sides of the family are both assessed, because 50% of the women with a *BRCA* mutation have inherited the mutation from their fathers. To help

surgeons advise women about testing, statistically based models that determine the probability that an individual carries a *BRCA* mutation have been developed. A hereditary risk of breast cancer is considered if a family includes two or more women who developed ovarian cancer or breast cancer before age 50 years. Any woman diagnosed with breast cancer before age 50 years or with ovarian cancer at any age is asked about first-, second-, and third-degree relatives on either side of the family with either of these diagnoses. Breast and ovarian cancer in the same individual, and male breast cancer at any age, also suggest the possibility of hereditary breast and ovarian cancer. The threshold for genetic testing is lower in individuals who are members of ethnic groups in whom the mutation prevalence is increased. For instance, the possibility of hereditary cancer is considered for any Ashkenazi Jewish woman with early-onset breast cancer.

BRCA MUTATION TESTING

Appropriate counseling for the individual being tested for *BRCA* mutation is strongly recommended, and documentation of informed consent is required.^{68–69} The test that is clinically available for analyzing *BRCA* mutation is gene sequence analysis. In a family with a history suggestive of hereditary breast cancer and no previously tested member, the most informative strategy is first to test an affected family member. This person undergoes complete sequence analysis of both the *BRCA1* and *BRCA2* genes. If a mutation is identified, relatives are usually tested only for that specific mutation. An individual of Ashkenazi Jewish ancestry is tested initially for the three specific mutations that account for hereditary breast and ovarian cancer in that population. If results of that test are negative, it may then be appropriate to fully analyze the *BRCA1* and *BRCA2* genes.

A positive test result is one that discloses the presence of a *BRCA* mutation that interferes with translation or function of the *BRCA* protein. A woman who carries a deleterious mutation has a breast cancer risk of up to 85% as well as a greatly increased risk of ovarian cancer. A negative test result is interpreted according to the individual's personal and family history, especially whether a mutation has been previously identified in the family, in which case the woman is generally tested only for that specific mutation. If the mutation is not present, the woman's risk of breast or ovarian cancer may be no greater than that of the general population. In addition, no *BRCA* mutation can be passed on to the woman's children. In the absence of a previously identified mutation, a negative test result in an affected individual generally indicates that a *BRCA* mutation is not responsible for the familial cancer. However, the possibility remains of an unusual abnormality in one of these genes that cannot yet be identified through clinical testing. It also is possible that the familial cancer is indeed caused by an identifiable *BRCA* mutation but that the individual tested had sporadic cancer, a situation known as *phenocopy*. This is especially possible if the individual tested developed breast cancer close to the age of onset of the general population (age 60 years or older) rather than before age 50 years, as is characteristic of *BRCA* mutation carriers. Overall, the false-negative rate for *BRCA* mutation testing is <5%. Some test results, especially when a single base-pair change (missense mutation) is identified, may be difficult to interpret. This is because single base-pair changes do not always result in a nonfunctional protein. Thus, missense mutations not located within critical functional domains, or those that cause only minimal changes in protein structure, may not be disease associated and are usually reported as indeterminate results. In communicating indeterminate results to women, care must be taken to relay the uncertain cancer risk associated with this type of mutation and to emphasize that ongoing research might clarify its meaning. In addition, testing other family members with breast cancer to determine if a genetic variant tracks with their breast cancer may provide clarification as to its significance. Indeterminate genetic variance currently accounts for 12% of the test results.

Concern has been expressed that the identification of hereditary risk for breast cancer may interfere with access to affordable health insurance. This concern refers to discrimination directed against an individual or family based solely on an apparent or perceived genetic variation from the normal human genotype. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) made it illegal in the United States for group health plans to consider genetic information as a pre-existing condition or to use it to deny or limit coverage. Most states also have passed laws that prevent genetic discrimination in the provision of

health insurance. In addition, individuals applying for health insurance are not required to report whether relatives have undergone genetic testing for cancer risk, only whether those relatives have actually been diagnosed with cancer. Currently there is little documented evidence of genetic discrimination resulting from findings of available genetic tests.

CANCER PREVENTION FOR BRCA MUTATION CARRIERS

Risk management strategies for *BRCA1* and *BRCA2* mutation carriers include the following:

1. Prophylactic mastectomy and reconstruction
2. Prophylactic oophorectomy and hormone replacement therapy
3. Intensive surveillance for breast and ovarian cancer
4. Chemoprevention

Although removal of breast tissue reduces the likelihood that *BRCA1* and *BRCA2* mutation carriers will develop breast cancer, mastectomy does not remove all breast tissue and women continue to be at risk because a germline mutation is present in any remaining breast tissue. For postmenopausal *BRCA1* and *BRCA2* mutation carriers who have not had a mastectomy, it may be advisable to avoid hormone replacement therapy, because no data exist regarding the effect of the therapy on the penetrance of breast cancer susceptibility genes. Because breast cancers in *BRCA* mutation carriers have the same mammographic appearance as breast cancers in noncarriers, a screening mammogram is likely to be effective in *BRCA* mutation carriers, provided it is performed and interpreted by an experienced radiologist with a high level of suspicion. Present screening recommendations for *BRCA* mutation carriers who do not undergo prophylactic mastectomy include clinical breast examination every 6 months and mammography every 12 months beginning at age 25 years, because the risk of breast cancer in *BRCA* mutation carriers increases after age 30 years. Recent attention has been focused on the use of magnetic resonance imaging (MRI) for breast cancer screening in high-risk individuals and known *BRCA* mutation carriers. MRI appears to be more sensitive at detecting breast cancer in younger women with dense breasts.⁷⁰ However, MRI does lead to the detection of benign breast lesions that cannot easily be distinguished from malignancy, and these false-positive events can result in more interventions, including biopsies. The current recommendations from the American Cancer Society are for annual MRI in women with a 20 to 25% or greater lifetime risk of developing breast cancer, including women with a strong family history of breast or ovarian cancer and women who were treated for Hodgkin's disease in their teens or early twenties.⁷¹ Despite a 49% reduction in the incidence of breast cancer in high-risk women taking tamoxifen, it is too early to recommend the use of tamoxifen uniformly for *BRCA* mutation carriers. Cancers arising in *BRCA1* mutation carriers are usually high grade and are most often hormone receptor negative. Approximately 66% of *BRCA1*-associated DCIS lesions are estrogen receptor negative, which suggests early acquisition of the hormone-independent phenotype. Tamoxifen appears to be more effective at preventing estrogen receptor-positive breast cancers.

The risk of ovarian cancer in *BRCA1* and *BRCA2* mutation carriers ranges from 20 to 40%, which is 10 times higher than that in the general population. Prophylactic oophorectomy is a reasonable prevention option in mutation carriers. The American College of Obstetrics and Gynecology recommends that women with a documented *BRCA1* or *BRCA2* mutation consider prophylactic oophorectomy at the completion of childbearing or at the time of menopause. Hormone replacement therapy is discussed with the patient at the time of oophorectomy. The Cancer Genetics Studies Consortium recommends yearly transvaginal ultrasound timed to avoid ovulation and annual measurement of serum cancer antigen 125 levels beginning at age 25 years as the best screening modalities for ovarian carcinoma in *BRCA* mutation carriers who have opted to defer prophylactic oophorectomy.

Other hereditary syndromes associated with an increased risk of breast cancer include Cowden disease (*PTEN* mutations, in which cancers of the thyroid, GI tract, and benign skin and subcutaneous nodules are also seen), Li-Fraumeni syndrome (p53 mutations, also associated with sarcomas, lymphomas, and adrenocortical tumors), and syndromes of breast and melanoma.

EPIDEMIOLGY AND NATURAL HISTORY OF BREAST CANCER

Epidemiology

Breast cancer is the most common site-specific cancer in women and is the leading cause of death from cancer for women aged 20 to 59 years.⁷²⁻⁷³ It accounts for 26% of all newly diagnosed cancers in females and is responsible for 15% of the cancer-related deaths in women.⁷³ It was predicted that approximately 182,460 invasive breast cancers would be diagnosed in women in the United States in 2008 and that 40,480 would die from breast cancer.⁷⁴ Breast cancer was the leading cause of cancer-related mortality in women until 1987, when it was surpassed by lung cancer (Fig. 17-14). In the 1970s, the probability that a woman in the United States would develop breast cancer was estimated at 1 in 13; in 1980 it was 1 in 11; and in 2004 it was 1 in 8. Cancer registries in Connecticut and upper New York State document that the age-adjusted incidence of new breast cancer cases had steadily increased since the mid-1940s. The incidence in the United States, based on data from nine Surveillance, Epidemiology, and End Results (SEER) registries, has been decreasing by 23% per year since 2000. The increase had been approximately 1% per year from 1973 to 1980, and there was an additional increase in incidence of 4% between 1980 and 1987, which was characterized by frequent detection of small primary cancers. The increase in breast cancer incidence occurred primarily in women ≥55 years and paralleled a marked increase in the percentage of older women who had mammograms taken. At the same time, incidence rates for regional metastatic disease dropped and breast cancer mortality declined. From 1960 to 1963, 5-year overall survival rates for breast cancer were 63 and 46% in white and African American women, respectively, whereas the rates for 1981 to 1983 were 78 and 64%, respectively. For 1987 to 1989 rates were 85 and 71%, respectively.

Death rates for cancer at selected organ sites in U.S. females. These are age-adjusted rates per 100,000 population. †The uterine cancer death rate is derived by combining the cervical and corpus death rates. Note the steep rise in the lung cancer death rate after 1960.

(Reproduced with permission from Jemal A, et al: Cancer statistics, 2008. *CA Cancer J Clin* 58:71, 2008.)

There is a 10-fold variation in breast cancer incidence among different countries worldwide. Cyprus and Malta have the highest age-adjusted mortality for breast cancer (29.6 per 100,000 population), whereas Haiti has the lowest (2.0 deaths per 100,000 population). The United States has an age-adjusted mortality for breast cancer of 19.0 cases per 100,000 population. Women living in less-industrialized nations tend to have a lower incidence of breast cancer than women living in industrialized countries, although Japan is an exception. In the United States, Mormons, Seventh Day Adventists, American Indians, Alaska natives, Hispanic/Latina Americans, and Japanese and Filipino women living in Hawaii have a below-average incidence of breast cancer, whereas nuns (due to nulliparity) and Ashkenazi Jewish women have an above-average incidence.

The incidence rates of breast cancer increased in most countries through the 1990s. Since the estimates for 1990, there was an overall increase in incidence rates of approximately 0.5% annually. It was predicted that there would be approximately 1.4

million new cases in 2010. The cancer registries in China have noted annual increases in incidence of up to 3 to 4%, and in eastern Asia, increases are similar.

Recent data from the SEER program reveal declines in breast cancer incidence over the past decade, and this is widely attributed to decreased use of hormone replacement therapy as a consequence of the Women's Health Initiative reports.⁷⁵

Breast cancer burden has well-defined variations by geography (Fig. 17-15), regional lifestyle, and racial or ethnic background.⁷⁶ In general, both breast cancer incidence and mortality are relatively lower among the female populations of Asia and Africa, relatively underdeveloped nations, and nations that have not adopted the Westernized reproductive and dietary patterns. In contrast, European and North American women and women from heavily industrialized or westernized countries have a substantially higher breast cancer burden. These international patterns are mirrored in breast cancer incidence and mortality rates observed for the racially, ethnically, and culturally diverse population of the United States (Fig. 17-16).⁷⁷

Breast cancer incidence and mortality rates in the United States, 1998 to 2002, by ethnic background.

(Reproduced from Ries.⁷⁷)

Although often related, the factors that influence breast cancer incidence may differ from those that affect mortality. Incidence rates are lower among populations that are heavily weighted with women who begin childbearing at young ages and who have multiple full-term pregnancies followed by prolonged lactation. These are features that characterize many underdeveloped nations and also many eastern nations. Breast cancer mortality rates should be lower in populations that have a lower incidence, but the mortality burden will simultaneously be adversely affected by the absence of effective mammographic screening programs for early detection and diminished access to multidisciplinary cancer treatment programs. These features are likely to account for much of the disproportionate mortality risks that are seen in underdeveloped nations. Similar factors probably account for differences in breast cancer burden observed among the various racial and ethnic groups within the United States. Interestingly, breast cancer incidence and mortality rates rise among second- and third-generation Asian Americans as they adopt Western lifestyles.

Disparities in breast cancer survival among subsets of the American population are appropriately generating increased publicity because they are closely linked to disparities in socioeconomic status. Poverty rates and proportions of the population that lack health care insurance are two to three times higher among minority racial and ethnic groups such as African Americans and Hispanic/Latino Americans. These socioeconomic disadvantages create barriers to effective breast cancer screening and result in delayed breast cancer diagnosis, advanced stage distribution, inadequacies in comprehensive treatment, and ultimately increased mortality rates. Furthermore, the rapid growth in the Hispanic population is accompanied by increasing problems in health education because of linguistic barriers between physicians and recently immigrated, non-English-speaking patients. Recent studies also are documenting inequities in the treatments delivered to minority breast cancer patients, such as increased rates of

failure to provide systemic therapy and breast reconstruction. Some of the treatment delivery disparities are related to inadequately controlled comorbidities (such as hypertension and diabetes), which are more prevalent in minority populations. However, some studies that adjust for these factors report persistent and unexplained unevenness in treatment recommendations. It is clear that breast cancer disparities associated with racial or ethnic background have a multifactorial cause, and improvements in outcome will require correction of many public health problems at both the patient and provider levels.

Advances in the ability to characterize breast cancer subtypes and the genetics of the disease are now provoking speculation regarding possible hereditary influences on breast cancer risk that are related to racial or ethnic ancestry.⁷⁸ These questions become particularly compelling when one looks at disparities in breast cancer burden between African Americans and white Americans. Lifetime risk of breast cancer is lower for African Americans, yet a paradoxically increased breast cancer mortality risk also is seen. African Americans also have a younger age distribution for breast cancer; among women <45 years of age, breast cancer incidence is highest among African Americans compared to other subsets of the American population. Lastly and most provocatively, African American women of all ages have notably higher incidence rates for estrogen receptor–negative tumors. These same patterns of disease are seen in contemporary female populations of western, sub-Saharan Africa, who are likely to share ancestry with African American women as a consequence of the Colonial-era slave trade. Interestingly, male breast cancer also is seen with increased frequency among both African Americans and Africans.

Natural History

Bloom and colleagues described the natural history of breast cancer based on the records of 250 women with untreated breast cancers who were cared for on charity wards in the Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis (Fig. 17-17).⁷⁹ The 5- and 10-year survival rates for these women were 18.0 and 3.6%, respectively. Only 0.8% survived for 15 years or longer. Autopsy data confirmed that 95% of these women died of breast cancer, whereas the remaining 5% died of other causes. Almost 75% of the women developed ulceration of the breast during the course of the disease. The longest surviving patient died in the nineteenth year after diagnosis.

PRIMARY BREAST CANCER

More than 80% of breast cancers show productive fibrosis that involves the epithelial and stromal tissues. With growth of the cancer and invasion of the surrounding breast tissues, the accompanying desmoplastic response entraps and shortens Cooper's suspensory ligaments to produce a characteristic skin retraction. Localized edema (peau d'orange) develops when drainage of lymph fluid from the skin is disrupted. With continued growth, cancer cells invade the skin, and eventually ulceration occurs. As new areas of skin are invaded, small satellite nodules appear near the primary ulceration. The size of the primary breast cancer correlates with disease-free and overall survival, but there is a close association between cancer size and axillary lymph node involvement (Fig. 17-18). In general, up to 20% of breast cancer recurrences are local-regional, >60% are distant, and 20% are both local-regional and distant.

B. Risk of metastases according to breast cancer volume and diameter.

(Reproduced with permission from Koscielny S et al: Breast cancer: Relationship between the size of the primary tumour and the probability of metastatic dissemination. *Br J Cancer* 49:709, 1984.)

AXILLARY LYMPH NODE METASTASES

As the size of the primary breast cancer increases, some cancer cells are shed into cellular spaces and transported via the lymphatic network of the breast to the regional lymph nodes, especially the axillary lymph nodes. Lymph nodes that contain metastatic cancer are at first ill defined and soft but become firm or hard with continued growth of the metastatic cancer. Eventually the lymph nodes adhere to each other and form a conglomerate mass. Cancer cells may grow through the lymph node capsule and fix to contiguous structures in the axilla, including the chest wall. Typically, axillary lymph nodes are involved sequentially from the low (level I) to the central (level II) to the apical (level III) lymph node groups. Although >95% of the women who die of breast cancer have distant metastases, the most important prognostic correlate of disease-free and overall survival is axillary lymph node status (see Fig. 17-18A). Women with node-negative disease have less than a 30% risk of recurrence, compared with as much as a 75% risk for women with node-positive disease.

DISTANT METASTASES

At approximately the twentieth cell doubling, breast cancers acquire their own blood supply (neovascularization). Thereafter, cancer cells may be shed directly into the systemic venous blood to seed the pulmonary circulation via the axillary and intercostal veins or the vertebral column via Batson's plexus of veins, which courses the length of the vertebral column. These cells are scavenged by natural killer lymphocytes and macrophages. Successful implantation of metastatic foci from breast cancer predictably occurs after the primary cancer exceeds 0.5 cm in diameter, which corresponds to the twenty-seventh cell doubling. For 10 years after initial treatment, distant metastases are the most common cause of death in breast cancer patients. For this reason, conclusive results cannot be derived from breast cancer trials until at least 5 to 10 years have elapsed. Although 60% of the women who develop distant metastases will do so within 24 months of treatment, metastases may become evident as late as 20 to 30 years after treatment of the primary cancer. Common sites of involvement, in order of frequency, are bone, lung, pleura, soft tissues, and liver.

HISTOPATHOLOGY OF BREAST CANCER

Carcinoma in Situ

Cancer cells are in situ or invasive depending on whether or not they invade through the basement membrane.^{80,81} Broders's original description of in situ breast cancer stressed the absence of invasion of cells into the surrounding stroma and their confinement within natural ductal and alveolar boundaries.⁸⁰ Because areas of invasion may be minute, the accurate diagnosis of in situ cancer necessitates the analysis of multiple microscopic sections to exclude invasion. In 1941, Foote and Stewart published a landmark description of LCIS, which distinguished it from DCIS.⁸¹ In the late 1960s, Gallagher and Martin published their study of whole-breast sections and described a stepwise progression from benign breast tissue to in situ cancer and subsequently to invasive cancer. They coined the term *minimal breast cancer* (LCIS, DCIS, and invasive cancers smaller than 0.5 cm in size) and stressed the importance of early detection.⁸⁵ It is now recognized that each type of minimal breast cancer has a distinct clinical and biologic behavior. Before the widespread use of mammography, diagnosis of breast cancer was by physical examination. At that time, in situ cancers constituted <6% of all breast cancers, and LCIS was more frequently diagnosed than DCIS by a ratio of >2:1. However, when screening mammography became popular, a 14-fold increase in the incidence of in situ cancer (45%) was demonstrated, and DCIS was more frequently diagnosed than LCIS by a ratio of >2:1. Table 17-9 lists the clinical and pathologic characteristics of DCIS and LCIS. *Multicentricity* refers to the occurrence of a second breast cancer outside the breast quadrant of the primary cancer (or at least 4 cm away), whereas *multifocality* refers to the occurrence of a second cancer within the same breast quadrant as the primary cancer (or within 4 cm of it). Multicentricity occurs in 60 to 90% of

women with LCIS, whereas the rate of multicentricity for DCIS is 40 to 80%. LCIS occurs bilaterally in 50 to 70% of cases, whereas DCIS occurs bilaterally in 10 to 20% of cases.

Table 17-9 Salient Characteristics of In Situ Ductal (DCIS) and Lobular (LCIS) Carcinoma of the Breast

	LCIS	DCIS
Age (years)	44–47	54–58
Incidence ^a	2–5%	5–10%
Clinical signs	None	Mass, pain, nipple discharge
Mammographic signs	None	Microcalcifications
Premenopausal	2/3	1/3
Incidence of synchronous invasive carcinoma	5%	2–46%
Multicentricity	60–90%	40–80%
Bilaterality	50–70%	10–20%
Axillary metastasis	1%	1–2%
Subsequent carcinomas:		
Incidence	25–35%	25–70%
Laterality	Bilateral	Ipsilateral
Interval to diagnosis	15–20 y	5–10 y
Histologic type	Ductal	Ductal

^a In biopsy specimens of mammographically detected breast lesions.

LOBULAR CARCINOMA IN SITU

LCIS originates from the terminal duct lobular units and develops only in the female breast. It is characterized by distention and distortion of the terminal duct lobular units by cancer cells, which are large but maintain a normal nuclear:cytoplasmic ratio. Cytoplasmic mucoid globules are a distinctive cellular feature. LCIS may be observed in breast tissues that contain microcalcifications, but the calcifications associated with LCIS typically occur in adjacent tissues. This neighborhood calcification is a feature that is unique to LCIS and contributes to its diagnosis. The frequency of LCIS in the general population cannot be reliably determined because it usually presents as an incidental finding. The average age at diagnosis is 44 to 47 years, which is approximately 15 to 25 years younger than the age at diagnosis for invasive breast cancer. LCIS has a distinct racial predilection, occurring 12 times more frequently in white women than in African American women. Invasive breast cancer develops in 25 to 35% of women with LCIS. Invasive cancer may develop in either breast, regardless of which breast harbored the initial focus of LCIS, and is detected synchronously with LCIS in 5% of cases. In women with a history of LCIS, up to 65% of subsequent invasive cancers are ductal, not lobular, in origin. For these reasons, LCIS is regarded as a marker of increased risk for invasive breast cancer rather than as an anatomic precursor.

DUCTAL CARCINOMA IN SITU

Although DCIS is predominantly seen in the female breast, it accounts for 5% of male breast cancers. Published series suggest a detection frequency of 7% in all biopsy tissue specimens. The term *intraductal carcinoma* is frequently applied to DCIS, which

carries a high risk for progression to an invasive cancer. Histologically, DCIS is characterized by a proliferation of the epithelium that lines the minor ducts, resulting in papillary growths within the duct lumina. Early in their development, the cancer cells do not show pleomorphism, mitoses, or atypia, which leads to difficulty in distinguishing early DCIS from benign hyperplasia. The papillary growths (papillary growth pattern) eventually coalesce and fill the duct lumina so that only scattered, rounded spaces remain between the clumps of atypical cancer cells, which show hyperchromasia and loss of polarity (cribriform growth pattern). Eventually pleomorphic cancer cells with frequent mitotic figures obliterate the lumina and distend the ducts (solid growth pattern). With continued growth, these cells outstrip their blood supply and become necrotic (comedo growth pattern). Calcium deposition occurs in the areas of necrosis and is a common feature seen on mammography. DCIS is now frequently classified based on nuclear grade and the presence of necrosis (Table 17-10). Based on multiple consensus meetings, grading of DCIS has been recommended. Although there is no universal agreement on classification, most systems endorse the use of cytologic grade and presence or absence of necrosis.⁸²

Table 17-10 Classification of Breast Ductal Carcinoma In Situ (DCIS)			
Histologic Subtype	Determining Characteristics		DCIS Grade
	Nuclear Grade	Necrosis	
Comedo	High	Extensive	High
Intermediate ^a	Intermediate	Focal or absent	Intermediate
Noncomedo ^b	Low	Absent	Low

^a Often a mixture of noncomedo patterns.

^b Solid, cribriform, papillary, or focal micropapillary.

Source: Adapted with permission from Connolly JL, et al: Ductal carcinoma in situ of the breast: Histologic subtyping and clinical significance. *PPO Updates* 10:1, 1996.

The risk for invasive breast cancer is increased nearly fivefold in women with DCIS.⁸³ The invasive cancers are observed in the ipsilateral breast, usually in the same quadrant as the DCIS that was originally detected, which suggests that DCIS is an anatomic precursor of invasive ductal carcinoma (Fig. 17-19).

Ductal carcinoma in situ (DCIS). Craniocaudal (A) and mediolateral oblique (B) mammographic views show a poorly defined 1.2-cm mass (arrow) containing microcalcifications. Histopathologic preparation of the surgical specimen (C) confirms DCIS with areas of invasion (hematoxylin and eosin stain, x32).

Invasive Breast Carcinoma

Invasive breast cancers have been described as lobular or ductal in origin.^{84–87} Early classifications used the term *lobular* to describe invasive cancers that were associated with LCIS, whereas all other invasive cancers were referred to as *ductal*. Current histologic classifications recognize special types of breast cancers (10% of total cases), which are defined by specific histologic features. To qualify as a special-type cancer, at least 90% of the cancer must contain the defining histologic features. Eighty percent of invasive breast cancers are described as invasive ductal carcinoma of no special type (NST). These cancers generally have a worse prognosis than special-type cancers. Foote and Stewart originally proposed the following classification for invasive breast cancer⁸¹ :

1. Paget's disease of the nipple
2. Invasive ductal carcinoma
3. Adenocarcinoma with productive fibrosis (scirrhous, simplex, NST), 80%
4. Medullary carcinoma, 4%
5. Mucinous (colloid) carcinoma, 2%
6. Papillary carcinoma, 2%
7. Tubular carcinoma, 2%
8. Invasive lobular carcinoma, 10%

9. Rare cancers (adenoid cystic, squamous cell, apocrine)

Paget's disease of the nipple was described in 1874. It frequently presents as a chronic, eczematous eruption of the nipple, which may be subtle but may progress to an ulcerated, weeping lesion. Paget's disease usually is associated with extensive DCIS and may be associated with an invasive cancer. A palpable mass may or may not be present. A nipple biopsy specimen will show a population of cells that are identical to the underlying DCIS cells (pagetoid features or pagetoid change). Pathognomonic of this cancer is the presence of large, pale, vacuolated cells (Paget cells) in the rete pegs of the epithelium. Paget's disease may be confused with superficial spreading melanoma. Differentiation from pagetoid intraepithelial melanoma is based on the presence of S-100 antigen immunostaining in melanoma and carcinoembryonic antigen immunostaining in Paget's disease. Surgical therapy for Paget's disease may involve lumpectomy, mastectomy, or modified radical mastectomy, depending on the extent of involvement and the presence of invasive cancer.

Invasive ductal carcinoma of the breast with productive fibrosis (scirrhous, simplex, NST) accounts for 80% of breast cancers and presents with macroscopic or microscopic axillary lymph node metastases in up to 60% of cases. This cancer usually occurs in perimenopausal or postmenopausal women in the fifth to sixth decades of life as a solitary, firm mass. It has poorly defined margins and its cut surfaces show a central stellate configuration with chalky white or yellow streaks extending into surrounding breast tissues. The cancer cells often are arranged in small clusters, and there is a broad spectrum of histologic types with variable cellular and nuclear grades (Fig. 17-20).

(Courtesy of Dr. R. L. Hackett.)

Medullary carcinoma is a special-type breast cancer; it accounts for 4% of all invasive breast cancers and is a frequent

phenotype of *BRCA1* hereditary breast cancer. Grossly, the cancer is soft and hemorrhagic. A rapid increase in size may occur secondary to necrosis and hemorrhage. On physical examination, it is bulky and often positioned deep within the breast. Bilaterality is reported in 20% of cases. Medullary carcinoma is characterized microscopically by (a) a dense lymphoreticular infiltrate composed predominantly of lymphocytes and plasma cells; (b) large pleomorphic nuclei that are poorly differentiated and show active mitosis; and (c) a sheet-like growth pattern with minimal or absent ductal or alveolar differentiation (Fig. 17-21). Approximately 50% of these cancers are associated with DCIS, which characteristically is present at the periphery of the cancer, and <10% demonstrate hormone receptors. In rare circumstances, mesenchymal metaplasia or anaplasia is noted. Because of the intense lymphocyte response associated with the cancer, benign or hyperplastic enlargement of the lymph nodes of the axilla may contribute to erroneous clinical staging. Women with this cancer have a better 5-year survival rate than those with NST or invasive lobular carcinoma.

Mucinous carcinoma (colloid carcinoma), another special-type breast cancer, accounts for 2% of all invasive breast cancers and typically presents in the elderly population as a bulky tumor. This cancer is defined by extracellular pools of mucin, which surround aggregates of low-grade cancer cells. The cut surface of this cancer is glistening and gelatinous in quality. Fibrosis is variable, and when abundant it imparts a firm consistency to the cancer. Approximately 66% of mucinous carcinomas display hormone receptors. Lymph node metastases occur in 33% of cases, and 5- and 10-year survival rates are 73 and 59%, respectively. Because of the mucinous component, cancer cells may not be evident in all microscopic sections, and analysis of multiple sections is essential to confirm the diagnosis of a mucinous carcinoma.

Papillary carcinoma is a special-type cancer of the breast that accounts for 2% of all invasive breast cancers. It generally presents in the seventh decade of life and occurs in a disproportionate number of nonwhite women. Typically, papillary carcinomas are small and rarely attain a size of 3 cm in diameter. These cancers are defined by papillae with fibrovascular stalks and multilayered epithelium. McDivitt and colleagues noted that these tumors showed a low frequency of axillary lymph node metastases and had 5- and 10-year survival rates similar to those for mucinous and tubular carcinoma.⁸⁸

Tubular carcinoma is another special-type breast cancer and accounts for 2% of all invasive breast cancers. It is reported in as many as 20% of women whose cancers are diagnosed by mammographic screening and usually is diagnosed in the perimenopausal or early menopausal periods. Under low-power magnification, a haphazard array of small, randomly arranged tubular elements is seen. Approximately 10% of women with tubular carcinoma or with invasive cribriform carcinoma, a special-type cancer closely related to tubular carcinoma, will develop axillary lymph node metastases, which are usually confined to the lowest axillary lymph nodes (level I). However, the presence of metastatic disease in one or two axillary lymph nodes does not adversely affect survival. Distant metastases are rare in tubular carcinoma and invasive cribriform carcinoma. Long-term survival approaches 100%.

Invasive lobular carcinoma accounts for 10% of breast cancers. The histopathologic features of this cancer include small cells with rounded nuclei, inconspicuous nucleoli, and scant cytoplasm (Fig. 17-22). Special stains may confirm the presence of intracytoplasmic mucin, which may displace the nucleus (signet-ring cell carcinoma). At presentation, invasive lobular carcinoma varies from clinically inapparent cancers to those that replace the entire breast with a poorly defined mass. It is frequently multifocal, multicentric, and bilateral. Because of its insidious growth pattern and subtle mammographic features, invasive lobular carcinoma may be difficult to detect.

DIAGNOSIS OF BREAST CANCER

In 33% of breast cancer cases, the woman discovers a lump in her breast. Other less frequent presenting signs and symptoms of breast cancer include (a) breast enlargement or asymmetry; (b) nipple changes, retraction, or discharge; (c) ulceration or erythema of the skin of the breast; (d) an axillary mass; and (e) musculoskeletal discomfort. However, up to 50% of women presenting with breast complaints have no physical signs of breast pathology. Breast pain usually is associated with benign disease.

Misdiagnosed breast cancer accounts for the greatest number of malpractice claims for errors in diagnosis and for the largest number of paid claims. Litigation often involves younger women, whose physical examination and mammogram may be misleading. If a young woman (≤ 45 years) presents with a palpable breast mass and equivocal mammographic findings, ultrasound examination and biopsy are used to avoid a delay in diagnosis.

Examination

INSPECTION

The surgeon inspects the woman's breast with her arms by her side (Fig. 17-23A), with her arms straight up in the air (Fig. 17-23B), and with her hands on her hips (with and without pectoral muscle contraction).^{89,90} Symmetry, size, and shape of the breast are recorded, as well as any evidence of edema (peau d'orange), nipple or skin retraction, or erythema. With the arms

extended forward and in a sitting position, the woman leans forward to accentuate any skin retraction.

Fig. 17-23.

Examination of the breast. **A.** Inspection of the breast with arms at sides. **B.** Inspection of the breast with arms raised. **C.** Palpation of the breast with the patient supine. **D.** Palpation of the axilla.

PALPATION

As part of the physical examination, the breast is carefully palpated. Examination of the patient in the supine position (see Fig. 17-23C) is best performed with a pillow supporting the ipsilateral hemithorax. The surgeon gently palpates the breast from the ipsilateral side, making certain to examine all quadrants of the breast from the sternum laterally to the latissimus dorsi muscle and from the clavicle inferiorly to the upper rectus sheath. The surgeon performs the examination with the palmar aspects of the fingers, avoiding a grasping or pinching motion. The breast may be cupped or molded in the surgeon's hands to check for retraction. A systematic search for lymphadenopathy then is performed. Figure 17-23D shows the position of the patient for examination of the axilla. By supporting the upper arm and elbow, the surgeon stabilizes the shoulder girdle. Using gentle palpation, the surgeon assesses all three levels of possible axillary lymphadenopathy. Careful palpation of supraclavicular and parasternal sites also is performed. A diagram of the chest and contiguous lymph node sites is useful for recording location, size, consistency, shape, mobility, fixation, and other characteristics of any palpable breast mass or lymphadenopathy (Fig. 17-24).

Imaging Techniques

MAMMOGRAPHY

Mammography has been used in North America since the 1960s, and the techniques used continue to be modified and improved to enhance image quality (Fig. 17-25A and C).⁹¹⁻⁹⁴ Conventional mammography delivers a radiation dose of 0.1 cGy per study. By comparison, chest radiography delivers 25% of this dose. However, there is no increased breast cancer risk associated with the radiation dose delivered with screening mammography. Screening mammography is used to detect unexpected breast cancer in asymptomatic women. In this regard, it supplements history taking and physical examination. With screening mammography, two views of the breast are obtained, the craniocaudal (CC) view (Fig. 17-25D) and the mediolateral oblique (MLO) view (Fig. 17-25E). The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. Diagnostic mammography is used to evaluate women with abnormal findings such as a breast mass or nipple discharge. In addition to the MLO and CC views, a diagnostic examination may use views that better define the nature of any abnormalities, such as the 90-degree lateral and spot compression views. The 90-degree lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammographic abnormality that is obscured by overlying tissues (Fig. 17-25F). The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques (×1.5) often are combined with spot compression to better resolve calcifications and the margins of masses. Mammography also is used to guide interventional procedures, including

needle localization and needle biopsy.

Mammography and xeromammography. **A.** Mammogram of a premenopausal breast with a dense fibroglandular pattern. **B.** Xeromammogram of the breast shown in **A**. Xeromammography allows visualization from the nipple to the ribs, whereas mammography permits better visualization of the axillary tail of Spence. **C.** Mammogram of a postmenopausal breast with a sparse fibroglandular pattern. **D.** Invasive breast cancer (*arrow*) shown in the craniocaudal mammography view. **E.** Invasive breast cancer (*arrow*) shown in the mediolateral oblique mammography view. **F.** Cone-compression mammography view of the cancer seen in **D** and **E**. Note that the speculated margins of the cancer are accentuated by cone compression. (Courtesy of Dr. B. Steinbach.)

An experienced radiologist can detect breast cancer with a false-positive rate of 10% and a false-negative rate of 7%. Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50% of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammographic abnormality. The clinical impetus for screening mammography came from the Health Insurance Plan study and the Breast Cancer Detection Demonstration Project, which demonstrated a 33% reduction in mortality for women after screening mammography.

Mammography was more accurate than clinical examination for the detection of early breast cancers, providing a true-positive rate of 90%. Only 20% of women with nonpalpable cancers had axillary lymph node metastases, compared with 50% of women with palpable cancers.⁹⁵ Current guidelines of the National Comprehensive Cancer Network suggest that normal-risk women ≥ 20 years of age should have a breast examination at least every 3 years. Starting at age 40 years, breast examinations should be performed yearly and a yearly mammogram should be taken. Prospective randomized studies of mammography screening confirm a 40% reduction in stage II, III, and IV cancer in the screened population, with a 30% increase in overall survival.

Xeromammography techniques are identical to those of mammography with the exception that the image is recorded on a

xerography plate, which provides a positive rather than a negative image (see Fig. 17-25B). Details of the entire breast and the soft tissues of the chest wall may be recorded with one exposure. Screen film mammography has replaced xeromammography because it requires a lower dose of radiation and provides similar image quality. Digital mammography was developed to allow the observer to manipulate the degree of contrast in the image. This is especially useful in women with dense breasts and women <50 years of age. Recently, investigators directly compared digital vs. screen film mammography in a prospective trial enrolling over 42,000 women.⁹⁶ They found that digital and screen film mammography had similar accuracy; however, digital mammography was more accurate in women <50 years of age, women with mammographically dense breasts, and premenopausal or perimenopausal women.

DUCTOGRAPHY

The primary indication for ductography is nipple discharge, particularly when the fluid contains blood. Radiopaque contrast media is injected into one or more of the major ducts and mammography is performed. A duct is gently enlarged with a dilator and then a small, blunt cannula is inserted under sterile conditions into the nipple ampulla. With the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected and CC and MLO mammographic views are obtained without compression. Intraductal papillomas are seen as small filling defects surrounded by contrast media (Fig. 17-26). Cancers may appear as irregular masses or as multiple intraluminal filling defects.

Fig. 17-26.

Ductogram. Craniocaudal (A) and mediolateral oblique (B) mammographic views demonstrate a mass (arrows) posterior to the nipple and outlined by contrast, which also fills the proximal ductal structures.

(Courtesy of Dr. B. Steinbach.)

ULTRASONOGRAPHY

Second only to mammography in frequency of use for breast imaging, ultrasonography is an important method of resolving equivocal mammographic findings, defining cystic masses, and demonstrating the echogenic qualities of specific solid abnormalities. On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center (Fig. 17-27). Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well-defined anterior and posterior margins. Breast cancer characteristically has irregular walls (Fig. 17-28) but may have smooth margins with acoustic enhancement. Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization of breast lesions. Its findings are highly reproducible and it has a high patient acceptance rate, but it does not reliably detect lesions that are ≤ 1 cm in diameter.

Breast cancer. **A.** Craniocaudal mammographic view of a palpable mass (*arrows*). **B.** Ultrasound image demonstrating a solid mass with irregular borders (*arrows*) consistent with cancer.

MAGNETIC RESONANCE IMAGING

In the process of evaluating MRI as a means of characterizing mammographic abnormalities, additional breast lesions have been detected. However, in the circumstance of negative findings on both mammography and physical examination, the probability of a breast cancer being diagnosed by MRI is extremely low. There is current interest in the use of MRI to screen the breasts of high-risk women and of women with a newly diagnosed breast cancer. In the first case, women who have a strong family history of breast cancer or who carry known genetic mutations require screening at an early age, but mammographic evaluation is limited because of the increased breast density in younger women. In the second case, an MRI study of the contralateral breast in women with a known breast cancer has shown a contralateral breast cancer in 5.7% of these women.

Breast Biopsy

NONPALPABLE LESIONS

Image-guided breast biopsies are frequently required to diagnose nonpalpable lesions.⁹⁷ Ultrasound localization techniques are used when a mass is present, whereas stereotactic techniques are used when no mass is present (microcalcifications only). The combination of diagnostic mammography, ultrasound or stereotactic localization, and fine-needle aspiration (FNA) biopsy achieves almost 100% accuracy in the diagnosis of breast cancer. However, although FNA biopsy permits cytologic evaluation, core-needle or open biopsy also permits the analysis of breast tissue architecture and allows the pathologist to determine whether invasive cancer is present. This permits the surgeon and patient to discuss the specific management of a breast cancer

before therapy begins. Core-needle biopsy is preferred over open biopsy for nonpalpable breast lesions because a single surgical procedure can be planned based on the results of the core biopsy. The advantages of core-needle biopsy include a low complication rate, avoidance of scarring, and a lower cost.

PALPABLE LESIONS

FNA biopsy of a palpable breast mass can easily proceed in an outpatient setting.⁹⁸ A 1.5-in, 22-gauge needle attached to a 10-mL syringe is used. Use of a syringe holder enables the surgeon performing the FNA biopsy to control the syringe and needle with one hand while positioning the breast mass with the opposite hand. After the needle is placed in the mass, suction is applied while the needle is moved back and forth within the mass. Once cellular material is seen at the hub of the needle, the suction is released and the needle is withdrawn. The cellular material is then expressed onto microscope slides. Both air-dried and 95% ethanol-fixed microscopic sections are prepared for analysis. When a breast mass is clinically and mammographically suspicious, the sensitivity and specificity of FNA biopsy approaches 100%. Core-needle biopsy of palpable breast masses is performed using a 14-gauge needle, such as the Tru-Cut needle. Automated devices also are available. Tissue specimens are placed in formalin and then processed to paraffin blocks. Although the false-negative rate for core-needle biopsy specimens is very low, a tissue specimen that does not show breast cancer cannot conclusively rule out that diagnosis because a sampling error may have occurred. The clinical, radiographic, and pathologic findings should be in concordance. If the biopsy findings do not concur with the clinical and radiographic findings, the clinician should proceed with an image-guided or open biopsy to be certain that the target lesion has been adequately sampled for diagnosis.

BREAST CANCER STAGING AND BIOMARKERS

Breast Cancer Staging

The clinical stage of breast cancer is determined primarily through physical examination of the skin, breast tissue, and regional lymph nodes (axillary, supraclavicular, and cervical).⁹⁹ However, clinical determination of axillary lymph node metastases has an accuracy of only 33%. Mammography, chest radiography, and intraoperative findings (primary tumor size, chest wall invasion) also provide necessary staging information. Pathologic stage combines the findings from pathologic examination of the resected primary breast cancer and axillary or other regional lymph nodes. Fisher and colleagues found that accurate predictions regarding the occurrence of distant metastases were possible after resection and pathologic analysis of 10 or more level I and II axillary lymph nodes.¹⁰⁰ A frequently used staging system is the TNM (tumor, nodes, and metastasis) system. The American Joint Committee on Cancer (AJCC) has modified the TNM system for breast cancer (Tables 17-11 and 17-12). Koscielny and colleagues demonstrated that tumor size correlates with the presence of axillary lymph node metastases (see Fig. 17-18B). Others have shown an association between tumor size, axillary lymph node metastases, and disease-free survival. The single most important predictor of 10- and 20-year survival rates in breast cancer is the number of axillary lymph nodes involved with metastatic disease. Routine biopsy of internal mammary lymph nodes is not generally performed; however, with the advent of sentinel lymph node dissection and the use of preoperative lymphoscintigraphy for localization of the sentinel nodes, surgeons have begun to biopsy the internal mammary nodes in some cases. The sixth edition of the AJCC staging system does allow for staging based on findings from the internal mammary sentinel nodes.⁹⁹ Drainage to the internal mammary nodes is more frequent with central and medial quadrant cancers. Clinical or pathologic evidence of metastatic spread to supraclavicular lymph nodes is no longer considered systemic or stage IV disease, but routine scalene or supraclavicular lymph node biopsy is not indicated.

Table 17-11 TNM Staging System for Breast Cancer

Primary tumor (T) Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3); if other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple with no tumor (NOTE: Paget's disease associated with a tumor is classified according to the size of the tumor)
T1	Tumor \leq 2 cm in greatest dimension
T1mic	Microinvasion \leq 0.1 cm or less in greatest dimension
T1a	Tumor >0.1 cm but not >0.5 cm in greatest dimension
T1b	Tumor >0.5 cm but not >1 cm in greatest dimension
T1c	Tumor >1 cm but not >2 cm in greatest dimension
T2	Tumor >2 cm but not >5 cm in greatest dimension
T3	Tumor >5 cm in greatest dimension
T4	Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle
T4b	Edema (including peau d'orange), or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

Regional lymph nodes—Clinical (N)

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ^a ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N3	Metastasis only in clinically apparent ^a ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis; metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ^a ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph nodes(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

Regional lymph nodes—Pathologic (pN)

pNX	Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
pN0 ^b	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells [NOTE: Isolated tumor cells (ITC) are defined as single tumor cells or small cell clusters not >0.2 mm, which are usually

	detected only by immunohistochemical (IHC) or molecular methods but which may be verified on hematoxylin and eosin stains; ITCs do not usually show evidence of malignant activity (e.g., proliferation or stromal reaction)]
pN0(i-)	No regional lymph node metastasis histologically, negative IHC results
pN0(i+)	No regional lymph node metastasis histologically, positive IHC results, no IHC cluster >0.2 mm
pN0(mol-)	No regional lymph node metastasis histologically, negative molecular findings [reverse-transcriptase polymerase chain reaction (RT-PCR)]
pN0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)
pN1	Metastasis in 1 to 3 axillary lymph nodes, and/or in internal mammary nodes with microscopic disease detected by sentinel lymph nodes dissection, not clinically apparent ^c
pN1mi	Micrometastasis (>0.2 mm, none >2.0 mm)
pN1a	Metastasis in 1 to 3 axillary lymph nodes
pN1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, not clinically apparent ^c
pN1c	Metastasis in 1 to 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ^c (if associated with >3 positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden)
pN2	Metastasis in 4 to 9 axillary lymph nodes, or in clinically apparent ^a internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN2a	Metastasis in 4 to 9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastasis in clinically apparent ^a internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN3	Metastasis in ≥10 axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ^a ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in >3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastasis in ≥10 axillary lymph nodes (at least one tumor deposit >2.0 mm), or metastasis to the infraclavicular lymph nodes
pN3b	Metastasis in clinically apparent ^a ipsilateral internal mammary lymph nodes in the presence of ≥1 positive axillary lymph nodes; or in >3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection, not clinically apparent ^c
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

^a *Clinically apparent* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

^b Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based

solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node" e.g., pN–(I+) (sn).

^c*Not clinically apparent* is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

Biomarkers

Breast cancer biomarkers are of several types. Risk factor biomarkers are those associated with increased cancer risk.^{101–105} These include familial clustering and inherited germline abnormalities, proliferative breast disease with atypia, and mammographic densities. Exposure biomarkers are a subset of risk factors that include measures of carcinogen exposure such as DNA adducts. Surrogate endpoint biomarkers are biologic alterations in tissue that occur between cancer initiation and development. These biomarkers are used as endpoints in short-term chemoprevention trials and include histologic changes, indices of proliferation, and genetic alterations leading to cancer. Prognostic biomarkers provide information regarding cancer outcome irrespective of therapy, whereas predictive biomarkers provide information regarding response to therapy. Candidate prognostic and predictive biomarkers and biologic targets for breast cancer include (a) indices of proliferation such as

proliferating cell nuclear antigen (PCNA) and Ki-67; (b) indices of apoptosis and apoptosis modulators such as bcl-2 and the bax:bcl-2 ratio; (c) indices of angiogenesis such as vascular endothelial growth factor (VEGF) and the angiogenesis index; (d) growth factors and growth factor receptors such as human epidermal growth factor receptor 2 (HER-2)/*neu*, epidermal growth factor receptor (EGFr), transforming growth factor, platelet-derived growth factor, and the insulin-like growth factor family; (e) the steroid hormone receptor pathway; (f) the cell cycle, cyclins, and cyclin-dependent kinases; (g) the proteasome; (h) the COX-2 enzyme; (i) the peroxisome proliferator-activated receptors (PPARs); (j) tumor-suppressor genes such as p53; and (k) the mammalian target of rapamycin (mTOR) signaling pathway.

INDICES OF PROLIFERATION

PCNA is a nuclear protein associated with a DNA polymerase whose expression increases in phase G₁ of the cell cycle, reaches its maximum at the G₁/S interface, and then decreases through G₂.^{106–109} Immunohistochemical staining for PCNA outlines the proliferating compartments in breast tissue. Good correlation is noted between PCNA expression and (a) cell-cycle distributions seen on flow cytometry based on DNA content, and (b) uptake of bromodeoxyuridine and the proliferation-associated Ki-67 antigen. Individual proliferation markers are associated with slightly different phases of the cell cycle and are not equivalent. PCNA and Ki-67 expression are positively correlated with p53 overexpression, high S-phase fraction, aneuploidy, high mitotic index, and high histologic grade in human breast cancer specimens, and are negatively correlated with estrogen receptor content.

INDICES OF APOPTOSIS

Alterations in programmed cell death (apoptosis), which may be triggered by p53-dependent or p53-independent factors, may be important prognostic and predictive biomarkers in breast cancer.^{110–112} Bcl-2 family proteins appear to regulate a step in the evolutionarily conserved pathway for apoptosis, with some members functioning as inhibitors of apoptosis and others as promoters of apoptosis. *BCL2* is the only oncogene that acts by inhibiting apoptosis rather than by directly increasing cellular proliferation. The death-signal protein bax is induced by genotoxic stress and growth factor deprivation in the presence of wild-type (normal) p53 and/or AP-1/fos. The bax:bcl-2 ratio and the resulting formation of either bax-bax homodimers, which stimulate apoptosis, or bax–bcl-2 heterodimers, which inhibit apoptosis, represent an intracellular regulatory mechanism with prognostic and predictive implications. In breast cancer, overexpression of bcl-2 and a decrease in the bax:bcl-2 ratio correlate with high histologic grade, the presence of axillary lymph node metastases, and reduced disease-free and overall survival rates. Similarly, decreased bax expression correlates with axillary lymph node metastases, a poor response to chemotherapy, and decreased overall survival.

INDICES OF ANGIOGENESIS

Angiogenesis is necessary for the growth and invasiveness of breast cancer and promotes cancer progression through several different mechanisms, including delivery of oxygen and nutrients and the secretion of growth-promoting cytokines by endothelial cells.^{113,114} VEGF induces its effect by binding to transmembrane tyrosine kinase receptors. Overexpression of VEGF in invasive breast cancer is correlated with increased microvessel density and recurrence in node-negative breast cancer. An angiogenesis index has been developed in which microvessel density (CD31 expression) is combined with expression of thrombospondin (a negative modulator of angiogenesis) and p53 expression. Both VEGF expression and the angiogenesis index may have prognostic and predictive significance in breast cancer. Antiangiogenesis breast cancer therapy is now being studied in human trials. The use of bevacizumab (a monoclonal antibody to VEGF) was recently approved by the U.S. Food and Drug Administration (FDA) for use in metastatic breast cancer in combination with paclitaxel chemotherapy. This approval was based on results from a phase III trial by the Eastern Cooperative Oncology Group. The group's E2100 trial showed that when bevacizumab was added to paclitaxel chemotherapy, median progression-free survival increased to 11.3 months from the 5.8 months seen in patients who

received paclitaxel alone.

GROWTH FACTOR RECEPTORS AND GROWTH FACTORS

Overexpression of EGFr in breast cancer correlates with estrogen receptor–negative status and with p53 overexpression.^{116–118} Similarly, increased immunohistochemical membrane staining for the HER-2/*neu* growth factor receptor in breast cancer is associated with mutated p53 Ki-67 overexpression and estrogen receptor–negative status. HER-2/*neu* is a member of the EGFr family of growth factor receptors in which ligand binding results in receptor homodimerization and tyrosine phosphorylation by tyrosine kinase domains within the receptor. Tyrosine phosphorylation is followed by signal transduction, which results in changes in cell behavior. An important property of this family of receptors is that ligand binding to one receptor type also may result in heterodimerization between two different receptor types that are coexpressed; this leads to transphosphorylation and transactivation of both receptors in the complex (transmodulation). In this context, the lack of a specific ligand for the HER-2/*neu* receptor suggests that HER-2/*neu* may function solely as a coreceptor, modulating signaling by other EGFr family members. HER-2/*neu* is both an important prognostic factor and a predictive factor in breast cancer.¹¹⁹ When overexpressed in breast cancer, HER-2/*neu* promotes enhanced growth and proliferation, and increases invasive and metastatic capabilities. Clinical studies have shown that patients with HER-2/*neu*–overexpressing breast cancer have poorly differentiated tumors with high proliferation rates, positive lymph nodes, decreased hormone receptor expression, and an increased risk of recurrence and death due to breast cancer.^{119–123} Routine testing of the primary tumor specimen for HER-2/*neu* expression should be performed on all invasive breast cancers. This can be done with immunohistochemical analysis to evaluate for overexpression of the cell-surface receptor at the protein level or by using fluorescent in situ hybridization to evaluate for gene amplification. Patients whose tumors overexpress HER-2/*neu* are candidates for anti–HER-2/*neu* therapy. Trastuzumab (Herceptin) is a recombinant humanized monoclonal antibody directed against HER-2/*neu*. Randomized clinical trials have demonstrated that single-agent trastuzumab therapy is an active and well-tolerated option for first-line treatment of women with HER-2/*neu*–overexpressing metastatic breast cancer. More recently, adjuvant trials demonstrated that trastuzumab also was highly effective in the treatment of women with early-stage breast cancer when used in combination with chemotherapy. Patients who received trastuzumab in combination with chemotherapy had a 52% reduction in the risk of breast cancer recurrence compared with those who received chemotherapy alone.¹²⁴

STEROID HORMONE RECEPTOR PATHWAY

Hormones play an important role in the development and progression of breast cancer. Estrogens, estrogen metabolites, and other steroid hormones such as progesterone all have been shown to have an effect. Breast cancer risk is related to estrogen exposure over time. In postmenopausal women, hormone replacement therapy consisting of estrogen plus progesterone increases the risk of breast cancer by 26% compared to placebo.¹²⁵ Patients with hormone receptor–positive tumors survive two to three times longer after a diagnosis of metastatic disease than do patients with hormone receptor–negative tumors. Patients with tumors negative for both estrogen receptors and progesterone receptors are not considered candidates for hormonal therapy. Tumors positive for estrogen or progesterone receptors have a higher response rate to endocrine therapy than tumors that do not express estrogen or progesterone receptors. Tumors positive for both receptors have a response rate of >50%, tumors negative for both receptors have a response rate of <10%, and tumors positive for one receptor but not the other have an intermediate response rate of 33%. The determination of estrogen and progesterone receptor status used to require biochemical evaluation of fresh tumor tissue. Today, however, estrogen and progesterone receptor status can be measured in archived tissue using immunohistochemical techniques. Hormone receptor status also can be measured in specimens obtained with fine-needle aspiration biopsy or core-needle biopsy, and this can help guide treatment planning. Testing for estrogen and progesterone receptors should be performed on all primary invasive breast cancer specimens. The tumor hormone receptor status

should be ascertained for both premenopausal and postmenopausal patients to identify patients who are most likely to benefit from endocrine therapy.

The remaining biomarkers and biologic targets listed earlier are still in preclinical and clinical trials evaluating their importance in breast cancer for both prognostic and predictive purposes.

COEXPRESSION OF BIOMARKERS

Selection of optimal therapy for breast cancer requires both an accurate assessment of prognosis and an accurate prediction of response to therapy. The breast cancer markers that are most important in determining therapy are estrogen receptor, progesterone receptor, and HER-2/*neu*. Clinicians evaluate clinical and pathologic staging and the expression of estrogen receptor, progesterone receptor, and HER-2/*neu* in the primary tumor to assess prognosis and assign therapy. Adjuvant! Online (<http://www.adjuvantonline.com>) is a program available to clinicians that incorporates clinical and pathologic factors for an individual patient and calculates risk of recurrence and death due to breast cancer and then provides an assessment of the reduction in risk of recurrence that would be expected with the use of combination chemotherapy, endocrine therapy, or both of these. Adjuvant! Online was developed using information from the SEER database, the Early Breast Cancer Trialists' Collaborative Group overview analyses, and results from other individual published trials.¹²⁶ The website is updated and modified as new information becomes available. Clinicopathologic factors are used to separate breast cancer patients into broad prognostic groups, and treatment decisions are made on this basis (Table 17-13). When this approach is used, up to 70% of early breast cancer patients receive adjuvant chemotherapy that is either unnecessary or ineffective. As described earlier, a wide variety of biomarkers have been shown to individually predict prognosis and response to therapy, but they do not improve the accuracy of either the assessment of prognosis or the prediction of response to therapy.

Table 17-13 Traditional Prognostic and Predictive Factors for Invasive Breast Cancer	
Tumor Factors	Host Factors
Nodal status	Age
Tumor size	Menopausal status
Histologic/nuclear grade	Family history
Lymphatic/vascular invasion	Previous breast cancer
Pathologic stage	Immunosuppression
Hormone receptor status	Nutrition
DNA content (ploidy, S-phase fraction)	Prior chemotherapy
Extent of intraductal component	Prior radiation therapy
HER-2/ <i>neu</i> expression

As knowledge regarding cellular, biochemical, and molecular biomarkers for breast cancer increases, prognostic indices are being developed that combine the predictive power of several individual biomarkers with the relevant clinicopathologic factors.

Most recently, technologic advances have led to the ability to measure the expression of multiple genes in a tumor sample simultaneously. This gene expression profiling can provide information about tumor behavior that can be used in determining prognosis and therapy.¹²⁷ These high-throughput analyses require bioinformatics support that can categorize and analyze the immense amount of data that are generated. This allows for a detailed stratification of breast cancer patients for assessment of prognosis and for prediction of response to therapy. The *Oncotype DX* is a 21-gene assay that has been validated in newly

diagnosed patients with node-negative, estrogen receptor–positive breast cancer.¹²⁸ A recurrence score is generated, and those patients with high recurrence scores are found to benefit the most from chemotherapy, whereas those with low recurrence scores benefit most from tamoxifen and may not require chemotherapy. There is currently an ongoing clinical trial, the Trial Assessing Individualized Options for Treatment for breast cancer (TAILORx), that randomly assigns patients with an intermediate recurrence score to hormonal therapy alone or to chemotherapy followed by hormonal therapy. The MammaPrint test was recently approved by the FDA for use in patients with newly diagnosed, node-negative breast cancer. The MammaPrint test is based on a 70-gene profile, and fresh tissue is required to perform the assay. The *Oncotype DX* assay is performed using paraffin-embedded tumor tissue and therefore can be carried out on archived samples.

OVERVIEW OF BREAST CANCER THERAPY

Before diagnostic biopsy, the surgeon must discuss with the patient the possibility that a suspicious mass or mammographic finding may be a breast cancer. Once a diagnosis of breast cancer is made, the type of therapy offered to a breast cancer patient is determined by the stage of the disease. Laboratory tests and imaging studies are performed based on the initial stage as presented in Table 17-14. Before therapy is initiated, the patient and the surgeon must share a clear perspective on the planned course of treatment.

Table 17-14 Diagnostic Studies for Breast Cancer Patients					
	Cancer Stage				
	0	I	II	III	IV
History & physical	X	X	X	X	X
Complete blood count, platelet count		X	X	X	X
Liver function tests and alkaline phosphatase level		X	X	X	X
Chest radiograph		X	X	X	X
Bilateral diagnostic mammograms, ultrasound as indicated	X	X	X	X	X
Hormone receptor status		X	X	X	X
HER-2/ <i>neu</i> expression		X	X	X	X
Bone scan ^a			X	X	X
Abdominal (without or without pelvis) computed tomographic scan or ultrasound or magnetic resonance imaging			X	X	X

^a Bone scan performed for stage II only if localized symptoms are present or serum alkaline phosphatase level is elevated. Abdominal imaging and bone scanning are indicated for evaluation of symptoms or abnormal laboratory test results at any presenting stage.

In Situ Breast Cancer (Stage 0)

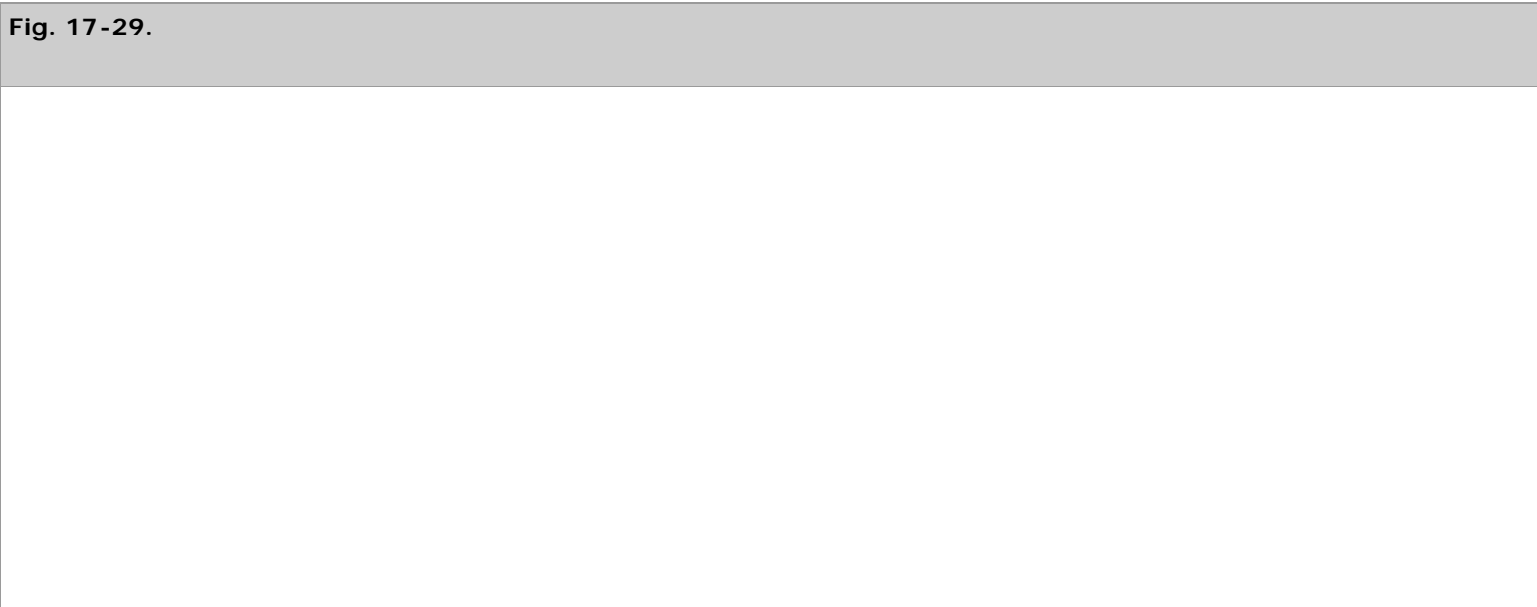

Both LCIS and DCIS may be difficult to distinguish from atypical hyperplasia or from cancers with early invasion.^{50,129–134} Expert pathologic review is required in all cases. Bilateral mammography is performed to determine the extent of the in situ cancer and to exclude a second cancer. Because LCIS is considered a marker for increased risk rather than an inevitable precursor of invasive disease, the current treatment options for LCIS include observation, chemoprevention with tamoxifen, and bilateral total mastectomy. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently

develops in 25 to 35% of these women. There is no benefit to excising LCIS, because the disease diffusely involves both breasts in many cases and the risk of invasive cancer is equal for both breasts. The use of tamoxifen as a risk reduction strategy should be considered in women with a diagnosis of LCIS.

Women with DCIS and evidence of extensive disease (>4 cm of disease or disease in more than one quadrant) usually require mastectomy. For women with limited disease, lumpectomy and radiation therapy are recommended. Low-grade DCIS of the solid, cribriform, or papillary subtype that is <0.5 cm in diameter may be managed by lumpectomy alone without radiation if the margins of resection are widely free of disease. For nonpalpable DCIS, needle localization techniques are used to guide the surgical resection. Specimen mammography is performed to ensure that all visible evidence of cancer is excised. Adjuvant tamoxifen therapy is considered for DCIS patients. The gold standard against which breast conservation therapy for DCIS is evaluated is mastectomy. Women treated with mastectomy have local recurrence and mortality rates of <2%. Women treated with lumpectomy and adjuvant radiation therapy have a similar mortality rate, but the local recurrence rate increases to 9%. Forty-five percent of these recurrences will be invasive cancer when radiation therapy is not used. The use of radiation therapy markedly decreases the risk of in-breast recurrence and significantly reduces the risk that any recurrence will be invasive disease. Both Lagios and Gump noted that recurrence of DCIS was greatest when the cancers were >2.5 cm in size, the criteria for histologic confirmation of clear margins were not rigorously applied, and the DCIS was of the comedo type. They noted that recurrences frequently occurred within the original surgery site, which indicates that inadequate clearance of DCIS, rather than the biology of the cancer, was responsible.¹³⁵

Early Invasive Breast Cancer (Stage I, IIA, or IIB)

NSABP B-06 compared total mastectomy to lumpectomy with or without radiation therapy in the treatment of women with stage I and II breast cancer.^{136–143} After 5- and 8-year follow-up periods, the disease-free, distant disease-free, and overall survival rates for lumpectomy with or without radiation therapy were similar to those observed after total mastectomy. However, the incidence of ipsilateral breast cancer recurrence (in-breast recurrence) was higher in the lumpectomy group not receiving radiation therapy. These findings supported the use of lumpectomy and radiation therapy in the treatment of stage I and II breast cancer. Reanalysis of the study results was undertaken after 20 years of follow-up. The reanalysis confirmed that there was no difference in disease-free survival rates after total mastectomy or after lumpectomy with or without adjuvant radiation therapy. The in-breast recurrence rate was higher in the lumpectomy alone group (39.2%) than in the lumpectomy plus adjuvant radiation therapy group (14.3%). These findings are detailed in Fig. 17-29.

Results of the National Surgical Adjuvant Breast and Bowel Project B-06 trial. Life-table analysis showing the incidence of recurrent cancer in the ipsilateral breast after lumpectomy or lumpectomy with adjuvant radiation therapy in 1137 patients with clear surgical margins.

(Reproduced with permission from Fisher B, Anderson S: Reanalysis and results after 12 years of follow-up in a randomized clinical trial comparing total mastectomy with lumpectomy with or without irradiation in the treatment of breast cancer. *N Engl J Med* 333:1456, 1995. Copyright © Massachusetts Medical Society. All rights reserved.)

Currently, mastectomy with assessment of axillary lymph node status and breast conserving surgery with assessment of axillary lymph node status and radiation therapy are considered equivalent treatments for patients with stage I and II breast cancer. Axillary lymphadenopathy confirmed to be metastatic disease or metastatic disease in a sentinel lymph node (see later) necessitates an axillary lymph node dissection. Breast conservation is considered for all patients because of the important cosmetic advantages. Relative contraindications to breast conservation therapy include (a) prior radiation therapy to the breast or chest wall, (b) involved surgical margins or unknown margin status after re-excision, (c) multicentric disease, and (d) scleroderma or lupus erythematosus.

Traditionally, dissection of the level I and II axillary lymph nodes has been performed in early invasive breast cancer. Sentinel lymph node dissection is now considered the standard for evaluation of the axillary lymph node status in women who have clinically negative lymph nodes. Candidates for this procedure have clinically uninvolved axillary lymph nodes with a T1 or T2 primary breast cancer. Controversy remains about the suitability of sentinel node dissection in women with larger primary tumors (T3) and those treated with neoadjuvant chemotherapy.¹⁴⁴ If the sentinel lymph node cannot be identified or is found to harbor metastatic disease, then an axillary lymph node dissection should be performed.

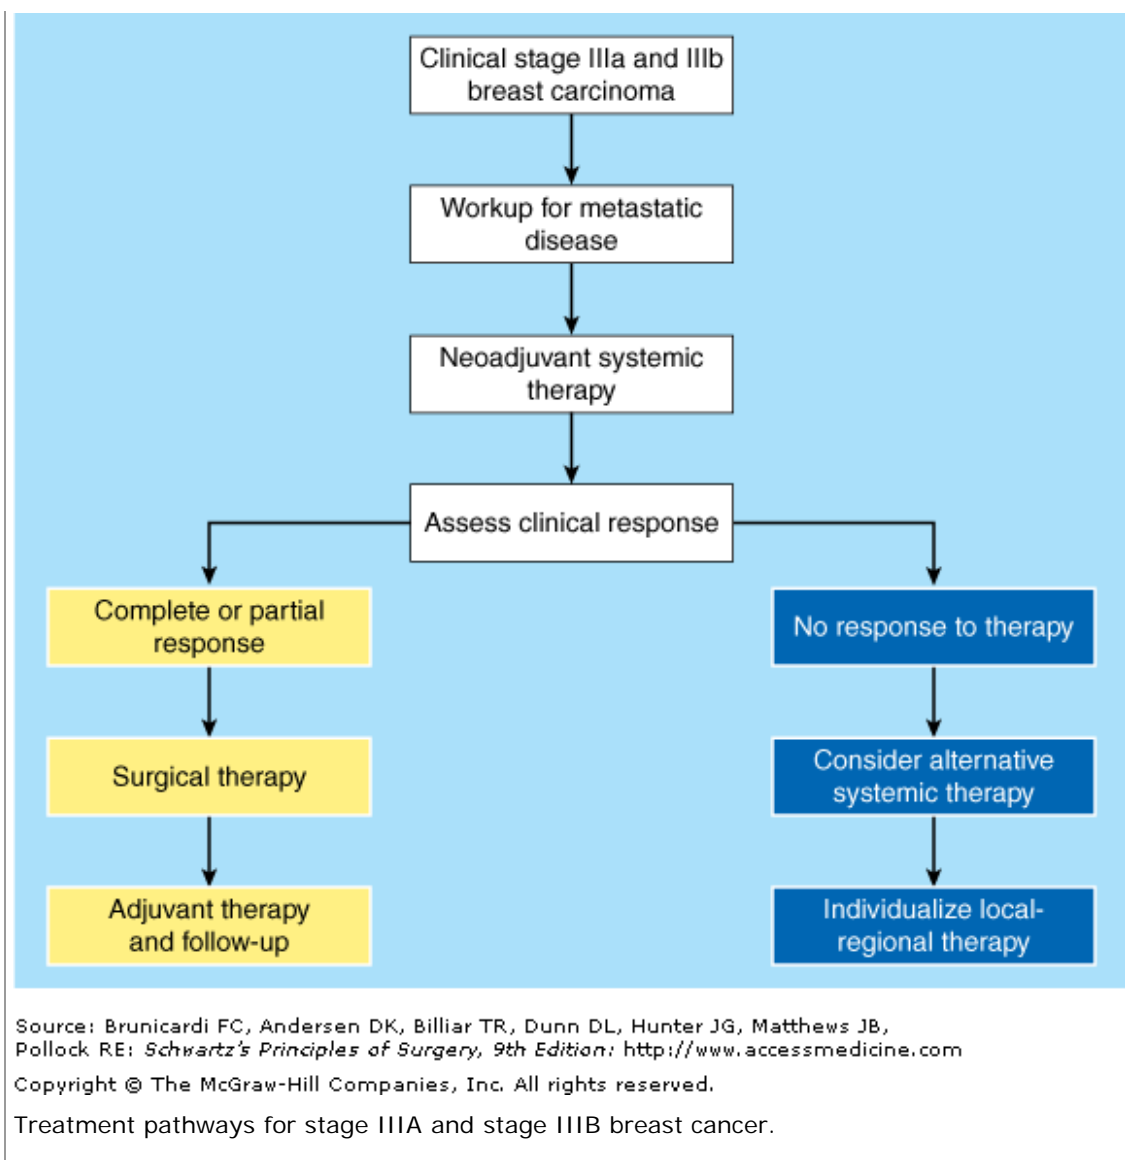

Adjuvant chemotherapy for patients with early invasive breast cancer is considered for all patients with node-positive cancers, all patients with cancers that are >1 cm, and patients with node-negative cancers of >0.5 cm when adverse prognostic features are present. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, HER-2/*neu* overexpression, and negative hormone receptor status. Tamoxifen therapy is considered for women with hormone receptor-positive cancers that are >1 cm. HER-2/*neu* expression is determined for all patients with newly diagnosed breast

cancer and may be used to provide prognostic information in patients with node-negative breast cancer and predict the relative efficacy of various chemotherapy regimens. Trastuzumab is the only HER-2/*neu*-targeted agent that is currently approved for use in the metastatic and the adjuvant setting. The FDA approved trastuzumab in November 2006 for use as part of a treatment regimen containing doxorubicin, cyclophosphamide, and paclitaxel for treatment of HER-2/*neu*-positive, node-positive breast cancer.

Advanced Local-Regional Breast Cancer (Stage IIIA or IIIB)

Women with stage IIIA and IIIB breast cancer have advanced local-regional breast cancer but have no clinically detected distant metastases.¹⁴⁵ In an effort to provide optimal local-regional disease-free survival as well as distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy (Fig. 17-30). Neoadjuvant chemotherapy should be considered in the initial management of all patients with locally advanced stage III breast cancer. Surgical therapy for women with stage III disease is usually a modified radical mastectomy, followed by adjuvant radiation therapy. Chemotherapy is used to maximize distant disease-free survival, whereas radiation therapy is used to maximize local-regional disease-free survival. In selected patients with stage IIIA cancer, neoadjuvant (preoperative) chemotherapy can reduce the size of the primary cancer and permit breast-conserving surgery. Investigators from the M. D. Anderson Cancer Center reported that low local-regional failure rates could be achieved in selected patients with stage III disease treated with neoadjuvant chemotherapy followed by breast-conserving surgery and radiation.¹⁴⁶ The 5-year actuarial ipsilateral breast tumor recurrence-free survival rates in this study were 95%. They noted that the ipsilateral breast tumor recurrence rates increased when patients had clinical N2 or N3 disease, >2 cm of residual disease in the breast at surgery, a pattern of multifocal residual disease in the breast at surgery, and lymphovascular space invasion in the primary tumor. This study and others demonstrate that breast-conserving surgery can be used for appropriately selected patients with locally advanced breast cancer who achieve a good response with neoadjuvant chemotherapy. For patients with stage IIIA disease who experience minimal response to chemotherapy and for patients with stage IIIB breast cancer, neoadjuvant chemotherapy can decrease the local-regional cancer burden enough to permit subsequent modified radical mastectomy to establish local-regional control. In both stage IIIA and IIIB disease, surgery is followed by adjuvant radiation therapy.

Internal Mammary Lymph Nodes

Metastatic disease to internal mammary lymph nodes may be occult, may be evident on chest radiograph or CT scan, or may present as a painless parasternal mass with or without skin involvement. There is no consensus regarding the need for internal mammary lymph node radiation therapy in women who are at increased risk for occult involvement (cancers involving the medial aspect of the breast, axillary lymph node involvement) but who show no signs of internal mammary lymph node involvement. Systemic chemotherapy and radiation therapy are indicated in the treatment of grossly involved internal mammary lymph nodes.

Distant Metastases (Stage IV)

Treatment for stage IV breast cancer is not curative but may prolong survival and enhance a woman's quality of life.¹⁴⁷ Hormonal therapies that are associated with minimal toxicity are preferred to cytotoxic chemotherapy. Appropriate candidates for initial hormonal therapy include women with hormone receptor–positive cancers; women with bone or soft tissue metastases only; and women with limited and asymptomatic visceral metastases. Systemic chemotherapy is indicated for women with hormone receptor–negative cancers, symptomatic visceral metastases, and hormone-refractory metastases. Women with stage IV breast cancer may develop anatomically localized problems that will benefit from individualized surgical treatment, such as brain metastases, pleural effusion, pericardial effusion, biliary obstruction, ureteral obstruction, impending or existing pathologic fracture of a long bone, spinal cord compression, and painful bone or soft tissue metastases. Bisphosphonates, which may be

given in addition to chemotherapy or hormone therapy, should be considered in women with bone metastases. Whether to perform surgical resection of the local-regional disease in women with stage IV breast cancer has recently been debated after several reports have suggested that women who undergo resection of the primary disease have improved survival over those who do not. Khan and associates used the National Cancer Data Base to identify patterns of treatment in women with metastatic breast cancer and found that those who had surgical resection with negative margins had a better prognosis than those women who did not have surgical therapy.¹⁴⁸ Gnerlich and colleagues reported similar findings using the SEER database, and there have been several reports subsequent to this study from single institutions that have confirmed these findings.¹⁴⁹ Some have suggested that the findings of improved survival are due to selection bias and that local therapy should be reserved for palliation of symptoms. A proposal has recently gone forward to study this question in a randomized fashion through the Breast Cancer Intergroup of North America. In the meantime, surgical management of patients with stage IV disease should be addressed by obtaining multidisciplinary input and by considering the treatment goals of each individual patient and the patient's treating physicians.

Local-Regional Recurrence

Women with local-regional recurrence of breast cancer may be separated into two groups: those who have had mastectomy and those who have had lumpectomy. Women treated previously with mastectomy undergo surgical resection of the local-regional recurrence and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered, and adjuvant radiation therapy is given if the chest wall has not previously received radiation therapy. Women treated previously with a breast conservation procedure undergo a mastectomy and appropriate reconstruction. Chemotherapy and antiestrogen therapy are considered.

Breast Cancer Prognosis

Survival rates for women diagnosed with breast cancer between 1983 and 1987 have been calculated based on SEER program data. The 5-year survival rate for patients with stage I disease is 94%; for patients with stage IIA disease, 85%; and for patients with stage IIB tumors, 70%. For patients with stage IIIA disease the 5-year survival rate is 52%; for patients with stage IIIB cancers, 48%; and for patients with stage IV tumors, 18%. Breast cancer survival has significantly increased over the past 2 decades due to improvements in screening and local and systemic therapies. Data from the American College of Surgeons National Cancer Data Base indicate the 5-year survival for patients with stage I cancer to be 100%; for those with stage IIA tumors, 92%; for those with stage IIB disease, 81%; for patients with stage IIIA cancers, 67%; and for those with stage IIIB disease, 54%.¹⁵⁰

SURGICAL TECHNIQUES IN BREAST CANCER THERAPY

Excisional Biopsy with Needle Localization

Excisional biopsy implies complete removal of a breast lesion with a margin of normal-appearing breast tissue. In the past, surgeons would obtain prior consent from the patient allowing mastectomy if the initial biopsy results confirmed cancer. Today it is important to consider the options for local therapy (lumpectomy vs. mastectomy with or without reconstruction) and the need for nodal assessment with sentinel node dissection. Figure 17-31 illustrates methods of obtaining a cosmetically acceptable breast scar. Excellent scars generally result from circumareolar incisions through which subareolar and centrally located breast lesions may be approached. Elsewhere, incisions that parallel Langer's lines, which are lines of tension in the skin that are generally concentric with the nipple-areola complex, result in acceptable scars except in the lower half of the breast, where the use of radial incisions typically provides the best outcome. Whenever possible, the surgeon should consider keeping the biopsy incision within the boundaries of the skin excision that may be required as part of a subsequent mastectomy (Fig. 17-32). When

the tumor is quite distant from the central breast, the biopsy incision can be excised separately from the primary mastectomy incision, should a mastectomy be required. Radial incisions in the upper half of the breast are not recommended because of possible scar contracture resulting in displacement of the ipsilateral nipple-areola complex. Similarly, curvilinear incisions in the lower half of the breast may displace the nipple-areolar complex downward.

Placement of breast biopsy incisions. Breast biopsy incisions are positioned within the boundaries of subsequent mastectomy skin incisions, and their placement allows for 1-cm or larger margins around the biopsy scar.

(Reproduced with permission from Souba et al,¹⁵⁷ p 802. Copyright Elsevier.)

After excision of a suspicious breast lesion, the biopsy tissue specimen is orientated for the pathologist using sutures, clips, or dyes. Additional margins (superior, inferior, medial, lateral, superficial, and deep) may be taken from the surgical bed to confirm complete excision of the suspicious lesion. Electrocautery or absorbable ligatures are used to achieve wound hemostasis. Although approximation of the breast tissues in the excision bed is usually not necessary, cosmesis may occasionally be facilitated by approximation of the surgical defect using 3-0 absorbable sutures. A running subcuticular closure of the skin using 4-0 or 5-0 absorbable monofilament sutures is performed, followed by approximation of the skin edges with adhesive skin closure strips (Steri-Strips). Wound drainage is avoided.

Excisional biopsy with needle localization requires a preoperative visit to the mammography suite for placement of a localization wire. The lesion can also be targeted by sonography in the imaging suite or in the operating room. The lesion to be excised is accurately localized by mammography, and the tip of a thin wire hook is positioned close to the lesion (Fig. 17-33). Using the wire hook as a guide, the surgeon subsequently excises the suspicious breast lesion while removing a margin of normal-appearing breast tissue. Before the patient leaves the operating room, specimen radiography is performed to confirm complete excision of the suspicious lesion (Fig. 17-34).

Sentinel Lymph Node Dissection

Sentinel lymph node dissection is primarily used to assess the regional lymph nodes in women with early breast cancers who are clinically node negative by physical examination and imaging studies.^{151–159} This method also is accurate in women with larger tumors (T3 N0), but nearly 75% of these women will prove to have axillary lymph node metastases on histologic examination. A recent publication of the American Society of Clinical Oncology made recommendations for the use of sentinel lymph node dissection in patients with early-stage breast cancer.¹⁴⁴ To develop practice guidelines analysts used data from one prospective randomized trial comparing sentinel node dissection with axillary node dissection, four meta-analyses, and published results from 69 single-institution and multicenter trials in which sentinel node dissection test performance was evaluated along with axillary node dissection. The American Society of Clinical Oncology guidelines did not recommend using sentinel node dissection in patients with T3, T4, or inflammatory breast cancers because the current level of evidence was felt to be insufficient. Other clinical situations in which the guidelines recommended against the use of sentinel node dissection included cases involving palpable axillary lymphadenopathy, pregnancy, DCIS without mastectomy, prior axillary surgery, or prior nononcologic breast surgery, and after preoperative chemotherapy. Although limited data are available, it was felt that sentinel node dissection was acceptable under the circumstances of multicentric tumors, DCIS with mastectomy, older age, obesity, male breast cancer, need for evaluation of internal mammary lymph nodes, and prior diagnostic or excisional biopsy, and before the use of preoperative systemic chemotherapy.

Evidence from large prospective studies suggests that the combination of intraoperative gamma probe detection of radioactive

colloid and intraoperative visualization of isosulfan blue dye (Lymphazurin) is more accurate for identification of sentinel nodes than the use of either agent alone. Some surgeons use preoperative lymphoscintigraphy, although it is not required for identification of the sentinel nodes. On the day before surgery, or the day of surgery, the radioactive colloid is injected either in the breast parenchyma around the primary tumor or prior biopsy site or into the subareolar region or subdermally in proximity to the primary tumor site. With a 25-gauge needle, 0.5 mCi of 0.2- μ m technetium 99m-labeled sulfur colloid is injected for same-day surgery or a higher dose of 2.5 mCi of technetium-labeled sulfur colloid is administered when the isotope is to be injected on the day before surgery. Subdermal injections are given in proximity to the cancer site or in the subareolar location. Later, in the operating room, 3 to 5 mL of isosulfan blue dye is injected either in the breast parenchyma or in the subareolar location. It is not recommended that the blue dye be used in a subdermal injection because this can result in tattooing of the skin. For nonpalpable cancers, the injection of the technetium-labeled sulfur colloid solution can be guided by either intraoperative ultrasound or by a localization wire that is placed preoperatively under ultrasound or stereotactic guidance. It is helpful for the radiologist to mark the skin overlying the breast cancer at the time of needle localization using an indelible marker. In women who have undergone previous excisional biopsy, the injections are made in the breast parenchyma around the biopsy cavity but not into the cavity itself. Women are told preoperatively that the isosulfan blue dye injection will cause a change in the color of their urine and that there is a very small risk of allergic reaction to the dye (1 in 10,000). Anaphylactic reactions have been documented. The use of radioactive colloid is safe, and radiation exposure is very low.

A hand-held gamma counter is used to transcutaneously identify the location of the sentinel lymph node. This can help to guide placement of the incision. A 3- to 4-cm incision is made in line with that used for an axillary dissection, which is a curved transverse incision in the lower axilla just below the hairline. After dissecting through the subcutaneous tissue, the surgeon dissects through the axillary fascia, being mindful to identify blue lymphatic channels. Following these channels can lead directly to the sentinel node and limit the amount of dissection through the axillary tissues. The gamma counter is used to facilitate the dissection and to pinpoint the location of the sentinel lymph node. As the dissection continues, the signal from the probe increases in intensity as the sentinel lymph node is approached. The sentinel lymph node also is identified by visualization of isosulfan blue dye in the afferent lymph vessel and in the lymph node itself. Before the sentinel lymph node is removed, a 10-second in vivo radioactivity count is obtained. After removal of the sentinel lymph node, a 10-second ex vivo radioactive count is obtained, and the lymph node is then sent to the pathology laboratory for either permanent- or frozen-section analysis. The lowest false-negative rates for sentinel lymph node dissection have been obtained when all blue lymph nodes and all lymph nodes with radiation counts >10% of the 10-second ex vivo count of the sentinel lymph node are harvested (10% rule). Based on this, the gamma counter is used before closing the axillary wound to measure residual radioactivity in the surgical bed. A search is made for additional sentinel lymph nodes. This procedure is repeated until residual radioactivity in the surgical bed is less than 10% of the 10-second ex vivo count of the most radioactive sentinel lymph node and all blue nodes have been removed.

Results from the NSABP B-32 randomized trial on the technical aspects of sentinel node surgery were recently published.¹⁶⁰ This trial compared sentinel node dissection alone with sentinel node dissection plus immediate axillary dissection in women with early-stage breast cancer. The overall success rate for identification of a sentinel node was 97.2%. The false-negative rate was reported to be 9.8% and was influenced by tumor location, type of diagnostic biopsy, and number of sentinel nodes removed at surgery. The authors reported that tumors located in the lateral breast were more likely to have a false-negative sentinel node. This may be explained by difficulty in discriminating the hot spot in the axilla when the radioisotope has been injected at the primary tumor site in the lateral breast. Those patients who had undergone an excisional biopsy before the sentinel node procedure were significantly more likely to have a false-negative sentinel node. This report further confirms that surgeons should use needle biopsy for diagnosis whenever possible and reserve excisional biopsy for the rare situations in which needle biopsy

findings are nondiagnostic. Finally, removal of a larger number of sentinel nodes at surgery appears to reduce the false-negative rate. In the NSABP B-32 trial, the false-negative rate was reduced from 17.7 to 10% when two sentinel nodes were recovered and to 6.9% when three sentinel nodes were removed. Yi and associates recently reported that the number of sentinel nodes that need to be removed for accurate staging is influenced by individual patient and primary tumor factors.¹⁶¹

Investigators in the NSABP B-32 trial reported finding sentinel nodes outside of the level I and II axillary nodes in 1.4% of cases. This finding was significantly influenced by the site of radioisotope injection. When a subareolar or periareolar injection site was used, there were no instances of sentinel nodes identified outside of the level I or II axilla, compared with a rate of 20% when a peritumoral injection was used. This supports the overall concept that the sentinel node is the first site of drainage from the lymphatic vessels of the primary tumor. Although many patients will have similar drainage patterns from injections given at the primary tumor site and at the subareolar plexus, some patients will have extra-axillary drainage, either alone or in combination with axillary node drainage, and this is best assessed with a peritumoral injection of the radioisotope.

The morbidity of sentinel node dissection alone vs. sentinel node dissection with a completion axillary node dissection has been reported by investigators from the American College of Surgeons Oncology Group Z0010 and Z0011 trials.^{162,163} Immediate effects of sentinel node dissection alone in the Z0010 trial included wound infection in 1%, axillary seroma in 7.1%, and axillary hematoma in 1.4%.¹⁶² At 6 months after surgery, axillary paresthesias were reported in 8.6% of patients, decreased range of motion in the upper extremity was present in 3.8%, and 6.9% had a change in arm circumference of >2 cm on the affected side, which was reported as lymphedema. Younger patients were more likely to experience paresthesias, whereas increasing age and body mass index were more predictive of lymphedema. When adverse surgical effects were examined in the Z0011 trial, patients who underwent sentinel node dissection with axillary dissection had more wound infections, seromas, and paresthesias than those patients who underwent sentinel node dissection alone. Lymphedema at 1 year after surgery was reported by 13% of patients in the sentinel node plus axillary dissection group but by only 2% in the sentinel node alone group. Arm circumference measurements were greater at 1 year in the group undergoing sentinel node plus axillary dissection, but the difference between the two groups was not statistically significant.¹⁶³

The initial publications from the NSABP and American College of Surgeons Oncology Group multicenter trials provide important information to clinicians regarding the use of sentinel node dissection in early-stage breast cancer patients. Information on recurrence patterns, survival differences, and the impact of micrometastases in the sentinel nodes on outcomes requires further maturation of the data. These trials do not address the use of sentinel node dissection in other patient populations, such as patients with DCIS, patients receiving preoperative chemotherapy, and patients with prior breast or axillary surgery.

Another area of sentinel node technology that requires standardization is the pathologic processing of the sentinel nodes. Most pathology laboratories perform a more detailed analysis of the sentinel nodes than is routinely done for axillary nodes recovered from a level I and II axillary node dissection. This can include examining thin sections of the node with step sectioning at multiple levels through the paraffin blocks or performing immunohistochemical staining of the sentinel node for cytokeratin or a combination of these techniques. Intraoperative assessment of sentinel nodes also varies for different clinicians and pathology laboratories. Some centers prefer to use touch preparation cytologic analysis of the sentinel nodes, whereas others use frozen-section analysis, and the sensitivity and specificity of these assays vary considerably. The GeneSearch Breast Lymph Node Assay is a real-time reverse-transcriptase polymerase chain reaction assay that detects breast tumor cell metastasis in lymph nodes through the identification of the gene expression markers mammaglobin and cytokeratin 19. These markers are present in higher levels in breast tissue and not in nodal tissue (cell type-specific messenger RNA). The GeneSearch assay generates expression data for genes of interest, which are then evaluated against predetermined criteria to provide a qualitative (positive/negative) result. The assay is designed to detect foci that correspond to metastases which are seen with examination by standard

hematoxylin and eosin staining and measure >0.2 mm. The GeneSearch assay results have been compared with permanent-section histologic analysis and frozen-section analysis of sentinel nodes in a prospective trial, and the assay was recently approved by the FDA for the intraoperative assessment of sentinel nodes.¹⁶⁴ When a positive node is identified intraoperatively by touch preparation, frozen-section analysis, or GeneSearch assay, the surgeon can proceed with immediate completion of axillary node dissection. Although there are a number of nomograms and predictive models designed to determine which patients with a positive sentinel node are at risk for harboring additional positive nonsentinel nodes in the axilla, completion axillary dissection remains the standard practice.¹⁶⁵

Breast Conservation

Breast conservation involves resection of the primary breast cancer with a margin of normal-appearing breast tissue, adjuvant radiation therapy, and assessment of regional lymph node status.^{166,167} Resection of the primary breast cancer is alternatively called *segmental mastectomy*, *lumpectomy*, *partial mastectomy*, *wide local excision*, and *tylectomy*. For many women with stage I or II breast cancer, breast-conserving therapy (BCT) is preferable to total mastectomy because BCT produces survival rates equivalent to those after total mastectomy while preserving the breast.¹⁶⁸ Six prospective randomized trials have shown that overall and disease-free survival rates are similar with BCT and mastectomy. Three of the studies showed higher local-regional failure rates in patients undergoing BCT; however, in two of these studies, there were no clear criteria for histologically negative margins.^{166–169} Recent data from the Early Breast Cancer Trialists' Collaborative Group revealed that avoiding local recurrence translates into a survival advantage.¹⁶⁹ When all of this information is taken together, BCT is considered to be oncologically equivalent to mastectomy.

In addition to being equivalent to mastectomy in terms of oncologic safety, BCT appears to offer advantages over mastectomy with regard to quality of life and aesthetic outcomes. BCT allows for preservation of breast shape and skin as well as preservation of sensation, and provides an overall psychologic advantage associated with breast preservation.

Breast conservation surgery is currently the standard treatment for women with stage 0, I, or II invasive breast cancer. Women with DCIS require only resection of the primary cancer and adjuvant radiation therapy without assessment of regional lymph nodes. When a lumpectomy is performed, a curvilinear incision lying concentric to the nipple-areola complex is made in the skin overlying the breast cancer when the tumor is in the upper aspect of the breast. Radial incisions are preferred when the tumor is in the lower aspect of the breast. Skin encompassing any prior biopsy site generally is excised, but skin excision is not otherwise necessary unless there is direct involvement of the overlying skin by the primary tumor. The breast cancer is removed with an envelope of normal-appearing breast tissue that is adequate to achieve at least a 2-mm cancer-free margin. Specimen orientation is performed by the surgeon. Additional margins from the surgical bed are taken as needed to provide a histologically negative margin. Requests for determination of hormone receptor status and HER-2/*neu* expression are conveyed to the pathologist.

Sentinel lymph node dissection is now the preferred staging procedure with a clinically node-negative axilla. When the procedures are sequenced in the operating room, the sentinel node procedure usually is performed before removal of the primary breast tumor. When indicated, intraoperative assessment of the sentinel node can proceed while the segmental mastectomy is being performed. When the sentinel lymph node does not contain metastatic disease, axillary lymph node dissection is avoided. It is the surgeon's responsibility to ensure complete removal of cancer in the breast. Ensuring surgical margins that are free of breast cancer will minimize the chances of local recurrence and will enhance cure rates. Local recurrence of breast cancer after conservation surgery is determined primarily by the adequacy of surgical margins. Cancer size and the extent of skin excision are not significant factors in this regard. It is the practice of many North American and European surgeons to undertake re-excision when residual cancer within 2 mm of a surgical margin is determined by histopathologic examination. If clear margins are not

obtainable with re-excision, mastectomy is required.

The use of oncoplastic surgery can be entertained at the time of segmental mastectomy or at a later time to improve the overall aesthetic outcome. Oncoplastic techniques range from a simple reshaping of breast tissue to local tissue rearrangement to the use of pedicled flaps or breast reduction techniques. The overall goal is to achieve the best possible aesthetic result. In determining which patients are candidates for oncoplastic breast surgery, several factors should be considered, including the extent of the resection of breast tissue necessary to achieve negative margins, the location of the primary tumor within the breast, and the size of the patient's breast and body habitus. Oncoplastic techniques are of prime consideration when (a) a significant area of breast skin will need to be resected with the specimen to achieve negative margins; (b) a large volume of breast parenchyma will be resected resulting in a significant defect; (c) the tumor is located between the nipple and the inframammary fold, an area often associated with unfavorable cosmetic outcomes; or (d) excision of the tumor and closure of the breast may result in malpositioning of the nipple.

Mastectomy and Axillary Dissection

A skin-sparing mastectomy removes all breast tissue, the nipple-areola complex, and scars from any prior biopsy procedures.^{170,171} There is a recurrence rate of less than 6 to 8%, comparable to the long-term recurrence rates reported with standard mastectomy, when skin-sparing mastectomy is used for patients with T1 to T3 cancers. A total (simple) mastectomy without skin sparing removes all breast tissue, the nipple-areola complex, and skin. An extended simple mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I axillary lymph nodes. A modified radical mastectomy removes all breast tissue, the nipple-areola complex, skin, and the level I and level II axillary lymph nodes. The Halsted radical mastectomy removes all breast tissue and skin, the nipple-areola complex, the pectoralis major and pectoralis minor muscles, and the level I, II, and III axillary lymph nodes. The use of systemic chemotherapy and hormonal therapy as well as adjuvant radiation therapy for breast cancer have nearly eliminated the need for the radical mastectomy.

For a variety of biologic, economic, and psychosocial reasons, some women desire mastectomy rather than breast conservation. Women who are less concerned about cosmesis may view mastectomy as the most expeditious and desirable therapeutic option because it avoids the cost and inconvenience of radiation therapy. Women whose primary breast cancers cannot be excised with a reasonable cosmetic result or those who have extensive microcalcifications are best treated with mastectomy. Women with large cancers that occupy the subareolar and central portions of the breast and women with multicentric primary cancers also undergo mastectomy.

MODIFIED RADICAL MASTECTOMY

A modified radical mastectomy preserves both the pectoralis major and pectoralis minor muscles, allowing removal of level I and level II axillary lymph nodes but not the level III (apical) axillary lymph nodes (Figs. 17-35 and 17-36).¹⁷⁰ The Patey modification removes the pectoralis minor muscle and allows complete dissection of the level III axillary lymph nodes (Figs. 17-37 and 17-38). A modified radical mastectomy permits preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and usually penetrates the pectoralis minor to supply the lateral border of the pectoralis major. Anatomic boundaries of the modified radical mastectomy are the anterior margin of the latissimus dorsi muscle laterally, the midline of the sternum medially, the subclavius muscle superiorly, and the caudal extension of the breast 2 to 3 cm inferior to the inframammary fold inferiorly (see Fig. 17-35 *inset*). Skin-flap thickness varies with body habitus but ideally is 7 to 8 mm inclusive of skin and tela subcutanea. Once the skin flaps are fully developed, the fascia of the pectoralis major muscle and the overlying breast tissue are elevated off the underlying musculature, which allows for the complete removal of the breast.

Modified radical mastectomy (Patey): axillary lymph node dissection. The dissection proceeds from lateral to medial, with complete visualization of the anterior and inferior aspects of the axillary vein. Loose areolar tissue at the junction of the axillary vein and the anterior margin of the latissimus dorsi muscle is swept inferomedially inclusive of the lateral (axillary) lymph node group (level I). Care is taken to preserve the thoracodorsal artery, vein, and nerve in the deep axillary space. The lateral lymph node group is resected in continuity with the subscapular lymph node group (level I) and the external mammary lymph node group (level I). Dissection anterior to the axillary vein allows removal of the central lymph node group (level II) and the apical (subclavicular) lymph node group (level III). The superomedial limit of this dissection is the clavipectoral fascia (Halsted's ligament). *Inset* depicts division of the insertion of the pectoralis minor muscle at the coracoid process. The surgeon's finger shields the underlying brachial plexus.

Modified radical mastectomy (Patey): completed dissection. The completed dissection includes the pectoralis minor muscle from its insertion to its origin from the second to fifth ribs. Rotter's lymph nodes (level I) are left attached to the pectoralis minor muscle as it is removed. Both medial and lateral pectoral nerves are preserved to ensure innervation of the lateral and medial heads (respectively) of the pectoralis major muscle. *Inset* depicts the positioning of closed-suction catheters, which are brought out through the inferior flap. The lateral catheter is placed 2 cm inferior to the axillary vein. The medial catheter is positioned anterior to the pectoralis major muscle.

(Reproduced with permission from Bland et al,¹⁷⁰ p 909. Copyright Elsevier.)

Subsequently, an axillary lymph node dissection is performed. The most lateral extent of the axillary vein is identified and the areolar tissue of the lateral axillary space is elevated as the vein is cleared on its anterior and inferior surfaces. The areolar tissues at the junction of the axillary vein and the anterior edge of the latissimus dorsi muscle, which include the lateral and subscapular lymph node groups (level I), are cleared in an inferomedial direction. Care is taken to preserve the thoracodorsal neurovascular bundle. The dissection then continues medially with clearance of the central axillary lymph node group (level II). The long thoracic nerve of Bell is identified and preserved as it travels in the investing fascia of the serratus anterior muscle. Every effort is made to preserve this nerve, because permanent disability with a winged scapula and shoulder weakness will follow denervation of the serratus anterior muscle. If there is palpable lymphadenopathy at the apex of the axilla, the tendinous portion of the pectoralis minor muscle is divided near its insertion onto the coracoid process (see Fig. 17-37 *inset*), which allows dissection of the axillary vein medially to the costoclavicular (Halsted's) ligament. Finally, the breast and axillary contents are removed from the surgical bed and are sent for pathologic assessment. The Patey modification originally involved removal of the pectoralis muscle (see Fig. 17-38). However, some surgeons now divide only the tendon of the pectoralis minor muscle at its insertion onto the coracoid process while leaving the rest of the muscle intact.

Seromas beneath the skin flaps or in the axilla represent the most frequent complication of mastectomy and axillary lymph node

dissection, reportedly occurring in as many as 30% of cases. The use of closed-system suction drainage reduces the incidence of this complication. Catheters are retained in the wound until drainage diminishes to <30 mL per day. Wound infections occur infrequently after a mastectomy and the majority are a result of skin-flap necrosis. Cultures of specimens taken from the infected wound for aerobic and anaerobic organisms, débridement, and antibiotic therapy are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed with early wound exploration for control of hemorrhage and re-establishment of closed-system suction drainage. The incidence of functionally significant lymphedema after a modified radical mastectomy is 10 to 20%. Extensive axillary lymph node dissection, the delivery of radiation therapy, the presence of pathologic lymph nodes, and obesity are predisposing factors. The use of individually fitted compressive sleeves and intermittent compression devices may be necessary.

Reconstruction of the Breast and Chest Wall

The goals of reconstructive surgery after a mastectomy for breast cancer are wound closure and breast reconstruction, which is either immediate or delayed.¹⁷² For most women, wound closure after mastectomy is accomplished with simple approximation of the wound edges. However, if a more radical removal of skin and subcutaneous tissue is necessary, a pedicled myocutaneous flap from the latissimus dorsi muscle is generally the best approach for wound coverage. A skin graft provides functional coverage that will tolerate adjuvant radiation therapy; however, this is not preferred, because poor graft adherence may delay delivery of radiation therapy. Breast reconstruction after prophylactic mastectomy or after mastectomy for early invasive breast cancer is performed at the same time as the mastectomy. This allows for a skin-sparing mastectomy to be performed, which offers the best overall cosmetic outcomes. Reconstruction can proceed with an expander/implant reconstruction or with autologous tissue such as a pedicled myocutaneous flap or a free flap using microvascular techniques. In patients with advanced breast cancer reconstruction is delayed until after completion of adjuvant radiation therapy to ensure that local-regional control of disease is obtained. If chest wall coverage is needed to replace a large skin or soft tissue defect, many different types of myocutaneous flaps are employed, but the latissimus dorsi and the rectus abdominus myocutaneous flaps are most frequently used. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. A transverse rectus abdominis myocutaneous (TRAM) flap consists of a skin paddle based on the underlying rectus abdominis muscle, which is supplied by vessels from the deep inferior epigastric artery. The free TRAM flap uses microvascular anastomoses to establish blood supply to the flap. When the bony chest wall is involved with cancer, resection of a portion of the bony chest wall is indicated. If only one or two ribs are resected and soft tissue coverage is provided, reconstruction of the bony defect is usually not necessary, because scar tissue will stabilize the chest wall. If more than two ribs are sacrificed, it is advisable to stabilize the chest wall with prosthetic material, which is then covered with soft tissue by using a latissimus dorsi or TRAM flap.

NONSURGICAL BREAST CANCER THERAPIES

Radiation Therapy

Radiation therapy is used for all stages of breast cancer depending on whether the patient is undergoing BCT or mastectomy.^{173–179} For women with limited DCIS (stage 0) in whom negative margins are achieved by segmental mastectomy, adjuvant radiation therapy is given to reduce the risk of local recurrence. Low-grade DCIS of the solid, cribriform, or papillary subtypes that is <0.5 cm in diameter and is excised with widely negative margins may be managed by excision alone. For women with stage I, IIA, or IIB breast cancer in which negative margins are achieved by segmental mastectomy, adjuvant radiation therapy is given to reduce the risk of local recurrence. Those women treated with mastectomy who have cancer at the surgical margins are at sufficiently high risk for local recurrence to warrant the use of adjuvant radiation therapy to the chest wall and

supraclavicular lymph nodes. Women with metastatic disease involving four or more axillary lymph nodes and premenopausal women with metastatic disease involving one to three lymph nodes also are at increased risk for recurrence and are candidates for the use of chest wall and supraclavicular lymph node radiation therapy. In advanced local-regional breast cancer (stage IIIA or IIIB), women are at high risk for recurrent disease after surgical therapy, and adjuvant radiation therapy is used to reduce the recurrence rates (Fig. 17-39). Current recommendations for stages IIIA and IIIB breast cancer are (a) adjuvant radiation therapy to the breast and supraclavicular lymph nodes after neoadjuvant chemotherapy and segmental mastectomy with or without axillary lymph node dissection, (b) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after neoadjuvant chemotherapy and mastectomy with or without axillary lymph node dissection, and (c) adjuvant radiation therapy to the chest wall and supraclavicular lymph nodes after segmental mastectomy or mastectomy with axillary lymph node dissection and adjuvant chemotherapy.

The use of partial breast irradiation (PBI) for patients treated with breast-conserving surgery is currently being compared with whole-breast irradiation in a phase III randomized trial. PBI can be delivered via brachytherapy, external beam radiation therapy using three-dimensional conformal radiation, or intensity-modulated radiation therapy. Although initial results are promising in highly selected low-risk populations, PBI should be used in the clinical setting only as part of a prospective trial.

Chemotherapy

ADJUVANT CHEMOTHERAPY

The Early Breast Cancer Trialists' Collaborative Group overview analysis of adjuvant chemotherapy demonstrated reductions in the odds of recurrence and of death in women ≤ 70 years of age with stage I, IIA, or IIB breast cancer.^{180–185} For those ≥ 70 years of age, the lack of definitive clinical trial data regarding adjuvant chemotherapy prevented definitive recommendations. Adjuvant chemotherapy is of minimal benefit to women with negative nodes and cancers ≤ 0.5 cm in size and is not recommended. Women with negative nodes and cancers 0.6 to 1.0 cm are divided into those with a low risk of recurrence and those with unfavorable prognostic features that portend a higher risk of recurrence and a need for adjuvant chemotherapy. Adverse prognostic factors include blood vessel or lymph vessel invasion, high nuclear grade, high histologic grade, HER-2/*neu* overexpression, and negative hormone receptor status. Adjuvant chemotherapy is recommended for women with these unfavorable prognostic features. Table 17-15 lists the frequently used chemotherapy regimens for breast cancer.

Table 17-15 Adjuvant Chemotherapy Regimens for Breast Cancer	
HER-2/ <i>neu</i> Negative (Non–Trastuzumab-Containing Regimens)	HER-2/ <i>neu</i> Positive (Trastuzumab-Containing Regimens)
FAC/CAF	AC → T + concurrent trastuzumab (T = paclitaxel)
FEC/CEF	
AC or EC	Docetaxel + trastuzumab → FEC
TAC (T = docetaxel)	TCH (docetaxel, carboplatin, trastuzumab)

For women with hormone receptor–negative cancers that are >1 cm in size, adjuvant chemotherapy is appropriate. However, women with node-negative hormone receptor–positive cancers and T1 tumors are candidates for antiestrogen therapy with or without chemotherapy. For special-type cancers (tubular, mucinous, medullary, etc), adjuvant chemotherapy or antiestrogen therapy for cancers <3 cm in size is controversial. For women with node-positive tumors or with a special-type cancer that is >3 cm, the use of chemotherapy is appropriate. Those with hormone receptor–positive tumors should receive antiestrogen therapy as well. Current treatment recommendations for stage IIIA breast cancer include preoperative chemotherapy with a doxorubicin

(Adriamycin)-containing regimen followed by either a modified radical mastectomy or segmental mastectomy with axillary dissection followed by adjuvant radiation therapy. These recommendations are based in part on the results of the NSABP B-15 trial. In this study, women with node-positive, tamoxifen-nonresponsive cancers who were ≤ 59 years of age were randomly assigned to receive either 2 months of therapy with doxorubicin and cyclophosphamide or 6 months of cyclophosphamide, methotrexate, and cyclophosphamide, methotrexate, 5-fluorouracil. There was no difference in relapse-free survival or overall survival rates, and women preferred the shorter regimen.¹⁸⁶

NEOADJUVANT (PREOPERATIVE) CHEMOTHERAPY

In the early 1970s, the National Cancer Institute in Milan, Italy, initiated two prospective randomized multimodality clinical trials for women with T3 or T4 breast cancer.¹⁸⁷ The best results were achieved when surgery was interposed between chemotherapy courses, with 82% local-regional control and 25% 5-year disease-free survival. The NSABP B-18 trial evaluated the role of neoadjuvant chemotherapy in women with operable stage II and III breast cancer.¹⁸⁸ Women entered into this study were randomly assigned to receive either surgery followed by chemotherapy or neoadjuvant chemotherapy followed by surgery. There was no difference in the 5-year disease-free survival rates for the two groups, but after neoadjuvant chemotherapy there was an increase in the number of lumpectomies performed and a decreased incidence of node positivity. It was suggested that neoadjuvant chemotherapy be considered for the initial management of breast cancers judged too large for initial lumpectomy.

The use of neoadjuvant chemotherapy has expanded from its initial use in the setting of large and locally advanced breast cancers to use in any patient who is deemed to be a candidate for systemic chemotherapy based on primary tumor factors or nodal staging. The use of neoadjuvant chemotherapy offers the opportunity to observe the response of the intact primary tumor and any regional nodal metastases to a specific chemotherapy regimen.¹⁸⁹ For patients whose tumors remain stable in size or even progress with the initial neoadjuvant chemotherapy regimen, a new regimen can be instituted that uses another class of agents.

After treatment with neoadjuvant chemotherapy, patients are assessed for clinical and pathologic response to the regimen. Patients whose tumors achieve a pathologic complete response to neoadjuvant chemotherapy have been shown to have survival outcomes far superior to those of patients whose tumors demonstrate only a partial response or remain stable. Patients who experience progression of disease during neoadjuvant chemotherapy have the poorest survival.¹⁹⁰

Current recommendations for treatment of operable advanced local-regional breast cancer are neoadjuvant chemotherapy with a doxorubicin-containing or taxane-containing regimen, followed by mastectomy or lumpectomy with axillary lymph node dissection if necessary, followed by adjuvant radiation therapy. For inoperable stage IIIA and for stage IIIB breast cancer, neoadjuvant chemotherapy is used to decrease the local-regional cancer burden. This may then permit subsequent modified radical or radical mastectomy, which is followed by adjuvant radiation therapy.

Nodal Evaluation in Patients Receiving Neoadjuvant Chemotherapy

The management of the axilla after neoadjuvant chemotherapy has not been specifically addressed in randomized trials. Standard practice has been to perform an axillary lymph node dissection after chemotherapy or to perform a sentinel lymph node dissection before chemotherapy for nodal staging before chemotherapy is initiated. A number of small single-institution studies, one multicenter study, and a recent meta-analysis have explored the use of sentinel lymph node dissection at the completion of chemotherapy. The published results from these studies have demonstrated the feasibility of sentinel lymph node dissection in breast cancer patients after neoadjuvant chemotherapy and have suggested that the procedure is accurate for nodal staging in this patient population.^{191,192} Although the issue has not been specifically addressed in the published trials, the presence of suspected or documented axillary metastases at initial presentation generally is considered a relative

contraindication to sentinel lymph node dissection after neoadjuvant chemotherapy, and these patients usually undergo axillary lymph node dissection after completion of chemotherapy.

NEOADJUVANT ENDOCRINE THERAPY

Neoadjuvant endocrine therapy has most commonly been used in elderly women who were deemed poor candidates for surgery or cytotoxic chemotherapy. However, as clinicians have gained experience with neoadjuvant treatment strategies, it is now clear from examination of predictors of complete pathologic response that estrogen receptor–positive tumors do not shrink in response to chemotherapy as readily as estrogen receptor–negative tumors.¹⁹³ Fisher and colleagues examined the results of the NSABP B-14 and B-20 trials and found that, as age increased, women obtained less benefit from chemotherapy. They recommended that factors¹⁹⁴ including tumor estrogen receptor concentration, nuclear grade, histologic grade, tumor type, and markers of proliferation should be considered in these patients before choosing between the use of chemotherapy and hormonal therapy. If in fact the tumor is estrogen receptor rich, these patients may benefit more from endocrine therapy in the neoadjuvant setting than they might if they received standard chemotherapy. Neoadjuvant endocrine therapy has been shown to shrink tumors, enabling breast-conserving surgery in women with hormone receptor–positive disease who otherwise would have to be treated with mastectomy.

With the use of neoadjuvant chemotherapy or endocrine therapy, observation of the response of the intact tumor and/or nodal metastases to a specific regimen could ultimately help to define which patients will benefit from specific therapies in the adjuvant setting. In adjuvant trials the primary endpoint is typically survival, whereas in neoadjuvant trials the endpoints are more often clinical or pathologic response rates. There are a number of clinical trials underway comparing neoadjuvant chemotherapy and endocrine therapy regimens with pretreatment and posttreatment biopsy samples obtained from the primary tumors in all of the participants. These samples are being subjected to intensive genomic and proteomic analyses that may help to define a more personalized or individualized approach to breast cancer treatment in the future.

For women with stage IV breast cancer, an antiestrogen (tamoxifen for premenopausal women or an aromatase inhibitor for postmenopausal women) is the preferred therapy. However, women with hormone receptor–negative cancers with symptomatic visceral metastasis or with hormone-refractory cancer may receive systemic chemotherapy. Pamidronate may be given to women with osteolytic bone metastases in addition to hormonal therapy or standard chemotherapy.¹⁹⁵ Women with metastatic breast cancer also may be enrolled into clinical trials exploring novel biologic therapies alone or in combination with chemotherapeutics.

Antiestrogen Therapy

Within the cytosol of breast cancer cells are specific proteins (receptors) that bind and transfer steroid moieties into the cell nucleus to exert specific hormonal effects.^{184,196–200} The most widely studied hormone receptors are the estrogen receptor and progesterone receptor. Hormone receptors are detectable in >90% of well-differentiated ductal and lobular invasive cancers. Sequential studies of hormone receptor status reveal no differences between the primary cancer and metastatic disease in the same patient.

After binding to estrogen receptors in the cytosol, tamoxifen blocks the uptake of estrogen by breast tissue. Clinical responses to antiestrogen are evident in >60% of women with hormone receptor–positive breast cancers but in <10% of women with hormone receptor–negative breast cancers. An overview analysis by the Early Breast Cancer Trialists' Collaborative Group showed that adjuvant therapy with tamoxifen produced a 25% reduction in the annual risk of breast cancer recurrence and a 7% reduction in annual breast cancer mortality.²⁰¹ The analysis also showed a 39% reduction in the risk of cancer in the contralateral breast. The antiestrogens do have defined toxicity, including bone pain, hot flashes, nausea, vomiting, and fluid retention. Thrombotic events occur in <3% of treated women. Cataract surgery is more frequently performed in patients receiving tamoxifen. A long-

term risk of tamoxifen use is endometrial cancer, although it occurs rarely. Tamoxifen therapy usually is discontinued after 5 years. In postmenopausal women, aromatase inhibitors are now considered as first-line therapy in the adjuvant setting or as a secondary agent after 1 to 2 years of adjuvant tamoxifen therapy. The aromatase inhibitors are less likely to cause endometrial cancer but do lead to changes in bone mineral density that may result in osteoporosis and an increased rate of fractures in postmenopausal women.

The NSABP P-1 trial was the first large-scale U.S. breast cancer prevention trial, and it demonstrated a 49% reduction in the incidence of invasive breast cancer in high-risk women who were treated with tamoxifen.⁵⁰ This reduction was demonstrated for all age groups treated, for all projected levels of risk, and for women with a prior history of either LCIS or atypical ductal hyperplasia. The reduction was demonstrable within the first year of follow-up and continued through a 6-year follow-up period. This led to approval of tamoxifen as a chemopreventive agent for women with a Gail relative risk of 1.70 or greater. Treatment consists of tamoxifen (20 mg/d) for up to 5 years to reduce the risk of breast cancer. The NSABP P-2 prevention trial compared the use of raloxifene, a selective estrogen receptor modulator used to prevent osteoporosis in postmenopausal women, with the use of tamoxifen in postmenopausal women at increased risk for breast cancer (Study of Tamoxifen and Raloxifene, or STAR trial). In the STAR trial, 19,747 postmenopausal women were randomly assigned to receive tamoxifen (20 mg daily) or raloxifene (60 mg daily) for 5 years. The initial results revealed 163 invasive breast cancers in the tamoxifen group and 168 invasive breast cancers in the raloxifene group.⁶⁰ Fewer noninvasive cancers were diagnosed in the tamoxifen group. An important outcome was the finding of 36% fewer cases of uterine cancer in the raloxifene group. Overall there were no differences between tamoxifen and raloxifene with respect to the risks of other invasive cancers, ischemic heart disease events, numbers of stroke, or osteoporotic fractures reported. The number of thromboembolic events and incidence of cataracts were lower in the raloxifene group. Overall, the STAR trial revealed that raloxifene is as effective as tamoxifen for reducing the risk of invasive breast cancer in high-risk women. There was a difference in favor of tamoxifen with respect to number of noninvasive breast cancers, but this was not statistically significant. Perhaps most importantly when a chemoprevention regimen is considered, raloxifene appears to have a better toxicity profile than tamoxifen, including both a lower risk of thromboembolic events and a lower risk of cataracts.

Tamoxifen therapy is also considered for women with DCIS that is found to be estrogen receptor positive on immunohistochemical studies. The goals of such therapy are to decrease the risk of an ipsilateral recurrence after breast conservation therapy for DCIS and to decrease the risk of a primary invasive breast cancer or a contralateral breast cancer event.

Node-negative women with hormone receptor–positive breast cancers that are 1 to 3 cm in size are candidates for adjuvant endocrine therapy with or without chemotherapy. For node-positive women and for all women with a cancer that is >3 cm in size, the use of endocrine therapy in addition to adjuvant chemotherapy is appropriate. Women with hormone receptor–positive cancers achieve significant reduction in risk of recurrence and mortality due to breast cancer through the use of endocrine therapies. For women with stage IV breast cancer, an antiestrogen is the preferred initial therapy. For women with prior antiestrogen exposure, recommended second-line hormonal therapies include aromatase inhibitors in postmenopausal women and progestins, androgens, high-dose estrogen, or oophorectomy (medical, surgical, or radioablative) in premenopausal women. Women who respond to hormonal therapy with either shrinkage of their breast cancer or long-term stabilization of disease receive additional hormonal therapy at the time of progression. Women with hormone receptor–negative cancers, with symptomatic visceral metastasis, or with hormone-refractory disease receive systemic chemotherapy rather than hormone therapy.

Ablative Endocrine Therapy

In the past, oophorectomy, adrenalectomy, and/or hypophysectomy were the primary endocrine modalities used to treat metastatic breast cancer, but today they are rarely used. Oophorectomy was used in premenopausal breast cancer patients who presented with skin or bony metastases after a disease-free interval that exceeded 18 months. In contrast, pharmacologic doses of exogenous estrogens were given to postmenopausal women with similar recurrences. For both groups, the response rates were nearly 30%. Adrenalectomy and hypophysectomy were effective in individuals who had previously responded to either oophorectomy or exogenous estrogen therapy, and the response to these additional procedures was nearly 30%. Visceral metastases (lung, liver) responded infrequently to any form of hormonal manipulation. Aminoglutethimide blocks enzymatic conversion of cholesterol to Δ^5 -pregnenolone and inhibits the conversion of androstenedione to estrogen in peripheral tissues. Dose-dependent and transient side effects include ataxia, dizziness, and lethargy. After treatment with this agent (medical adrenalectomy), adrenal suppression necessitates glucocorticoid therapy. Neither permanent adrenal insufficiency nor acute crises have been observed. Because the adrenal glands are the major site for production of endogenous estrogens after menopause, treatment with aminoglutethimide has been compared prospectively with surgical adrenalectomy and hypophysectomy in postmenopausal women and is equally efficacious.

Anti-Her-2/*Neu* Antibody Therapy

The determination of tumor HER-2/*neu* expression for all newly diagnosed patients with breast cancer is now recommended.^{201–204} It is used for prognostic purposes in node-negative patients to assist in the selection of adjuvant chemotherapy because response rates appear to be better with doxorubicin-based adjuvant chemotherapy in patients with tumors that overexpress HER-2/*neu*, and as baseline information in case the patient develops recurrent disease that may benefit from anti-HER-2/*neu* therapy (trastuzumab). Patients with tumors that overexpress HER-2/*neu* may benefit if trastuzumab is added to paclitaxel chemotherapy. Cardiotoxicity may develop if trastuzumab is delivered concurrently with doxorubicin-based chemotherapy.

Trastuzumab was initially approved for the treatment of HER-2/*neu*-positive breast cancer in patients with metastatic disease. Once efficacy was demonstrated for patients with metastatic disease, the NSABP and the North Central Cancer Treatment Group conducted phase III trials evaluating the impact of adjuvant trastuzumab therapy in patients with early-stage breast cancer. After approval from the FDA, these groups amended their adjuvant trastuzumab trials (B-31 and N9831, respectively), to provide for a joint efficacy analysis. The first joint interim efficacy analysis demonstrated an improvement in 3-year disease-free survival from 75% in the control arm to 87% in the trastuzumab arm (hazard ratio = 0.48, $P < .0001$). There was an accompanying 33% reduction in mortality in the patients who received trastuzumab (hazard ratio = 0.67, $P = .015$). The magnitude of reduction in hazard for disease-free survival events crossed prespecified early reporting boundaries, so the data-monitoring committees for both groups recommended that randomized accrual to the trials be ended, and the results were subsequently published.¹²⁴

Buzdar and colleagues at the M. D. Anderson Cancer Center reported the results of a randomized phase II neoadjuvant trial of trastuzumab in combination with sequential paclitaxel followed by FEC-75 (5-fluorouracil, epirubicin, cyclophosphamide) vs. the same chemotherapy regimen without trastuzumab in 42 women with early-stage operable breast cancer. The pathologic complete response rates in this trial increased from 25 to 66.7% when chemotherapy was given concurrently with trastuzumab. None of the patients receiving the concurrent trastuzumab and FEC regimen developed symptoms of congestive heart failure. However, given the small sample size in this report, the 95% confidence interval for developing heart failure was 0 to 14.8%.²⁰⁵ A subsequent report which included additional patients treated with concurrent chemotherapy and trastuzumab further confirmed the high pathologic complete response rates and continued to show that cardiac function was preserved.²⁰⁶ This regimen is currently being tested in a phase III multicenter trial sponsored by the American College of Surgeons Oncology Group.

SPECIAL CLINICAL SITUATIONS

Nipple Discharge

UNILATERAL NIPPLE DISCHARGE

Nipple discharge is a finding that can be seen in a number of clinical situations. It may be suggestive of cancer if it is spontaneous, unilateral, localized to a single duct, present in women ≥ 40 years of age, bloody, or associated with a mass. A trigger point on the breast may be present so that pressure around the nipple-areolar complex induces discharge from a single duct. In this circumstance, mammography and ultrasound are indicated for further evaluation. A ductogram also can be useful and is performed by cannulating a single discharging duct with a small nylon catheter or needle and injecting 1.0 mL of water-soluble contrast solution. Nipple discharge associated with a cancer may be clear, bloody, or serous. Testing for the presence of hemoglobin is helpful, but hemoglobin may also be detected when nipple discharge is secondary to an intraductal papilloma or duct ectasia. Definitive diagnosis depends on excisional biopsy of the offending duct and any associated mass lesion. A 3.0 lacrimal duct probe can be used to identify the duct that requires excision. Another approach is to inject methylene blue dye within the duct after ductography. The nipple must be sealed with collodion or a similar material so that the blue dye does not discharge through the nipple but remains within the distended duct facilitating its localization. Needle localization biopsy is performed when there is an associated mass that lies >2.0 to 3.0 cm from the nipple.

BILATERAL NIPPLE DISCHARGE

Nipple discharge is suggestive of a benign condition if it is bilateral and multiductal in origin, occurs in women ≤ 39 years of age, or is milky or blue-green. Prolactin-secreting pituitary adenomas are responsible for bilateral nipple discharge in $<2\%$ of cases. If serum prolactin levels are repeatedly elevated, plain radiographs of the sella turcica are indicated and thin section CT scan is required. Optical nerve compression, visual field loss, and infertility are associated with large pituitary adenomas.

Axillary Lymph Node Metastases in the Setting of an Unknown Primary Cancer

A woman who presents with an axillary lymph node metastasis that is consistent with a breast cancer metastasis has a 90% probability of harboring an occult breast cancer.²⁰⁷ However, axillary lymphadenopathy is the initial presenting sign in only 1% of breast cancer patients. Fine-needle aspiration biopsy, core-needle biopsy, or open biopsy of an enlarged axillary lymph node is performed to confirm metastatic disease. When metastatic cancer is found, immunohistochemical analysis may classify the cancer as epithelial, melanocytic, or lymphoid in origin. The presence of hormone receptors (estrogen or progesterone receptors) suggests metastasis from a breast cancer but is not diagnostic. The search for a primary cancer includes careful examination of the thyroid, breast, and pelvis, including the rectum. The breast should be examined with diagnostic mammography, ultrasonography, and MRI to evaluate for an occult primary lesion. Further radiologic and laboratory studies should include chest radiography and liver function studies. Chest, abdominal, and pelvic CT scans also are indicated, as is a bone scan to rule out distant metastasis. Suspicious findings on mammography, ultrasonography, or MRI necessitate breast biopsy. When a breast cancer is found, treatment consists of an axillary lymph node dissection with a mastectomy or preservation of the breast followed by whole-breast radiation therapy. Chemotherapy and endocrine therapy should be considered.

Breast Cancer during Pregnancy

Breast cancer occurs in 1 of every 3000 pregnant women, and axillary lymph node metastases are present in up to 75% of these women.²⁰⁸ The average age of the pregnant woman with breast cancer is 34 years. Fewer than 25% of the breast nodules developing during pregnancy and lactation will be cancerous. Ultrasonography and needle biopsy are used in the diagnosis of these nodules. Open biopsy may be required. Mammography is rarely indicated because of its decreased sensitivity during

pregnancy and lactation; however, the fetus can be shielded if mammography is needed. Approximately 30% of the benign conditions encountered will be unique to pregnancy and lactation (galactoceles, lobular hyperplasia, lactating adenoma, and mastitis or abscess). Once a breast cancer is diagnosed, complete blood count, chest radiography (with shielding of the abdomen), and liver function studies are performed.

Because of the potential deleterious effects of radiation therapy on the fetus, radiation cannot be considered until the fetus is delivered. A modified radical mastectomy can be performed during the first and second trimesters of pregnancy, even though there is an increased risk of spontaneous abortion after first-trimester anesthesia. During the third trimester, lumpectomy with axillary node dissection can be considered if adjuvant radiation therapy is deferred until after delivery. Lactation is suppressed. Chemotherapy administered during the first trimester carries a risk of spontaneous abortion and a 12% risk of birth defects. There is no evidence of teratogenicity resulting from administration of chemotherapeutic agents in the second and third trimesters. For this reason, many clinicians now consider the optimal strategy to be delivery of chemotherapy in the second and third trimesters as a neoadjuvant approach, which allows local therapy decisions to be made after the delivery of the baby. Pregnant women with breast cancer often present at a later stage of disease because breast tissue changes that occur in the hormone-rich environment of pregnancy obscure early cancers. However, pregnant women with breast cancer have a prognosis, stage by stage, that is similar to that of nonpregnant women with breast cancer.

Male Breast Cancer

Fewer than 1% of all breast cancers occur in men.^{209,210} The incidence appears to be highest among North Americans and the British, in whom breast cancer constitutes as much as 1.5% of all male cancers. Jewish and African American males have the highest incidence. Male breast cancer is preceded by gynecomastia in 20% of men. It is associated with radiation exposure, estrogen therapy, testicular feminizing syndromes, and Klinefelter's syndrome (XXY). Breast cancer is rarely seen in young males and has a peak incidence in the sixth decade of life. A firm, nontender mass in the male breast requires investigation. Skin or chest wall fixation is particularly worrisome.

DCIS makes up <15% of male breast cancer, whereas infiltrating ductal carcinoma makes up >85%. Special-type cancers, including infiltrating lobular carcinoma, have occasionally been reported. Male breast cancer is staged in the same way as female breast cancer, and stage by stage, men with breast cancer have the same survival rate as women. Overall, men do worse because of the advanced stage of their cancer (stage III or IV) at the time of diagnosis. The treatment of male breast cancer is surgical, with the most common procedure being a modified radical mastectomy. Sentinel node dissection has been shown to be feasible and accurate for nodal assessment in men presenting with a clinically node-negative axillary nodal basin. Adjuvant radiation therapy is appropriate in cases in which there is a high risk for local-regional recurrence. Eighty percent of male breast cancers are hormone receptor positive, and adjuvant tamoxifen is considered. Systemic chemotherapy is considered for men with hormone receptor-negative cancers and for men with large primary tumors, multiple positive nodes, and locally advanced disease.

Phyllodes Tumors

The nomenclature, presentation, and diagnosis of phyllodes tumors (including cystosarcoma phyllodes) have posed many problems for surgeons.²¹¹ These tumors are classified as benign, borderline, or malignant. Borderline tumors have a greater potential for local recurrence. Mammographic evidence of calcifications and morphologic evidence of necrosis do not distinguish between benign, borderline, and malignant phyllodes tumors. Consequently, it is difficult to differentiate benign phyllodes tumors from the malignant variant and from fibroadenomas. Phyllodes tumors are usually sharply demarcated from the surrounding breast tissue, which is compressed and distorted. Connective tissue composes the bulk of these tumors, which have mixed

gelatinous, solid, and cystic areas. Cystic areas represent sites of infarction and necrosis. These gross alterations give the gross cut tumor surface its classical leaf-like (phyllodes) appearance. The stroma of a phyllodes tumor generally has greater cellular activity than that of a fibroadenoma. After microdissection to harvest clusters of stromal cells from fibroadenomas and from phyllodes tumors, molecular biology techniques have shown the stromal cells of fibroadenomas to be either polyclonal or monoclonal (derived from a single progenitor cell), whereas those of phyllodes tumors are always monoclonal.

Most malignant phyllodes tumors (Fig. 17-40) contain liposarcomatous or rhabdomyosarcomatous elements rather than fibrosarcomatous elements. Evaluation of the number of mitoses and the presence or absence of invasive foci at the tumor margins may help to identify a malignant tumor. Small phyllodes tumors are excised with a margin of normal-appearing breast tissue. When the diagnosis of a phyllodes tumor with suspicious malignant elements is made, re-excision of the biopsy site to ensure complete excision of the tumor with a 1-cm margin of normal-appearing breast tissue is indicated. Large phyllodes tumors may require mastectomy. Axillary dissection is not recommended because axillary lymph node metastases rarely occur.

Inflammatory Breast Carcinoma

Inflammatory breast carcinoma (stage IIIB) accounts for <3% of breast cancers. This cancer is characterized by the skin changes of brawny induration, erythema with a raised edge, and edema (peau d'orange).²¹² Permeation of the dermal lymph vessels by cancer cells is seen in skin biopsy specimens. There may be an associated breast mass (Fig. 17-41). The clinical differentiation of inflammatory breast cancer may be extremely difficult, especially when a locally advanced scirrhous carcinoma invades dermal lymph vessels in the skin to produce peau d'orange and lymphangitis (Table 17-16). Inflammatory breast cancer also may be mistaken for a bacterial infection of the breast. More than 75% of women who have inflammatory breast cancer present with palpable axillary lymphadenopathy, and distant metastases also are frequently present. A report of the SEER program described distant metastases at diagnosis in 25% of white women with inflammatory breast carcinoma.

Inflammatory breast carcinoma. Stage IIIB cancer of the breast with erythema, skin edema (peau d'orange), nipple retraction, and satellite skin nodules.

Table 17-16 Inflammatory vs. Noninflammatory Breast Cancer

Inflammatory	Noninflammatory
Dermal lymph vessel invasion is present with or without inflammatory changes.	Inflammatory changes are present without dermal lymph vessel invasion.
Cancer is not sharply delineated.	Cancer is better delineated.
Erythema and edema frequently involve >33% of the skin over the breast.	Erythema is usually confined to the lesion, and edema is less extensive.
Lymph node involvement is present in >75% of cases.	Lymph nodes are involved in approximately 50% of the cases.
Distant metastases are present in 25% of cases.	Distant metastases are less common at presentation.
Distant metastases are more common at initial presentation.

Surgery alone and surgery with adjuvant radiation therapy have produced disappointing results in women with inflammatory breast cancer. However, neoadjuvant chemotherapy with a doxorubicin-containing regimen may effect dramatic regressions in up to 75% of cases. In this setting, modified radical mastectomy is performed to remove residual cancer from the chest wall and axilla. Adjuvant chemotherapy may be indicated depending on final pathologic assessment of the breast and regional nodes.

Finally, the chest wall and the supraclavicular, internal mammary, and axillary lymph node basins receive adjuvant radiation therapy. This multimodal approach results in 5-year survival rates that approach 30%.

Rare Breast Cancers

SQUAMOUS CELL (EPIDERMOID) CARCINOMA

Squamous cell (epidermoid) carcinoma is a rare cancer that arises from metaplasia within the duct system and generally is devoid of distinctive clinical or radiographic characteristics.²¹³ Regional metastases occur in 25% of patients, whereas distant metastases are rare.

ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinoma is very rare, accounting for <0.1% of all breast cancers. It is typically indistinguishable from adenoid cystic carcinoma arising in salivary tissues. These cancers are generally 1 to 3 cm in diameter at presentation and are well circumscribed. Axillary lymph node metastases are rare, but deaths from pulmonary metastases have been reported.

APOCRINE CARCINOMA

Apocrine carcinomas are well-differentiated cancers that have rounded vesicular nuclei and prominent nucleoli. There is a very low mitotic rate and little variation in cellular features. However, apocrine carcinomas may display an aggressive growth pattern.

SARCOMAS

Sarcomas of the breast are histologically similar to soft tissue sarcomas at other anatomic sites. This diverse group includes fibrosarcoma, malignant fibrous histiocytoma, liposarcoma, leiomyosarcoma, malignant schwannoma, rhabdomyosarcoma, osteogenic sarcoma, and chondrosarcoma. The clinical presentation is typically that of a large, painless breast mass with rapid growth. Diagnosis is by core-needle biopsy or by open incisional biopsy. Sarcomas are graded based on cellularity, degree of differentiation, nuclear atypia, and mitotic activity. Primary treatment is wide local excision, which may necessitate mastectomy. Axillary dissection is not indicated unless there is palpable lymphadenopathy. Angiosarcomas are classified as de novo, as postradiation, or as arising in association with postmastectomy lymphedema. In 1948, Stewart and Treves described lymphangiosarcoma of the upper extremity in women with ipsilateral lymphedema after radical mastectomy.²¹⁴ *Angiosarcoma* is now the preferred name. The average interval between modified radical or radical mastectomy and the development of an angiosarcoma is 10.5 years. Sixty percent of women developing this cancer have a history of adjuvant radiation therapy. Forequarter amputation may be necessary to palliate the ulcerative complications and advanced lymphedema.

LYMPHOMAS

Primary lymphomas of the breast are rare, and there are two distinct clinicopathologic variants. One type occurs in women ≤ 39 years of age, is frequently bilateral, and has the histologic features of Burkitt's lymphoma. The second type is seen in women ≥ 40 years of age and is usually of the B-cell type. Breast involvement by Hodgkin's lymphoma has been reported. An occult breast lymphoma may be diagnosed after detection of palpable axillary lymphadenopathy. Treatment depends on the stage of disease. Lumpectomy or mastectomy may be required. Axillary dissection for staging and for clearance of palpable disease is appropriate. Recurrent or progressive local-regional disease is best managed by chemotherapy and radiation therapy. The prognosis is favorable, with 5- and 10-year survival rates of 74 and 51%, respectively.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 18. Disorders of the Head and Neck >

KEY POINTS

1. Disorders of the head and neck can cause significant cosmetic and functional impairment. The practitioner must be empathetic to the effect of these morbidities on quality of life.
2. Infectious conditions of the head and neck may present with life-threatening sequelae such as loss of airway or intracranial extension.
3. Patients with obstructive sleep apnea require evaluation to determine the specific anatomic site(s) of involvement. Long-term cardiovascular problems are a significant concern in these patients.
4. Repair of traumatic soft-tissue injuries requires precise realignment of anatomic landmarks such as the gray line and vermilion border.
5. The key principle in the surgical repair of facial fractures is immobilization, which may require plates, screws, wires, and/or intermaxillary fixation.
6. Concurrent abuse of tobacco and alcohol are synergistic in increasing the risk of developing head and neck cancer.
7. Hoarseness, a nonhealing oral ulcer, or cervical lymphadenopathy of greater than 2 weeks duration requires evaluation.
8. Monomodality therapy (surgery or radiation) is used for early stage (I/II) head and neck cancer, whereas combination surgery and chemoradiation is used with advanced stage (III/IV) malignancies.
9. The most significant recent advance in the treatment of head and neck cancer is the use of epidermal growth factor receptor inhibitor-based chemotherapy.

A COMPLEX REGION

The head and neck constitute a complex anatomic region where different pathologies may affect an individual's ability to see, smell, hear, speak, obtain nutrition and hydration, or breathe. The use of a multidisciplinary approach to many of the disorders in this region is essential in an attempt to achieve the best functional results with care. This chapter reviews many of the common diagnoses encountered in the field of otolaryngology-head and neck surgery and aims to provide an overview that clinicians can use as a foundation for understanding of this region. As is the case with every field of surgery, care for patients with disorders of the head and neck is constantly changing as issues of quality of life and the economics of medicine continue to evolve.

BENIGN CONDITIONS OF THE HEAD AND NECK

Ear Infections

Infections may involve the external, middle, and/or internal ear. In each of these scenarios, the infection may follow an acute or chronic course and may be associated with both otologic and intracranial complications. Otitis externa typically refers to infection of the skin of the external auditory canal (EAC).¹ Acute otitis externa is commonly known as *swimmer's ear*, because moisture that persists within the canal after swimming often initiates the process and leads to skin maceration and itching. Typically, the patient subsequently traumatizes the canal skin by scratching (i.e., with a cotton swab or fingernail), thus eroding the normally protective skin/cerumen barrier. Because the environment within the external ear canal is already dark, warm, and humid, it then becomes susceptible to rapid microbial proliferation and tissue cellulitis. The most common organism responsible is *Pseudomonas aeruginosa*, although other bacteria and fungi may also be implicated. Table 18-1 summarizes the microbiology of common otolaryngologic conditions. Symptoms and signs of otitis externa include itching during the initial phases and pain with swelling of the canal soft tissues as the infection progresses. Infected, desquamated debris accumulates within the canal. In the chronic inflammatory stage of the infection, the pain subsides, but profound itching occurs for prolonged periods with gradual thickening

of the external canal skin. Standard treatment requires removal of debris under otomicroscopy and application of appropriate topical antimicrobials such as neomycin/polymyxin or quinolone-containing eardrops, which often include topical steroid such as hydrocortisone or dexamethasone to nonspecifically decrease pain and swelling. Recent studies have demonstrated superiority of quinolone-containing preparations in achieving faster clinical resolution.¹ Nonantibiotic antimicrobial preparations, such as 2% acetic acid, may also have a role, particularly for mixed bacterial/fungal infections. The patient should also be instructed to keep the ear dry. Systemic antibiotics are reserved for those with severe infections, diabetics, and immunosuppressed patients.

Table 18-1 Microbiology of Common Otolaryngologic Infections	
Condition	Microbiology
Otitis externa and malignant otitis externa	<i>Pseudomonas aeruginosa</i> , fungi (<i>Aspergillus</i> most common)
Acute otitis media	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i>
Chronic otitis media	Above bacteria, staphylococci, other streptococci; may be polymicrobial; exact role of bacteria unclear
Acute sinusitis	Viral upper respiratory infection, <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>M. catarrhalis</i>
Chronic sinusitis	Above bacteria, staphylococci, other streptococci; may be polymicrobial; exact role of bacteria unclear; may represent immune response to fungi
Pharyngitis	Viral, streptococci (usually pyogenes)

Diabetic, elderly, and immunodeficient patients are susceptible to a condition called *malignant otitis externa*, a fulminant necrotizing infection of the otologic soft tissues combined with osteomyelitis of the temporal bone. In addition to the above findings, cranial neuropathies may be observed. The classic physical finding is granulation tissue along the floor of the EAC. Symptoms include persistent otalgia for longer than 1 month and purulent otorrhea for several weeks. These patients require aggressive medical therapy, including IV antibiotics covering *Pseudomonas*.² Other gram-negative bacteria and fungi are occasionally implicated, necessitating culture-directed therapy in those cases. Patients who do not respond to medical management require surgical débridement. This condition may progress to involvement of the adjacent skull base and soft tissues, meningitis, brain abscess, and death.

In its acute phase, otitis media typically implies a bacterial infection of the middle ear. This diagnosis accounts for 25% of pediatric antibiotic prescriptions and is the most common bacterial infection of childhood. Most cases occur before 2 years of age and are secondary to immaturity of the eustachian tube. Contributing factors include upper respiratory viral infection and day-care attendance, as well as craniofacial conditions affecting eustachian tube function, such as cleft palate. It is also possible that social factors such as day-care attendance and the overprescription of antibiotics has led to antibiotic resistance.

Classification of the infection as acute is based upon the duration of the process being less than 3 weeks. In this phase, otalgia and fever are the most common symptoms and physical exam reveals a bulging, opaque tympanic membrane (Fig. 18-1). The most common organisms responsible are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. If the process lasts 3 to 8 weeks, it is deemed subacute. Chronic otitis media, lasting more than 8 weeks, usually results from an unresolved acute otitis media. Twenty percent of patients demonstrate a persistent middle ear effusion 8 weeks after resolution of the acute phase. Rather than a purely infectious process, however, it represents chronic inflammation and hypersecretion by the middle ear mucosa associated with eustachian tube dysfunction, viruses, allergy, ciliary dysfunction, and other factors. The bacteriology is variable, but often includes those found in acute otitis media and may be polymicrobial. The exact role of bacteria in the pathophysiology is controversial. The patient experiences otalgia, ear fullness, and conductive hearing loss. Physical examination reveals a retracted tympanic membrane that may exhibit an opaque character or an air-fluid level. Bubbles may be seen behind the retracted membrane.

Acute otitis media.

Treatment for uncomplicated otitis media is oral antibiotic therapy. However, penicillin resistance of the commonly implicated organisms is rising such that almost 100% of *Moraxella*, 50 to 70% of *Haemophilus*, and up to 40% of pneumococcal strains are resistant.³ Beta-lactamase-resistant combinations, cephalosporins, and macrolides are often required, although amoxicillin and sulfas are still considered first-line drugs. Chronic otitis media is frequently treated with myringotomy and tube placement (Fig. 18-2). This is indicated for frequent acute episodes, chronic effusions persisting beyond 3 months, and those associated with significant conductive hearing loss. The purpose of this procedure is to remove the effusion and provide a route for middle ear ventilation. Tympanic membrane perforation during acute otitis media frequently results in resolution of severe pain and provides for drainage of purulent fluid and middle ear ventilation. These perforations will heal spontaneously after the infection has resolved in the majority of cases. Chronic otitis media, however, may be associated with nonhealing tympanic membrane perforations. Patients may have persistent otorrhea, which is treated with topical drops. Preparations containing aminoglycoside are avoided, because this class of drugs is toxic to the inner ear. Solutions containing alcohol or acetic acid may be irritative or caustic to the middle ear, and are also avoided in the setting of a perforation.

Fig. 18-2.

Myringotomy and tube.

Nonhealing perforation requires surgical closure (tympanoplasty) after medical treatment of any residual acute infection. Chronic inflammation may also be associated with erosion of the ossicular chain, which can be reconstructed with various prostheses or autologous ossicular replacement techniques. Cholesteatoma is an epidermoid cyst of the middle ear and/or mastoid, which causes bone destruction secondary to its expansile nature and through enzymatic destruction. Cholesteatoma develops as a consequence of eustachian tube dysfunction and chronic otitis media secondary to retraction of squamous elements of the tympanic membrane into the middle ear space. Squamous epithelium may also migrate into the middle ear via a perforation. Chronic mastoiditis that fails medical management or is associated with cholesteatoma is treated by mastoidectomy.

Complications of otitis media may be grouped into two categories: intratemporal (otologic) and intracranial.⁴ Fortunately, complications are rare in the antibiotic era, but mounting antibiotic resistance necessitates an increased awareness of these conditions. Intratemporal complications include acute coalescent mastoiditis, petrositis, facial nerve paralysis, and labyrinthitis. In acute coalescing mastoiditis, destruction of the bony lamellae by an acute purulent process results in severe pain, fever, and swelling behind the ear. The mastoid air cells coalesce into one common space filled with pus. Mastoid infection may also spread to the petrous apex, causing retro-orbital pain and sixth-nerve palsy. These diagnoses are confirmed by computed tomographic (CT) scan.

Facial nerve paralysis may also occur secondary to an acute inflammatory process in the middle ear or mastoid.⁵ Intratemporal complications are managed by myringotomy tube placement in addition to appropriate IV antibiotics. In acute coalescent mastoiditis, and petrositis, mastoidectomy is also performed as necessary to drain purulent foci. Labyrinthitis refers to inflammation of the inner ear. Most cases are idiopathic or are secondary to viral infections of the endolymphatic space. The patient experiences vertigo with sensorineural hearing loss, and symptoms may smolder over several weeks. Labyrinthitis associated with middle ear infection may be serous or suppurative. In the former case, bacterial products and/or inflammatory mediators transudate into the inner ear via the round window membrane, establishing an inflammatory process therein. Total recovery is eventually possible after the middle ear is adequately treated. Suppurative labyrinthitis, however, is a much more toxic condition in which the acute purulent bacterial infection extends into the inner ear and causes marked destruction of the sensory hair cells and neurons of the eighth-nerve ganglion. This condition may hallmark impending meningitis and must be treated rapidly. The goal of management of inner ear infection, which occurs secondary to middle ear infection, is to "sterilize" the middle ear space with antibiotics and the placement of a myringotomy tube.

Meningitis is the most common intracranial complication. Otologic meningitis in children is most commonly associated with a *H. influenzae* type B infection. Other intracranial complications include epidural abscess, subdural abscess, brain abscess, otitic hydrocephalus (pseudotumor), and sigmoid sinus thrombophlebitis. In these cases, the otogenic source must be urgently treated with antibiotics and myringotomy tube placement.

Mastoidectomy and neurosurgical consultation may be necessary.

Bell's palsy, or idiopathic facial paralysis, may be considered within the spectrum of otologic disease given the facial nerve's course through the temporal bone. This entity is the most common etiology of facial nerve paralysis and is clinically distinct from that occurring as a complication of otitis media in that the otologic exam is normal. Historically, Bell's palsy was synonymous with "idiopathic" facial paralysis. It is now accepted, however, that the majority of these cases represent a viral neuropathy caused by herpes simplex. Treatment includes oral steroids plus antiviral therapy (i.e., acyclovir). Complete recovery is the norm, but does not occur universally, and selected cases may benefit from surgical decompression of the nerve within its bony canal. Electrophysiologic testing has been used to identify those patients in whom surgery might be indicated.⁶ The procedure involves decompression of the nerve via exposure in the middle cranial fossa. Varicella zoster virus may also cause facial nerve paralysis when the virus reactivates from dormancy in the nerve. This condition, known as *Ramsay Hunt syndrome*, is characterized by severe otalgia followed by the eruption of vesicles of the external ear. Treatment is similar to Bell's palsy, but full recovery is only seen in approximately two thirds of cases.

Traumatic facial nerve injuries may occur secondary to accidental trauma or surgical injury. The former is detailed in Sinus Inflammatory Disease below. Iatrogenic facial nerve trauma most often occurs during mastoidectomy.⁷ When the facial nerve is injured intraoperatively, it is explored. Injury to greater than 50% of the neural diameter of the facial nerve is addressed either with primary reanastomosis or reconstructed with the use a nerve graft. Complete recovery of nerve function is uncommon in these cases.

Sinus Inflammatory Disease

Sinusitis is a clinical diagnosis based on patient signs and symptoms.⁸ The Task Force on Rhinosinusitis (sponsored by the American Academy of Otolaryngology–Head and Neck Surgery) has established criteria to define "a history consistent with sinusitis" (Table 18-2). To qualify for the diagnosis, the patient must exhibit at least two major factors or one major and two minor factors. The classification of sinusitis as acute vs. subacute or chronic is primarily based on the time course over which those criteria have been met. If signs and symptoms are present for at least 7 to 10 days, but for less than 4 weeks, the process is designated acute sinusitis. Subacute sinusitis is present for 4 to 12 weeks and chronic sinusitis is diagnosed when the patient has had signs and symptoms for at least 12 weeks. In addition, the diagnosis of chronic sinusitis requires some objective demonstration of mucosal inflammatory disease. This may be accomplished by endoscopic examination or radiologically (i.e., CT scan).

Table 18-2 Factors Associated with a History of Rhinosinusitis ^a	
Major Factors	Minor Factors
Facial congestion/fullness	Headache
Facial pain/pressure	Maxillary dental pain
Nasal drainage/discharge	Cough
Postnasal drip	Halitosis (bad breath)
Nasal obstruction/blockage	Fatigue
Hyposmia/anosmia (decreased or absent sense of smell)	Ear pain, pressure, or fullness
	Fever
Fever (acute sinusitis only)	
Purulence on nasal endoscopy (diagnostic by itself)	

^aEither two major factors or one major and two minor factors are required. Purulence on nasal endoscopy is diagnostic. Fever is a major factor only in the acute stage.

Acute sinusitis typically follows a viral upper respiratory infection whereby sinonasal mucosal inflammation results in closure of the sinus ostium. This results in stasis of secretions, tissue hypoxia, and ciliary dysfunction. These conditions promote bacterial proliferation and acute inflammation. The mainstay of treatment is the use of antibiotics that are empirically directed toward the three most common organisms *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. As with otitis media, antibiotic resistance is a mounting concern. Nosocomial acute sinusitis frequently involves *Pseudomonas* or *S. aureus*, both of which may also exhibit significant antibiotic resistance. Other treatments include topical and systemic decongestants, nasal saline spray, topical nasal steroids, and oral steroids in selected cases. In the acute setting, surgery is

reserved for complications or pending complications, which may include extension to the eye (orbital cellulitis or abscess) or the intracranial space (meningitis, intracranial abscess). It should also be noted that, strictly speaking, a viral upper respiratory infection (common cold) is a form of acute sinusitis. The working definition outlined above, however, attempts to exclude these cases by requiring that symptoms be present for at least 7 to 10 days, by which time the common cold should be in a resolution phase. Use of this working definition strives to avoid unnecessary antibiotic prescriptions and further promotion of resistance.

Chronic sinusitis represents a heterogeneous group of patients with multifactorial etiologies contributing to ostial obstruction, ciliary dysfunction, and inflammation. Components of genetic predisposition, allergy, anatomic obstruction, bacteria, fungi, and environmental factors play varying roles, depending on the individual patient. As of yet, no immunologic "final common pathway" has been defined, but the clinical picture is well described. Diagnosis is suspected according to the criteria in Table 18-2, with clinical signs and symptoms persisting for at least 12 weeks. Chronic sinusitis may also be associated with the presence of nasal polyps. Chronic sinusitis with and without polyposis is thought to reflect an immunologically distinct disease process.⁸ Mucosal inflammation in nonpolypoid chronic sinusitis is predominantly mediated by neutrophils, consistent with immune response to bacterial infection. In contrast, inflammatory infiltrates observed in polypoid chronic sinusitis are typically eosinophilic. Multiple theories have been proposed for the latter condition, and recent investigation has suggested that patients with polyposis may mount abnormal immunologic reactions toward fungi that colonize the sinonasal tract or to staphylococcal enterotoxin.⁸ Regardless of pathophysiology, polyps themselves may further block sinus outflow, resulting in further stasis of secretions and bacterial proliferation.

Nasal endoscopy is a critical element of the diagnosis of chronic sinusitis. Anatomic abnormalities, such as septal deviation, nasal polyps, and purulence may be observed (Figs. 18-3 and 18-4). The finding of purulence or polypoid change by nasal endoscopy is supportive of the diagnosis of chronic sinusitis, if symptoms persist for at least 12 weeks. In this setting, purulence may represent an acute exacerbation of chronic sinusitis. Pus found on endoscopic exam may be cultured, and subsequent antibiotic therapy can be directed accordingly. The spectrum of bacteria found in chronic sinusitis is highly variable and includes higher prevalences of polymicrobial infections and antibiotic-resistant organisms. Overall, *S. aureus*, coagulase-negative staphylococci, gram-negative bacilli, and streptococci are isolated, in addition to the typical pathogens of acute sinusitis. The increased prevalence of community acquired methicillin resistant *S. aureus* is a mounting concern.⁹

Endoscopic view of pus in the middle meatus admixed with polypoid change. This can be swabbed for culture, as shown, in the outpatient setting under endoscopic guidance.

The diagnosis of chronic sinusitis can be confirmed by CT scan, which demonstrates mucosal thickening and/or sinus opacification. It should be underscored, however, that CT scan is probably not the diagnostic gold standard because many asymptomatic patients will demonstrate findings on sinus CT scan. Also, patients with positive findings on nasal endoscopy may have normal CT scans. Overall, the decision to treat medically should be based upon patient history and nasal endoscopy, rather than results of the CT scan. Furthermore, over 75% of patients with normal findings on nasal endoscopy will have normal CT scans, underscoring the importance of endoscopy in the decision-to-treat process. Although acute sinusitis often is treated empirically by the primary care practitioner, when clinical criteria for chronic sinusitis are met, this typically prompts otolaryngology referral for nasal endoscopy, aggressive medical therapy, and possibly surgery. When surgery is used, the CT scan, if acquired with the appropriate protocol, can also be used for stereotactic intraoperative navigation to confirm relationships between the disease process, medial orbital wall, and skull base during surgery (Fig. 18-5).

Fig. 18-5.

Triplanar computed tomographic reconstructions as used for intraoperative stereotactic navigation. The coronal (*upper left*), axial (*lower left*), and sagittal (*upper right*) planes are seen, with the cross hairs localizing the anatomic position indicated in the endoscopic view (*lower left*). This particular patient has classic allergic fungal sinusitis, which has the radiologic hallmark of whitish hyperdense foci with areas of gray sinus opacification, as is seen in the maxillary sinus on the coronal image and in the sphenoid on the sagittal view.

Medical management of chronic sinusitis includes a prolonged course of oral antibiotics for 3 to 6 weeks, nasal and/or oral steroids, and nasal irrigations with saline or antibiotic solutions.⁸ Underlying allergic disease may be managed with antihistamines and possible allergy immunotherapy. Although the role of these treatments in resolving chronic sinusitis remains questionable, they may be considered in patients with comorbid allergic rhinitis or as part of empiric management before consideration of surgery. The use of oral steroids may also be selected empirically, particularly in patients with comorbid chronic airway inflammatory diseases such as nasal polyps, allergic rhinitis, or asthma.¹⁰ The decision to use oral steroids must be individualized with consideration of the risks and side effects of these medications. As yet, there is no consensus regarding what constitutes a "maximum" course of medical therapy that should be attempted before consideration of surgery for chronic sinusitis. A proposed therapeutic algorithm is outlined (Fig. 18-6). It should be noted that unless there is suspicion of neoplasm or pending complication of sinusitis, the decision to proceed with surgery is highly individualized. This is because surgery for uncomplicated chronic sinusitis is elective, and patients who "fail" medical management will exhibit significant variability in symptoms, physical signs, and CT findings. More aggressive medical and surgical management may be necessary in patients with comorbid chronic inflammatory disease of the airways such as allergic rhinitis, nasal polyposis, and asthma. Surgery is typically preformed endoscopically where the goals are to remove polyps, enlarge the natural sinus ostia (see Fig. 18-5, Fig. 18-7), and to remove chronically infected bone to promote both ventilation and drainage of the sinus cavities. Inspissated mucin or pus is drained and cultured. Eventual resolution of the chronic inflammatory process can be attained

with a combination of meticulous surgery and directed medical therapy, although the patient must understand that surgery may not alter the underlying immunologic pathophysiology.

Endoscopic surgical enlargement of the left maxillary sinus and view of pus within the sinus lumen.

The role of fungi in sinusitis is an area of active investigation. Fungal sinusitis may take on both noninvasive and invasive forms. The noninvasive form includes the presence of a fungal ball and allergic fungal sinusitis, both of which occur in immunocompetent patients.

A fungal ball is typically seen in individuals with chronic (or recurrent acute) symptoms that are often subtle and limited to a single sinus. Patients may complain about the perception of a foul odor and occasionally report expelling fungal debris upon nose blowing. A fungal ball (Fig. 18-8) consisting of *Aspergillus fumigatus* usually is found in the maxillary sinus, with scant inflammatory cell infiltration. Surgery to remove the fungal ball and re-establish sinus ventilation is almost always curative. This can be accomplished endoscopically.

Fig. 18-8.

Sinus fungal ball.

Classic allergic fungal sinusitis is thought to involve direct stimulation of eosinophils by a subset of helper T cells (T_H2) primed by fungal antigens. This results in vigorous inflammation and polyp growth, and some have proposed that other forms of chronic sinusitis may represent more subtle manifestations of this pathophysiology.¹¹ Patients often present with chronic sinusitis that has been especially refractory to medical management. CT scan has characteristic features, and endoscopic evaluation reveals florid polyposis and inspissated mucin containing fungal debris and products of eosinophil breakdown. The implicated organisms are usually those of the Dematiaceae family, but *Aspergillus* species are also seen. Treatment includes systemic steroids, surgery, and nasal irrigations. Oral antifungal therapy is sometimes indicated as well.

Immunocompetent patients may occasionally develop an indolent form of invasive fungal sinusitis, but more commonly, invasive fungal sinusitis affects immunocompromised patients, diabetics, or the elderly.¹¹ Fungal invasion of the microvasculature causes ischemic necrosis and black eschar of the sinonasal mucosa. *Aspergillus* and fungi of the Mucoraceae family are often implicated with the latter more common in diabetic patients. Treatment requires aggressive surgical débridement and IV antifungals, but the prognosis is dismal.

Pharyngeal and Adenotonsillar Disease

The pharyngeal mucosa contains significant concentrations of lymphoid tissue, predisposing this area to reactive inflammatory changes. Lymphoid tissue of various pharyngeal subsites forms the so-called *Waldeyer's tonsillar ring*, consisting of the palatine tonsils ("the tonsils"), lingual tonsil (lymphoid tissue accumulation within the tongue base), and adenoid. The mucosa of the posterior and lateral pharyngeal walls is also rich with lymphoid cells. Infection, immune-mediated inflammatory disease, or local stressors, such as radiation or acid reflux, may initiate lymphoid reactivity and associated symptoms. Chronic or recurrent adenotonsillitis and adenotonsillar hypertrophy are the most common disorders affecting these structures.

In the vast majority of cases, infectious pharyngitis is viral rather than bacterial in origin. Most cases resolve without complication from supportive care and possibly antibiotics. Patients with tonsillitis typically present with sore throat, dysphagia, and fever. The mucosa is inflamed. Tonsillar exudates and cervical adenitis may be seen when the etiology is bacterial. If adenoiditis is present, the symptoms may be similar to those of sinusitis, but visual evaluation of the adenoid, at least in children, requires endoscopy and/or radiographic imaging (lateral neck soft-tissue x-ray). Tonsillitis and adenoiditis may follow acute, recurrent acute, and chronic temporal patterns.

It should be noted, however, that clinical diagnosis often is inaccurate for determining whether the process is bacterially induced. When the

patient also has hoarseness, rhinorrhea, cough, and no evidence of exudates or adenitis, an upper respiratory viral infection can be presumed. When a bacterial cause is suspected,¹² antibiotics should be initiated to cover the usual organisms: group A beta-hemolytic streptococci (*Streptococcus pyogenes*), *S. pneumoniae*, and group C and G streptococci. *H. influenzae* and anaerobes also have been implicated. It is particularly important to identify group A beta-hemolytic streptococci in pediatric patients to initiate timely antibiotic therapy, given the risk of rheumatic fever, which may occur in up to 3% of cases if antibiotics are not used. Historically, if bacterial pharyngitis was suspected in a child, oropharyngeal swab with culture was performed to identify group A beta-hemolytic streptococci. Currently, rapid antigen assays are available with sensitivity and specificity of approximately 85% and 90%, respectively. Some authors advocate culture only when these are negative. Unnecessary antibiotic therapy for patients who are unlikely to have a bacterial etiology should be avoided, given the already mounting antibiotic resistance problem. When suspicion for a bacterial process is high, or with positive culture/antigen assay results, treatment may include penicillins, cephalosporins, or macrolides in penicillin-allergic patients.

Complications of *S. pyogenes* pharyngitis may be systemic, including rheumatic fever, poststreptococcal glomerulonephritis, and scarlet fever. The incidence of glomerulonephritis is not influenced by antibiotic therapy. Scarlet fever results from production of erythrogenic toxins by streptococci. This causes a punctate rash, first appearing on the trunk and then spreading distally, sparing the palms and soles. The so-called *strawberry tongue* also is seen. Locoregional complications include peritonsillar abscess and, rarely, deep-neck space abscess. Peritonsillar abscess is typically drained transorally under local anesthesia, as is the authors' practice, but some suggest that needle aspiration without incision is sufficient.¹³ Deep neck space abscess, which more commonly is odontogenic in origin, usually requires operative incision and drainage via a transcervical approach.

Atypical cases of pharyngitis may be caused by *Corynebacterium diphtheriae*, *Bordetella pertussis* (whooping cough), syphilis, *Neisseria gonorrhoeae*, and fungi. Diphtheria is a potentially fatal condition associated with toxin-mediated tissue necrosis and a gray membrane on the mucosal surface. Cardiorespiratory collapse may ensue from systemic circulation of the toxin. Treatment includes the use of antitoxin. Fortunately, diphtheria is rare in developed countries as a consequence of childhood vaccinations. Childhood vaccination also has almost eliminated whooping cough in developed nations. This entity follows a protracted, but usually self-limiting course. During the secondary phase of syphilis, ulcerations with raised red margins (resembling the chancre lesion) may be observed on the pharyngotonsillar mucosa. Identification of these less typical organisms requires a high index of suspicion and application of appropriate culture techniques and/or serologic tests. *Candida albicans* is the most common fungal organism to cause pharyngitis. This organism is a normal component of the oral flora, but under conditions of immunosuppression, broad-spectrum antibacterial therapy, poor oral hygiene, or vitamin deficiency, it may become pathogenic. Whitish-cheesy or creamy mucosal patches are observed with underlying erythema, and diagnosis is easily established by Gram's stain of this material, revealing budding yeast and pseudohyphae. Oral and topical antifungals are usually effective, and immunosuppressed patients may require prophylactic therapy.

In addition to viral upper respiratory viruses, herpes simplex virus, Epstein-Barr virus (EBV), cytomegalovirus, and HIV are associated with pharyngitis. Systemic EBV infection represents clinical mononucleosis, although syphilis, cytomegalovirus, and HIV are known to cause mononucleosis-like syndromes. These conditions, particularly EBV, may exhibit an exudative pharyngotonsillitis that may be confused with a bacterial etiology. Progression of the clinical picture reveals lymphadenopathy, splenomegaly, and hepatitis. Diagnosis is established based on the detection of heterophile antibodies or atypical lymphocytes in the peripheral blood. Occasionally, pharyngeal biopsy or cervical lymph node biopsy is required to establish the diagnosis.

Noninfectious causes of pharyngitis must also be considered. These include mucositis from chemoradiation therapy, which may be associated with fungal superinfection. Pharyngitis may also be seen in immune-mediated conditions such as erythema multiforme, bullous pemphigoid, and pemphigus vulgaris. In addition, reflux is being increasingly identified as a cause of both laryngitis and pharyngitis, particularly when the symptoms are chronic. A 24-hour pH probe is the gold standard diagnostic test, and treatment is usually successful with lifestyle modification, although proton pump inhibitors are often prescribed.¹⁴

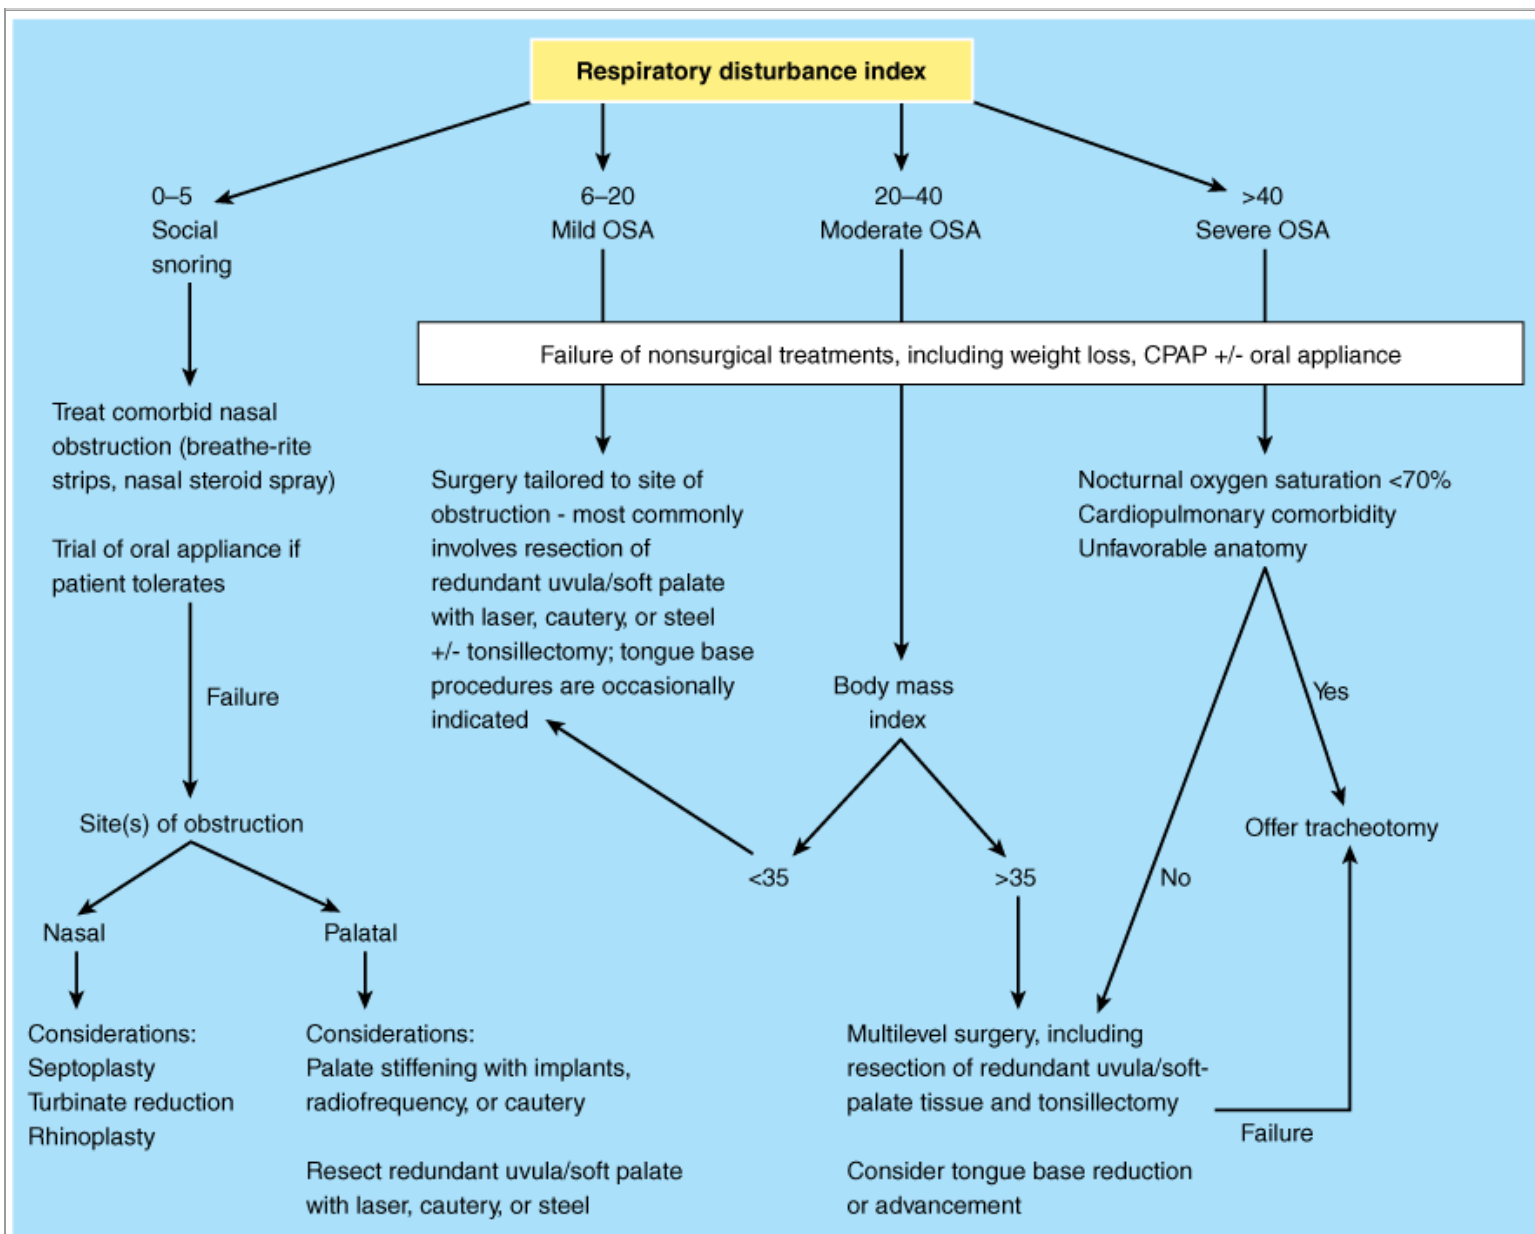

Obstructive adenotonsillar hyperplasia may present with nasal obstruction, rhinorrhea, voice changes, dysphagia, and sleep-disordered breathing or OSA, depending on the particular foci of lymphoid tissue involved.

Tonsillectomy and adenoidectomy are indicated for chronic or recurrent acute infection and for obstructive hypertrophy.¹⁵ The American Academy of Otolaryngology–Head and Neck Surgery Clinical Indicators Compendium suggests tonsillectomy after three or more infections per

year despite adequate medical therapy. Some feel that tonsillectomy is indicated in children who miss 2 or more weeks of school annually secondary to tonsil infections. Multiple techniques have been described, including electrocautery, sharp dissection, laser, and radiofrequency ablation. There is no consensus as to the best method. In cases of chronic or recurrent infection, surgery is considered only after failure of medical therapy. Patients with recurrent peritonsillar abscess should undergo tonsillectomy when the acute inflammatory changes have resolved. Selected cases, however, require tonsillectomy in the acute setting for the management of severe inflammation, systemic toxicity, or impending airway compromise. Adenoidectomy, in conjunction with myringotomy and tube placement, may be beneficial for children with chronic or recurrent otitis media.¹⁶ This is because the adenoid appears to function as a bacterial reservoir that seeds the middle ear via the eustachian tube. Adenoidectomy is also the first line of surgical management for children with chronic sinusitis. In addition to acting as a bacterial reservoir, an obstructive adenoid impairs mucociliary clearance from the sinonasal tract into the pharynx.

The primary complications of tonsillectomy¹⁷ include bleeding, airway obstruction, death, and readmission for dehydration secondary to postoperative dysphagia. Complications of adenoidectomy also include hemorrhage, as well as nasopharyngeal stenosis and velopharyngeal insufficiency. In the latter condition, nasal regurgitation of liquids and hypernasal speech are experienced. Patients with significant airway obstruction secondary to adenotonsillar hypertrophy are also at risk for postobstructive pulmonary edema syndrome, once the obstruction is relieved by adenotonsillectomy. Overall, bleeding is the most significant risk and may require a return trip to the operating room for control. With the exception of bleeding, which is observed in 3 to 5% of patients, most of these complications are rare or self limiting. It deserves special notation that adenotonsillectomy in a child with Down syndrome requires attention to the cervical spine. Patients with this syndrome may exhibit atlantoaxial instability, resulting in cervical spine injury if the neck is extended for the procedure. Baseline radiographs, with appropriate orthopedic or neurosurgical consultation, are indicated preoperatively. Surgery for adenotonsillar hypertrophy may be indicated when the patient exhibits sleep-disordered breathing.

Sleep disorders represent a continuum from simple snoring to upper airway resistance syndrome to obstructive sleep apnea (OSA).¹⁸ Upper airway resistance syndrome and OSA are associated with snoring, excessive daytime somnolence, fatigue, and frequent sleep arousals. In OSA, polysomnogram demonstrates at least 10 episodes of apnea or hypopnea per hour of sleep. The average number of apneas and hypopneas per hour can be used to calculate a respiratory disturbance index, which, along with oxygen saturation, can be used to grade the severity of OSA. These episodes occur as a result of collapse of the pharyngeal soft tissues during sleep. In adults, it should be noted that in addition to tonsil size, factors such as tongue size and body mass index (especially $>35 \text{ kg/m}^2$) are significant predictors of OSA. Other anatomic findings associated with OSA include obese neck, retrognathia, low hyoid bone, and enlarged soft palate. Surgery should be considered after failure of more conservative measures, such as weight loss, elimination of alcohol use, use of oral appliances to open the airway during sleep, and continuous positive airway pressure. Selection of surgical procedure should be tailored to the particular patient's pattern of obstruction. In children, surgical management typically involves tonsillectomy and/or adenoidectomy, because the disorder is usually caused, at least in part, by hypertrophy or collapse of these structures. In any individual patient, the anatomy must be carefully evaluated to determine whether the site of airway collapse is in the retropalatal region, retrolingual area, or both. A therapeutic algorithm for adults is proposed (Fig. 18-9), based on site of obstruction and severity of disease. In adults, uvulopalatoplasty is frequently performed to alleviate soft-palate collapse and is the most common operation performed for sleep-disordered breathing. The goal of this procedure is to remove redundant tissue from the uvula and soft palate, along with obstructive tonsillar tissue. This can be accomplished with cold steel, laser, and/or cautery. Adults with significant nasal obstruction may benefit from septoplasty, reduction in size of the inferior turbinates, and possibly external nasal surgery. Patients with a significant component of retrolingual obstruction may be candidates for tongue base reduction, tongue base advancement, or hyoid suspension. Additionally, a variety of maxillomandibular advancement procedures also have been described to enlarge the anterior-posterior dimension of the retrolingual airway. Patients with moderate to severe sleep apnea frequently manifest involvement of the tongue base. However, management of this subgroup may be difficult, as procedures addressing the retrolingual airway can involve difficult recovery, significant morbidity, and limited success. These patients often continue to require continuous positive airway pressure despite performance of multilevel surgical procedures. Patients with severe OSA (respiratory disturbance index >40 , lowest nocturnal oxygen saturation $<70\%$) and unfavorable anatomy or comorbid cardiopulmonary disease may require tracheotomy,¹⁹ which is the only surgical "cure" for OSA. Tracheotomy should be offered in patients with evidence of right heart failure (cor pulmonale), which is a potential sequela of severe OSA or undertreated cases of moderate OSA.

Algorithm of respiratory disturbance index. CPAP = continuous positive airway pressure; OSA = obstructive sleep apnea.

On the opposite end of the spectrum, many patients present with snoring but fail to exhibit OSA according to polysomnographic criteria. These "social snorers" may pursue elective procedures that stiffen the uvula and soft palate. This may be accomplished by the application of radiofrequency energy or cautery to induce submucosal scar, or by palatal implants. Elective uvulopharyngoplasty may also be a consideration in this population.

Benign Conditions of the Larynx

Disorders of voice may affect a wide array of patients with respect to age, gender, and socioeconomic status. The principal symptom of these disorders, at least when a mass lesion is present, is hoarseness. Other vocal manifestations include hypophonia or aphonia, breathiness, and pitch breaks. Benign laryngeal disorders may also be associated with airway obstruction, dysphagia, and reflux.²⁰ Smoking may also be a risk factor for benign disease, but this element of the history should raise the index of suspicion for malignancy.

Recurrent respiratory papillomatosis (RRP) reflects involvement of human papillomavirus (HPV) within the mucosal epithelium of the upper aerodigestive tract. The larynx is the most frequently involved site, and subtypes 6 and 11 are the most often implicated. The disorder typically presents in early childhood, secondary to viral acquisition during vaginal delivery. Many cases resolve after puberty, but the disorder may

progress into adulthood. Adult-onset RRP typically occurs in the third or fourth decade of life, is usually less severe, and is more likely to involve extralaryngeal sites of the upper aerodigestive tract. With laryngeal involvement, RRP is most likely to present with hoarseness, although airway compromise may be observed. The diagnosis can be established with office endoscopy. Currently, there is no "cure" for RRP. Treatment involves operative microlaryngoscopy with excision or laser ablation, and the natural history is eventual recurrence. Therefore, surgery has an ongoing role for palliation of the disease. Multiple procedures are typically required over the patient's lifetime. Several medical therapies, including intralesional cidofovir injection and oral indole-3-carbinol, are being investigated to determine their abilities to retard recurrence. Additionally, the advent of HPV vaccines has suggested a role for this therapy in prevention of RRP.²¹

Laryngeal granulomas typically occur in the posterior larynx on the arytenoid mucosa (Fig. 18-10). These lesions develop secondary to multiple factors,²² including reflux, voice abuse, chronic throat clearing, endotracheal intubation, and vocal fold paralysis. Effective management requires identification of the underlying cause(s). Patients report pain (often with swallowing) more commonly than vocal changes. In addition to fiber-optic laryngoscopy, work-up may include voice analysis, laryngeal electromyography (EMG), and pH probe testing.²³ Treatment is individualized, depending on the contributing factors identified. First-line modalities that may be used include voice rest, voice retraining therapy, and antireflux therapy. The management of vocal cord paresis/paralysis is discussed later in this section. It is notable that the majority of cases demonstrate a component of reflux and when maximal medical therapy has failed, fundoplication may be indicated. The role of surgical excision is somewhat controversial, because it does not address the underlying etiology and is frequently associated with recurrence. Nonetheless, excision is indicated when carcinoma is suspected or when the patient has airway obstruction. Surgery may also be indicated in selected cases when a granuloma has matured into a fibroepithelial polyp, or when the patient (e.g., a performing artist) requires prompt removal for voice restoration. Surgical excision is optimally performed under jet ventilation so as to avoid endotracheal intubation. During surgery, it is important to preserve the arytenoid perichondrium to promote epithelialization postoperatively.

Laryngeal granuloma.

Edema in the superficial lamina propria of the vocal cord is known as *polypoid corditis*, *polypoid laryngitis*, *polypoid degeneration of the vocal cord*, or *Reinke's edema*.²⁴ The superficial lamina propria just underlies the vibratory epithelial surface. Edema is thought to arise from injury to the capillaries that exist in this layer, with subsequent extravasation of fluid. Patients report progressive development of a rough, low-pitched voice. Females more commonly present for medical attention because the lowered vocal frequency is more evident, given the higher fundamental frequency of the female voice. The etiology is also multifactorial and may involve smoking, laryngopharyngeal reflux, hypothyroidism, and vocal hyperfunction. Most of these patients are heavy smokers. Findings are typically bilateral.

Focal, unilateral hemorrhagic vocal cord polyps are more common in men. These occur secondary to capillary rupture within the mucosa by shearing forces during voice abuse. Use of anticoagulant or antiplatelet drugs may be a risk factor. As with laryngeal granulomas, treatment of polypoid corditis and vocal cord polyps requires addressing the underlying factors. Conservative management includes absolute discontinuance of smoking, reflux management, and voice therapy. Notably, topical and systemic steroids are ineffective for these conditions. For polypoid corditis, elective surgery may be performed under microlaryngoscopy to evacuate the gelatinous matrix within the superficial lamina propria and trim excess mucosa. Focal polyps may be excised superficially under microlaryngoscopy. Surgery, particularly for polypoid corditis, will be less effective in patients who continue to smoke, although it should be noted that because of their heavy smoking history, surgery might be necessary to rule out occult malignancy. Surgery for polypoid corditis and hemorrhagic polyps may be accomplished either with cold steel or by using the carbon dioxide (CO₂) laser. Postoperative voice therapy is usually indicated.

Vocal cord cysts may occur under the laryngeal mucosa, particularly in regions containing mucous-secreting glands, such as the supraglottic larynx. Occasionally, they derive from minor salivary glands, and congenital cysts may persist as remnants of the branchial arch. Cysts may present in a variety of ways depending on the size and site of origin (Fig. 18-11). Cysts of the vocal cord may be difficult to distinguish from vocal polyps, and video stroboscopic laryngoscopy may be necessary to help establish the diagnosis. Cysts observed in children can be quite large, thus compromising the airway. Lesions of the true vocal cord usually present with hoarseness. Treatment again depends on the size and site of the cyst. Large cysts of the supraglottic larynx are treated by marsupialization with cold steel or a CO₂ laser. Those of the vocal cord itself require careful microsurgical technique for complete removal of the cyst while preserving the overlying mucosa.

Fig. 18-11.

Large cyst of vocal cord.

Leukoplakia of the vocal fold represents a white patch (which cannot be wiped off) on the mucosal surface, usually on the superior surface of the true vocal cord. Rather than a diagnosis per se, the term *leukoplakia* describes a finding on laryngoscopic examination. The significance of this finding is that it may represent squamous hyperplasia, dysplasia, and/or carcinoma. Lesions exhibiting hyperplasia have a 1 to 3% risk of progression to malignancy. In contrast, that risk is 10 to 30% for those demonstrating dysplasia. Furthermore, leukoplakia may be observed in association with inflammatory and reactive pathologies, including polyps, nodules, cysts, granulomas, and papillomas. The wide, differential diagnosis for leukoplakia necessitates sound clinical judgment when selecting lesions that require operative direct laryngoscopy with biopsy for histopathologic analysis. Features of ulceration and erythroplasia are particularly suggestive of possible malignancy. A history of smoking and alcohol abuse should also prompt a malignancy work-up. In the absence of suspected malignancy, conservative measures are used for 1 month.

These include reduction of caffeine and alcohol, which are dehydrating and promote laryngopharyngeal reflux, proper hydration, and elimination of vocal abuse behaviors. Antireflux therapy, including proton pump inhibitors, may be prescribed. Investigational therapies, including retinoids, also have been attempted. Any lesions that progress, persist, or recur should be considered for excisional biopsy.

Vocal cord paralysis most commonly is iatrogenic in origin,²⁵ following surgery to the thyroid, parathyroid, carotid, or cardiothoracic structures. Vocal cord paralysis may also be secondary to malignant processes in the lungs, thoracic cavity, skull base, or neck. In the pediatric population up to one fourth of cases may be neurologic in origin, with Arnold-Chiari malformation being the most common. Overall, the left vocal cord is more commonly involved secondary to the longer course of the recurrent laryngeal nerve (RLN) on that side, which extends into the thoracic cavity. When anterior approaches to the cervical spine are performed, however, the right RLN is at an increased risk, because it courses more laterally to the tracheoesophageal complex. Neurotoxic medications, trauma, intubation injury, and atypical infections are less common causes of vocal cord paralysis. The cause remains idiopathic in up to 20% of adults and 35% of children. These cases should prompt an imaging work-up to examine the course of the vagal/RLN in question: from the skull base to the aortic arch on the left, and from skull base to the subclavian on the right.

"Idiopathic" left true vocal cord paralysis may be a presenting sign of malignancy involving the lung, thyroid, or esophagus. Adults typically present with hoarseness and the voice may be breathy if the contralateral vocal cord has not compensated to close the glottic valve. If the proximal vagus nerve or the superior laryngeal nerve is involved, the patient may demonstrate aspiration secondary to diminished supraglottic sensation. Stridor, weak cry, and respiratory distress are seen in children, but adults typically do not exhibit signs of airway compromise unless paralysis is bilateral. Flexible fiber-optic laryngoscopy usually confirms the diagnosis, but laryngeal EMG may be necessary to distinguish vocal cord paralysis from mechanical fixation secondary to scar tissue or cricoarytenoid joint fixation. The position of the paralyzed fold depends on the residual innervation, pattern of reinnervation, and the degrees of atrophy and fibrosis of the laryngeal musculature. In bilateral vocal cord paralysis, the cords are often paralyzed in a paramedian position, creating airway compromise that necessitates tracheotomy. Once an airway is secure, vocal cord lateralization or arytenoidectomy may be performed electively to provide an adequate airway. Treatment of unilateral vocal cord paralysis includes speech therapy, which promotes glottic closure to optimize the voice and prevent aspiration. Some patients do well with this modality alone.

Surgical treatment to augment or medialize the paralyzed vocal fold is performed to provide a surface against which the contralateral normal fold may make contact. Injection laryngoplasty may be performed under office or operative laryngoscopy with a variety of autologous (fat, collagen) or alloplastic (hydroxylapatite, silicone, Teflon) compounds. Autologous materials are preferred. Teflon injection is of historical significance only secondary to the incidence of severe foreign body inflammatory reactions. Injection of the vocal fold increases its bulk to optimize closure with the contralateral normal fold. This technique also is useful for vocal cord atrophy, which may occur with aging. Recent trends include the use of micronized human collagen for this purpose, which has shown promising results. Laryngeal framework surgery involves the implantation of cartilage, hydroxylapatite, Gore-Tex, or silicone under the musculomembranous fold via an external approach through a window in the thyroid cartilage (Fig. 18-12).²⁶ This may be combined with procedures to adduct the vocal process of the arytenoids. Laryngeal reinnervation (with ansa cervicalis to RLN transfer) and pacing have also been attempted with varying success.

Cross-section of the larynx demonstrating the principle of medialization laryngoplasty. An implant is used to push the paralyzed vocal cord toward the midline.

Vascular Lesions

Vascular lesions can be broadly classified into two groups: hemangiomas and vascular malformations.²⁷ Hemangiomas are the most common vascular lesions present in infancy and childhood. These lesions are present at birth in up to 30% of cases, but usually become apparent in the first few weeks of life. The lesions proliferate in size over the first year before beginning involution, which subsequently occurs over the next 2 to 12 years. Forty percent of cases will resolve completely, while the remainder require intervention. Once the proliferative phase has ended, the lesion should be observed every 3 months for involution, and surgery should be considered for those that have not significantly involuted by 3 to 4 years of age. Surgical treatment of proliferating hemangiomas is reserved for lesions associated with severe functional or cosmetic problems, such as those involving the nasal tip or periorbital region. Treatment is performed with either the flashlamp-pumped pulsed-dye laser (FPDL), the potassium titanyl phosphate (KTP) laser, or the neodymium yttrium-aluminum garnet (Nd:YAG) laser, repeated every 4 to 6 weeks until the lesion disappears. Systemic steroids may be used to arrest rapidly proliferating lesions until the child reaches 12 to 18 months, after which growth should stabilize or involution begin. Subcutaneous interferon alfa-2a may also be used for this purpose. This treatment, however, is associated with neurologic side effects and should be used with caution.^{27,28} Vascular malformations, in contrast, are almost always present at birth and slowly enlarge without proliferation.²⁹ These may arise from capillaries, venules, veins, arteriovenous channels, and/or lymphatics. Capillary malformations usually involve the midline neck or forehead, and may fade with age. Venular malformations are also known as *port-wine stains*. These lesions often follow facial dermatomes and usually thicken with age. Venous malformations are composed of ectatic veins within the lips, tongue, or buccal area. These may present as purple masses or subcutaneous/submucosal nodules. Arteriovenous malformations are rare malformations of arteriovenous channels that failed to regress during development.

Lymphatic malformations or lymphangiomas of the head and neck usually involve the cervical area, in which case they are more commonly macrocystic and well demarcated. Those arising above the hyoid bone tend to be microcystic and have an infiltrative quality. Lymphangiomas may become secondarily infected and may rapidly enlarge, causing airway compromise. These lesions may also be associated with feeding difficulties and failure to thrive.

Capillary hemangiomas and superficial port-wine stains are effectively treated by FPDL. The KTP or Nd:YAG laser is used for deeper port-wine

stains. Venous malformations may be treated with laser, sclerotherapy, and/or surgical excision, depending on the depth, size, and location. Superficial lesions are treated with the Nd:YAG laser, which has deeper penetration than either the FPDL or KTP laser. Deeper venous malformations may benefit from Nd:YAG therapy of the superficial component followed by meticulous surgical excision of the deeper component. Sclerotherapy should be undertaken with extreme caution in the head and neck, because the valveless quality of the veins in this region introduces significant risk of cavernous sinus thrombosis. Arteriovenous malformations require formal surgical resection with negative margins. Preoperative angiographic embolization is frequently used to facilitate surgery. Microvascular reconstruction may be necessary, depending on the extent of the resection required. Surgical excision is also required for lymphatic malformations, although superficial lesions are sometimes treatable with the CO₂ laser. This often is difficult for microcystic cases given the infiltrative nature. Sclerotherapy with OK-432 is effective in macrocystic lymphangiomas, and multiple other sclerosing agents, including bleomycin, have been explored.³⁰

TRAUMA OF THE HEAD AND NECK

Management of soft-tissue trauma in the head and neck has several salient features. Skin injuries may be classified as abrasions, contusions, or lacerations. Abrasions represent superficial epidermal injury and are treated with cleansing, saline irrigation, and removal of dirt or other foreign bodies. The latter step is important because retained materials may form a nidus for infection or foreign-body reaction and may cause tattooing of the skin after healing. Topical antibiotic dressing is applied until re-epithelialization is complete. The patient is instructed to avoid sunlight, because this can cause pigmentary abnormalities during the healing process, which matures over a 6- to 12-month period. Contusions may include ecchymosis and/or frank hematoma. Treatment includes head-of-bed elevation to decrease tissue edema, application of ice, and drainage of hematoma. Lacerations must also be cleansed and irrigated, with removal of any associated dirt or foreign bodies. Most lacerations without significant tissue loss can be closed primarily, and primary closure is preferred when possible. Closure of trapdoor lacerations requires conservative undermining of surrounding tissue and good approximation of subdermal levels before epidermal closure. A pressure dressing is also applied. These measures are used to avoid a pincushion deformity (Fig. 18-13).

Trap door laceration (**A**) healed with a "pin cushion" deformity (**B**). Soft-tissue layers must be meticulously approximated (**C**) to avoid this complication.

Typically, subdermal layers are approximated with an absorbable 3-0 or 4-0 suture such as Vicryl or polydioxanone, and the skin is closed using 5-0 or 6-0 monofilament nylon or Prolene. Sutures are removed after 4 to 5 days, but may be removed earlier in thin-skinned areas. The wound is treated with antibiotic ointments. Systemic antibiotics are indicated for through-and-through mucosal lacerations, contaminated wounds, bite injuries, and when delayed closure is performed (>72 hours). The chosen antibiotic should cover *S. aureus*. In many such wounds, healing by secondary intention may be preferable.

Wound closure must be understood in the context of the cosmetic and functional anatomic landmarks of the head and neck. Management of injuries to the eyelid requires identification of the orbicularis oculi, which is closed in a separate layer. The gray line (conjunctival margin; Fig. 18-14) must be carefully approximated to avoid lid notching or height mismatch. Management of lip injuries follows the same principle. The orbicularis oris must be closed, and the vermillion border carefully approximated (Fig. 18-15). Injuries involving one fourth the width of the eyelid or one third the width of the lip may be closed primarily; otherwise, flap or grafting procedures may be required. With laceration of the auricle, key structures such as the helical rim and antihelix must be carefully aligned. These injuries must be repaired so that the cartilage is covered. The principles of auricular repair are predicated on the fact that the cartilage has no intrinsic blood supply and is thus susceptible to ischemic necrosis following trauma. The suture should be passed through the perichondrium, while placement through the cartilage itself should be avoided.

Approximation of the vermillion border is the key step in the repair of lip lacerations.

Auricular hematomas should be drained promptly, with placement of a bolster as a pressure dressing. A pressure dressing is frequently advocated after closure of an ear laceration. It also deserves note that the surgeon must avoid the temptation to perform aggressive débridement after injuries to the eyelid or auricle. Given the rich vascular supply to the face and neck, many soft-tissue components that appear devitalized will indeed survive.

Most traumatic facial nerve injuries are secondary to temporal bone trauma, which is discussed below in this section. Soft-tissue injuries occurring in the midface may involve distal facial nerve branches. Those injured anterior to a vertical line dropped from the lateral cantus do not require repair secondary to collateral innervation in the anterior midface. Posterior to this line, the nerve should be repaired, primarily if possible, using 8-0 to 10-0 monofilament suture to approximate the epineurium under microscopic visualization. If neural segments are missing, cable grafting is performed using either the greater auricular (provides 7 to 8 cm) or sural nerve (up to 30 cm) as a donor. Injuries to the buccal branch should alert the examiner to a possible parotid duct injury. This structure lies along an imaginary line drawn from the tragus to the midline upper lip, running along with the buccal branch of the facial nerve. The duct should be repaired over a 22-gauge stent or marsupialized into the oral cavity.

Facial bone fractures most commonly involve the mandible. Fractures most often involve the angle, body, or condyle, and in most cases, two or more sites are almost always involved (Fig. 18-16). Fractures are described as either favorable or unfavorable, depending on whether or not the masticatory musculature tends to pull the fracture into reduction or distraction. Vertically favorable fractures are brought into reduction by the masseter, while horizontally favorable fractures are brought into reduction by the pterygoid musculature. The fracture is usually evaluated radiographically using a Panorex, but specialized plain film views, and occasionally CT scan, are necessary in selected cases. Classical management of mandible fractures dictated closed reduction and a 6-week period of intermaxillary fixation (IMF) with arch bars applied via circumdental wiring. Comminuted, displaced, or unfavorable fractures underwent open reduction and wire fixation in addition to IMF. Currently,

arch bars and IMF are performed to establish occlusion. The fracture is then exposed and reduced, using transoral approaches where possible.

Transcervical approaches are required to address fractures of the ramus or posterior body, with careful attention given to preserving the marginal mandibular branch of the facial nerve. Rigid fixation is then accomplished by the application of plates and screws. Selected fractures, such as those of the body, benefit from dynamic compression plating, which applies pressure toward the fracture line. With rigid fixation, IMF is required to establish occlusion intraoperatively, and is not necessarily continued for a full 6 weeks postoperatively. This is preferable because IMF is associated with gingival and dental disease, as well as with significant weight loss and malnutrition, during the fixation period. New techniques have included the 4-point fixation technique, where the maxilla and mandible are held in occlusion by wires attached to intraoral cortical bone screws, with two screws above and below the occlusal line anteriorly. In edentulous patients, determining the baseline occlusion is of less significance because dentures may be refashioned once healing is complete. If IMF is required to aid in immobilization of the fracture in an edentulous patient, interosseous wiring and/or the fabrication of custom-made splints is required.

Midface fractures are classically described in three patterns: Le Fort I, II, and III. A full understanding of midface structure is first necessary (Fig. 18-17). Three vertical buttresses support the midface: the nasofrontal-maxillary, the frontozygomaticomaxillary, and pterygomaxillary.³¹ The five weaker, horizontal buttresses include the frontal bone, nasal bones, upper alveolus, zygomatic arches, and the infraorbital region. Classical signs of midface fractures in general include subconjunctival hemorrhage; malocclusion; midface numbness or hypesthesia (maxillary division of the trigeminal nerve); facial ecchymoses/hematoma; ocular signs/symptoms; and mobility of the maxillary complex.

Le Fort I fractures occur transversely across the alveolus, above the level of the teeth apices. In a pure Le Fort I fracture, the palatal vault is mobile while the nasal pyramid and orbital rims are stable. The Le Fort II fracture extends through the nasofrontal buttress, medial wall of the orbit, across the infraorbital rim, and through the zygomaticomaxillary articulation. The nasal dorsum, palate, and medial part of the infraorbital rim are mobile. The Le Fort III fracture is also known as *craniofacial disjunction*. The frontozygomaticomaxillary, frontomaxillary, and frontonasal suture lines are disrupted. The entire face is mobile from the cranium. It is convenient to conceptualize complex midface fractures according to these patterns (Fig. 18-18); however, in reality, fractures reflect a combination of these three types. Also, the fracture pattern may vary between the left and right sides of the midface. Lateral blows to the cheek may be associated with isolated zygoma fractures. The zygoma is typically displaced inferiorly and medially with disruption of the suture lines between the temporal, frontal, and maxillary bones and the zygoma. Disruption of the latter articulation may be associated with depression into the maxillary sinus and blood in the sinus cavity. Fractures of the midface and/or zygoma may be associated with an orbital blowout, whereas the orbital floor is disrupted and orbital soft tissues subsequently herniate into the maxillary sinus (Fig. 18-19). The mechanism of orbital blowout may involve propagation of adjacent fracture lines or may be the result of a sudden increase in intraorbital pressure during the injury. This may be associated with enophthalmos or entrapment of the inferior oblique muscle. The latter results in diplopia upon upward gaze. Entrapment is confirmed by forced duction testing, where, under topical or general anesthesia, the muscular attachment of the inferior oblique is grasped with forceps and manipulated to determine passive ocular mobility. Fractures of the midface, zygoma, and orbital floor are best evaluated using CT scan, and repair requires a combination of transoral and external approaches to achieve at least two points of fixation for each fractured segment.³² Significant areas of bone loss can be reconstructed with commercially available hydroxyapatite bone cements, an osteoconductive calcium-phosphate matrix. Blowout fractures demonstrating significant entrapment or enophthalmos are treated by orbital exploration and reinforcement of the floor with mesh or bone grafting.

Coronal computed tomography demonstrating an orbital blowout fracture with herniation of orbital contents into the maxillary sinus.

Temporal bone fractures occur in approximately one fifth of skull fractures. As with fractures of the mandible and midface, blunt trauma (from motor vehicle accident or assault) usually is implicated. Unfortunately, the incidence of temporal bone fracture from gunshot wounds to the head is rising. Fractures are divided into two patterns (Fig. 18-20), longitudinal and transverse, based on the clinical picture and CT imaging. In practice, most fractures are oblique. By classical descriptions, longitudinal fractures constitute 80% and are associated with lateral skull trauma.

Signs and symptoms include conductive hearing loss, ossicular injury, bloody otorrhea, and labyrinthine concussion. The facial nerve is injured in approximately 20% of cases. In contrast, the transverse pattern constitute only 20% of temporal bone fractures and occurs secondary to fronto-occipital trauma. The facial nerve is injured in 50% of cases. These injuries frequently involve the otic capsule to cause sensorineural hearing loss and loss of vestibular function. Hemotympanum may be observed. A cerebrospinal fluid (CSF) leak must be suspected in temporal bone trauma. This resolves with conservative measures in most cases. The most significant consideration in the management of temporal bone injuries is the status of the facial nerve. Delayed or partial paralysis will almost always resolve with conservative management. However, immediate paralysis that does not recover within 1 week should be considered for nerve decompression. Electroneurography and EMG have been used to help determine which patients with delayed-onset complete paralysis will benefit from surgical decompression. The finding of greater than 90% degeneration more than 72 hours after the onset of complete paralysis is considered an indication for surgery.³³ Multiple approaches have been described for facial nerve decompression, some of which sacrifice hearing. These patients may have severe intracranial or vascular injuries such that the decision to operate must also be made in the context of the patient's overall medical stability. It is of paramount importance to protect the eye in patients with facial nerve paralysis of any etiology, because absence of an intact blink reflex will predispose to corneal drying and abrasion. This requires the placement of artificial tears throughout the day with lubricant ointment, eye taping, and/or a humidity chamber at night.^{34,35}

TUMORS OF THE HEAD AND NECK

When a discussion of neoplasms of the head and neck is initiated, the conversation frequently focuses on squamous cell carcinoma. This is

because the majority of malignancies of this region are represented by this pathology. The diagnosis and treatment of lesions spanning from the lips and oral cavity to the larynx and hypopharynx requires a similar methodic approach.

The selection of treatment protocols varies for each site within the upper aerodigestive tract. The importance of multidisciplinary management cannot be underestimated. Presentation of cases before a tumor board allowing review of a patient's history, physical examination findings, imaging, and prior pathology specimens allows for confirmation of the patient's status. Additionally, it should encourage discussion from multiple points of view concerning the most appropriate treatment options available. Participation in the discussion with representatives of radiation oncology, medical oncology, surgical oncology, oral maxillofacial surgery/dental medicine, along with radiologists and pathologists specializing in upper aerodigestive tract disorders benefits not only the patient but also represents an excellent teaching opportunity for all disciplines.

The development of organ preservation protocol and the evolution of free tissue reconstructive techniques are some of the most significant advances made within the field during the last two decades. The future of the treatment of head and neck cancer lies within the field of molecular biology. As more is understood about the genetics of cancer, tailoring treatment options to a particular tumor mutation has the capacity to maximize survival while achieving the highest quality of life.

Etiology and Epidemiology

It should come as no surprise that abuse of tobacco and alcohol are the most common preventable risk factors associated with the development of head and neck cancers. This relationship is synergistic rather than additive. Smoking confers a 1.9-fold increased risk to males and a threefold increased risk to females for developing a head and neck carcinoma, when compared to nonsmokers. The risk increases as the number of years smoking and number of cigarettes smoked per day increases. Alcohol alone confers a 1.7-fold increased risk to males drinking one to two drinks per day, when compared to nondrinkers. This increased risk rises to greater than threefold for heavy drinkers. Individuals who both smoke (two packs per day) and drink (four units of alcohol per day) had an odds ratio of 35 for the development of a carcinoma when compared to controls.³⁶ Users of smokeless tobacco have a four times increased risk of oral cavity carcinoma when compared to nonusers.

Tobacco is the leading preventable cause of death in the United States and is responsible for one of every five deaths.³⁷ Approximately one fourth of U.S. adults habitually use tobacco products, with recent trends demonstrating an increase in the use of tobacco products by women. The evidence supporting the need for head and neck cancer patients to pursue smoking cessation after treatment is compelling. In a study by Moore,³⁸ 40% of patients who continued to smoke after definitive treatment for an oral cavity malignancy went on to recur or develop a second head and neck malignancy. For patients who stopped smoking after treatment, only 6% went on to develop a recurrence. Induction of specific p53 mutations within upper aerodigestive tract tumors has been noted in patients with histories of tobacco and alcohol use.^{39,40}

When smokers who develop head and neck squamous cell carcinomas are compared to nonsmokers, differences between the two populations emerge. Koch and associates⁴¹ noted that nonsmokers were represented by a disproportionate number of women and were more frequently at the extremes of age (<30 or >85 years of age). Tumors from nonsmokers presented more frequently in the oral cavity, specifically within the oral tongue, buccal mucosa, and alveolar ridge. Smokers presented more frequently with tumors of the larynx, hypopharynx, and floor of mouth. Former smokers, defined as those individuals who had quit greater than 10 years prior, demonstrated a profile more consistent with nonsmokers.

In India and Southeast Asia, the product of the areca catechu tree, known as a betel nut, is chewed in a habitual manner and acts as a mild stimulant similar to that of coffee. The nut is chewed in combination with lime and cured tobacco as a mixture known as a quid. The long-term use of the betel nut quid can be destructive to oral mucosa and dentition and is highly carcinogenic.⁴² Another habit associated with oral malignancy is that of reverse smoking, where the lighted portion of the tobacco product is within the mouth during inhalation. The risk of hard palate carcinoma is 47 times greater in reverse smokers when compared to nonsmokers.

HPV is an epitheliotropic virus that has been detected to varying degrees within samples of oral cavity squamous cell carcinoma. Infection alone is not considered sufficient for malignant conversion; however, results of multiple studies suggest a role of HPV in a subset of head and neck squamous cell carcinoma. Approximately 40% of tonsillar carcinomas demonstrate evidence of HPV types 16 and 18.

Environmental ultraviolet light exposure has been associated with the development of lip cancer. The projection of the lower lip, as it relates to this solar exposure, has been used to explain why the majority of squamous cell carcinomas arise along the vermilion border of the lower lip. In addition, pipe smoking also has been associated with the development of lip carcinoma. Factors such as mechanical irritation, thermal injury,

and chemical exposure have been described as an explanation for this finding.

Other entities associated with oral malignancy include Plummer-Vinson syndrome (achlorhydria, iron-deficiency anemia, mucosal atrophy of mouth, pharynx, and esophagus), chronic infection with syphilis, and immunocompromised status (30-fold increase with renal transplant).

Although evidence linking HIV infection to squamous cell carcinoma of the head and neck is lacking, several AIDS-defining malignancies, including Kaposi's sarcoma, and non-Hodgkin's lymphoma may require the care of an otolaryngologist.

Anatomy and Histopathology

The upper aerodigestive tract is divided into several distinct sites that include the oral cavity, pharynx, larynx, and nasal cavity/paranasal sinuses. Within these sites are individual subsites with specific anatomic relationships that affect diagnosis, tumor spread, and selection of treatment options. The spread of a tumor from one site to another is determined by the course of the nerves, blood vessels, lymphatic pathways, and fascial planes. The fascial planes serve as barriers to the direct invasion of tumor and facilitate the pattern of spread to regional lymph nodes.

The oral cavity extends from the vermillion border of the lip to the hard-palate/soft-palate junction superiorly, to circumvallate papillae inferiorly, and to the anterior tonsillar pillars laterally (Fig. 18-21). It is divided into seven subsites: lips, alveolar ridges, oral tongue, retromolar trigone, floor of mouth, buccal mucosa, and hard palate. Advanced oral cavity lesions may present with mandibular and/or maxillary involvement requiring special consideration at the time of resection and reconstruction. Regional metastatic spread of lesions of the oral cavity is to the lymphatics of the submandibular and the upper jugular region (levels I, II, and III).

Fig. 18-21.

Oral cavity landmarks.

The pharynx is divided into three regions: nasopharynx, oropharynx, and hypopharynx. The nasopharynx extends from the posterior nasal septum and choana to the skull base and includes the fossa of Rosenmüller and torus tubarius of the eustachian tubes laterally. The inferior margin of the nasopharynx is the superior surface of the soft palate. The adenoids, typically involuted in adults, are located with the posterior aspect of this site. Given the midline location of the nasopharynx, bilateral regional metastatic spread is common in these lesions.

Lymphadenopathy of the posterior triangle (level V) of the neck should provoke consideration for a nasopharyngeal primary.

The major sites within the oropharynx are the tonsillar region, base of tongue, soft palate, and posterolateral pharyngeal walls. Regional lymphatic drainage for oropharyngeal lesions frequently occurs to the upper and lower cervical lymphatics (levels II, III, IV). Retropharyngeal metastatic lymphatic spread may occur with oropharyngeal lesions.

The hypopharynx extends from the vallecula to the lower border of the cricoid posterior and lateral to the larynx. The subsites of this region include the pyriform fossa, the postcricoid space, and posterior pharyngeal wall. Regional lymphatic spread is frequently bilateral and to the mid- and lower cervical lymph nodes (levels III, IV).

The larynx is divided into three regions: the supraglottis, glottis, and subglottis. The supraglottic larynx includes the epiglottis, false vocal cords, medial surface of the aryepiglottic folds, and the roof of the laryngeal ventricles. The glottis includes the true vocal cords, anterior and posterior commissure, and the floor of the laryngeal ventricle. The subglottis extends from below the true vocal cords to the cephalic border of the cricoid within the airway. The supraglottis has a rich lymphatic network, which accounts for the high rate of bilateral spread of metastatic disease that is not typically seen with the glottis. Glottic and subglottic lesions, in addition to potential spread to the cervical chain lymph nodes, may also spread to the paralaryngeal and paratracheal lymphatics and require attention to prevent lower central neck recurrence.

Carcinogenesis

Development of a tumor represents the loss of cellular signaling mechanisms involved in the regulation of growth. Following malignant transformation, the processes of replication (mitosis), programmed cell death (apoptosis), and the interaction of a cell with its surrounding environment are altered. Advances in molecular biology have allowed for the identification of many of the mutations associated with this transformation.

Overexpression of mutant p53 is associated with carcinogenesis at multiple sites within the body. Point mutations in p53 have been reported in up to 45% of head and neck carcinomas. Koch and associates⁴¹ noted that p53 mutation is a key event in the malignant transformation of greater than 50% of head and neck squamous cell carcinomas in smokers.

Carcinogenesis has long been explained as a two-hit process, involving DNA damage and the progression of mutated cells through the cell cycle. These two events also are known as *initiation* and *promotion*. It has been proposed that up to six to 10 independent genetic mutations are required for the development of a malignancy. Overexpression of mitogenic receptors, loss of tumor-suppressor proteins, expression of oncogene-derived proteins that inhibit apoptosis, and overexpression of proteins that drive the cell cycle can allow for unregulated cell growth.

Genetic mutations may occur as a result of environmental exposure (e.g., radiation or carcinogen exposure), viral infection, or spontaneous mutation (deletions, translocations, frame shifts). Common genetic alterations, such as loss of heterozygosity at 3p, 4q, and 11q13, and the overall number of chromosomal microsatellite losses are found more frequently in the tumors of smokers than in the tumors of nonsmokers.⁴¹

Second Primary Tumors in the Head and Neck

Patients diagnosed with a head and neck cancer are predisposed to the development of a second tumor within the aerodigestive tract. The overall rate of second primary tumors is approximately 14%. A second primary tumor detected within 6 months of the diagnosis of the initial primary lesion is defined as a synchronous neoplasm. The prevalence of synchronous tumors is approximately 3 to 4%. The detection of a second primary lesion more than 6 months after the initial diagnosis is referred to as metachronous tumor. Eighty percent of second primaries are metachronous and at least half of these lesions develop within 2 years of the diagnosis of the original primary. The incidence and site of the second primary tumor vary and depend on the site and the inciting factors associated with the initial primary tumor. The importance of advocating smoking cessation and addressing alcoholism in these patients cannot be overemphasized.

Patients with a primary malignancy of the oral cavity or pharynx are most likely to develop a second lesion within the cervical esophagus, whereas patients with a carcinoma of the larynx are at risk for developing a neoplasm in the lung. As such, the presentation of a new-onset dysphagia, unexplained weight loss, or chronic cough/hemoptysis must be assessed thoroughly in patients with a history of prior treatment for a head and neck cancer.

A staging examination is recommended at the initial evaluation of all patients with primary cancers of the upper aerodigestive tract. This may involve a direct laryngoscopy, rigid/flexible esophagoscopy, and rigid/flexible bronchoscopy also known as "panendoscopy." Some surgeons argue against the use of bronchoscopy because of the low yield of the examination in asymptomatic patients with a normal chest x-ray.

Additionally, some surgeons prefer to use a barium swallow instead of esophagoscopy as a preoperative evaluation. Despite the different practices concerning pretreatment evaluation of asymptomatic patients, it should be noted that patients with symptoms potentially representing those of metastatic spread of disease require a work-up greater than a screening evaluation.

Staging

Staging for upper aerodigestive tract malignancies is defined by the American Joint Committee on Cancer⁴³ and follows the TNM (primary tumor, regional nodal metastases, distant metastasis) staging format. The T staging criteria for each site varies depending upon the relevant anatomy (e.g., vocal cord immobility is typical of T3 lesions). Table 18-3 demonstrates TNM staging for oral cavity lesions. The N classification system is uniform for all head and neck sites except for the nasopharynx.

Table 18-3 TNM Staging for Oral Cavity Carcinoma			
Primary tumor			
TX	Unable to assess primary tumor		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor is <2 cm in greatest dimension		
T2	Tumor >2 cm and <4 cm in greatest dimension		
T3	Tumor >4 cm in greatest dimension		
T4 (lip)	Primary tumor invading cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (e.g., nose or chin)		
T4a (oral)	Tumor invades adjacent structures (e.g., cortical bone, into deep tongue musculature, maxillary sinus) or skin of face		
T4b (oral)	Tumor invades masticator space, pterygoid plates, or skull base and/or encases the internal carotid artery		
Regional lymphadenopathy			
NX	Unable to assess regional lymph nodes		
N0	No evidence of regional metastasis		
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension		
N2a	Metastasis in single ipsilateral lymph node, >3 cm and <6 cm		
N2b	Metastasis in multiple ipsilateral lymph nodes, all nodes <6 cm		
N2c	Metastasis in bilateral or contralateral lymph nodes, all nodes <6 cm		
N3	Metastasis in a lymph node >6 cm in greatest dimension		
Distant metastases			
MX	Unable to assess for distant metastases		
M0	No distant metastases		
M1	Distant metastases		
TNM staging			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1–3	N1	M0
Stage IVa	T4a	N0	M0
	T4a	N1	M0
Stage IVb	T1–4a	N2	M0
	Any T	N3	M0
	T4b	Any N	M0
Stage IVc	Any T	Any N	M1

TNM = tumor, nodes, and metastasis.

Upper Aerodigestive Tract

LIP

The lips represent a transition from external skin to internal mucous membrane that occurs at the vermilion border. The underlying musculature of the orbicularis oris creates a circumferential ring that allows the mouth to have a sphincter-like function. Cancer of the lip is most commonly seen in white men from the ages of 50 to 70 years, but can be seen in younger patients, particularly those with fair complexions. Risk factors include prolonged exposure to sunlight, fair complexion, immunosuppression, and tobacco use.

The majority of lip malignancies present on the lower lip (88 to 98%), followed by the upper lip (2 to 7%) and oral commissure (1%). The histology of lip cancers is predominantly squamous cell carcinoma; however, other tumors, such as keratoacanthoma, verrucous carcinoma, basal cell carcinoma, malignant melanoma, minor salivary gland malignancies, and tumors of mesenchymal origin (e.g., malignant fibrous histiocytoma, leiomyosarcoma, and rhabdomyosarcoma), may also present in this location. Basal cell carcinoma presents more frequently on the upper lip than lower.

Clinical findings in lip cancer include an ulcerated lesion on the vermilion or cutaneous surface. Careful palpation is important in determining the actual size and extent of these lesions. The presence of paresthesia in the area adjacent to the lesion may indicate mental nerve involvement.

Characteristics of lip primaries that negatively affect prognosis include perineural invasion, involvement of the underlying maxilla/mandible, presentation on the upper lip or commissure, regional lymphatic metastasis, and age younger than 40 years at onset. Lip cancer results in fewer than 200 patient deaths annually and is stage dependent. Early diagnosis coupled with adequate treatment results in a high likelihood of disease control.

The treatment for lip cancer is determined by the overall health of the patient, size of the primary lesion, and the presence of regional metastases. Small primary lesions may be treated with surgery or radiation with equal success and acceptable cosmetic results. However, surgical excision with histologic confirmation of tumor-free margins is the preferred treatment modality. Lymph node metastasis occurs in fewer than 10% of patients with lip cancer (Fig. 18-22). The primary echelon of nodes at risk is in the submandibular and submental regions. In the presence of clinically evident neck metastasis, neck dissection is indicated. The overall 5-year cure rate of lip cancer approximates 90% and drops to 50% in the presence of neck metastases.⁴⁴ Postoperative radiation is administered to the primary site and neck for patients with close or positive margins, lymph node metastases, or perineural invasion.

The reconstruction of lip defects after tumor excision requires innovative techniques to provide oral competence, maintenance of dynamic function, and acceptable cosmesis. The typical lip length is 6 to 7 cm. This simple fact is important because the reconstructive algorithms available to the head and neck surgeon are based on the proportion of lip resected. Realignment of the vermilion border during the reconstruction and preservation of the oral commissure (when possible) are important principles in attempting to attain an acceptable cosmetic result. Resection with primary closure is possible with a defect of up to one third of the lip (Fig. 18-23). When the resection includes one third to one half of the lip, rectangular excisions can be closed using Burow's triangles in combination with advancement flaps and releasing incisions in the mental crease.^{44,45} Borrowing tissue from the upper lip can repair other medium-size defects. For larger defects of up to 75%, the Karapandzic flap uses a sensate, neuromuscular flap that includes the remaining orbicularis oris muscle, conserving its blood supply from branches of the labial artery (Fig. 18-24). The lip-switch (Abbe-Estlander) flap or a stair-step advancement technique can be used to repair defects of either the upper or lower lip. Microstomia is a potential complication with these types of lip reconstruction. For very large defects, Webster or Bernard types of repair using lateral nasolabial flaps with buccal advancement have also been described.⁴⁶ Details regarding specific techniques of reconstruction are not discussed in this chapter.⁴⁵

ORAL CAVITY

As previously mentioned in Anatomy and Histopathology, the oral cavity is composed of several sites with different anatomic relationships. The majority of tumors in the oral cavity are squamous cell carcinomas (>90%). Each site is briefly reviewed with emphasis placed on anatomy, diagnosis, and treatment options.

ORAL TONGUE

The oral tongue is a muscular structure with overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the

circumvallate papillae, whereas its ventral portion is contiguous with the anterior floor of mouth. The tongue is composed of four intrinsic and four extrinsic muscles separated at the midline by the median fibrous septum. Tumors of the tongue begin in the stratified epithelium of the surface and eventually invade into the deeper muscular structures. The tumors may present as ulcerations or as exophytic masses (Fig. 18-25).⁴⁷ The regional lymphatics of the oral cavity are to the submandibular space and the upper cervical lymph nodes (Fig. 18-26). The lingual nerve and the hypoglossal nerve may be directly invaded by locally extensive tumors (Fig. 18-27). Involvement results in ipsilateral paresthesias and deviation of the tongue on protrusion with fasciculations and eventual atrophy. Tumors on the tongue may occur on any surface, but are most commonly seen on the lateral and ventral surfaces.⁴⁸ Primary tumors of the mesenchymal components of the tongue include leiomyomas, leiomyosarcomas, rhabdomyosarcomas, and neurofibromas.

A and B. Anatomy of the floor of mouth and submandibular space. a. = artery; m. = muscle; n. = nerve.

Surgical treatment of small (T1–T2) primary tumors is wide local excision with either primary closure or healing by secondary intention. The CO₂ laser may be used for excision of early tongue cancers or for ablation of premalignant lesions. A partial glossectomy, which removes a significant portion of the lateral oral tongue, still permits reasonably effective postoperative function. Resection of larger tumors of the tongue that invade deeply can result in significant functional impairment. If lingual contact with the palate, lip and teeth is decreased, it will result in impaired articulation. The use of soft, pliable fasciocutaneous free flaps can provide intraoral bulk and preservation of tongue mobility. Prosthetic augmentation can allow for contact between the remaining tongue tissue and the palate, improving a patient's ability to speak and swallow. Treatment of the regional lymphatics is typically performed with the same modality used to address the primary site. When the primary site is addressed surgically, modified radical neck dissection (MRND) or selective neck dissection (SND) is performed. Depth of invasion of the primary tumor can direct the need for elective lymph node dissection with early stage lesions.⁴⁹

FLOOR OF MOUTH

The floor of mouth is the mucosally covered semilunar area that extends from the anterior tonsillar pillar posteriorly to the frenulum anteriorly, and from the inner surface of the mandible to the ventral surface of the oral tongue. The ostia of the submaxillary and sublingual glands are contained in the anterior floor of mouth. The muscular floor of mouth is composed of the sling-like genioglossus, mylohyoid, and hyoglossus muscles, which serve as a barrier to spread of disease. Invasion into these muscles can result in decreased tongue mobility and poor articulation. Another pathway for spread of tumor is along the salivary ducts, which can result in direct extension into the sublingual space.

Anterior or lateral extension to the mandibular periosteum is of primary importance in the preoperative assessment for these lesions. Imaging studies of the mandible, including CT scan, magnetic resonance imaging (MRI), and Panorex radiography, are helpful for ascertaining bone invasion. A careful clinical evaluation, which includes bimanual palpation to assess adherence or fixation to adjacent bone, is also essential (Fig. 18-28). The absence of fixation of the lesion to the inner mandibular cortex indicates that a mandible-sparing procedure is feasible.⁵⁰ Deep invasion into the intrinsic musculature of the tongue causes fixation and mandates a partial glossectomy in conjunction with resection of the floor of mouth. Lesions in the anterior floor of mouth may invade the sublingual gland or submandibular duct and require resection of either of these structures in continuity with the primary lesion. Direct extension of tumors into or through the sublingual space and into the submaxillary space may necessitate the need for removal of the primary tumor with the neck dissection specimen in continuity.

A and B. Differences in the transoral resection of a floor of mouth and alveolar ridge lesion.

The resection of large tumors of the floor of mouth may require a lip-splitting incision (Fig. 18-29) and immediate reconstruction. The goals are to obtain watertight closure to avoid a salivary fistula and to avoid tongue tethering to maximize mobility. For small mucosal lesions, wide local excision can be followed by placement of a split-thickness skin graft over the muscular bed. Larger defects that require marginal or segmental mandibulectomy require complex reconstruction with a fasciocutaneous or a vascularized osseous free flap.

Composite resection specimen of a T4 floor of mouth squamous cell.

ALVEOLUS/GINGIVA

The alveolar mucosa overlies the bone of the mandible and maxilla. It extends from the gingivobuccal sulcus to the mucosa of the floor of mouth and hard palate. The posterior limits are the pterygopalatine arch and the ascending portion of the ramus of the mandible. Because of the tight attachment of the alveolar mucosa to the mandibular and maxillary periosteum, treatment of lesions of the alveolar mucosa frequently requires resection of the underlying bone.

Marginal resection of the mandible can be performed for tumors of the alveolar surface that present with minimal bone invasion. Although access for such a procedure can be performed by using an anterior mandibulotomy (Fig. 18-30), use of transoral and pull-through procedures is preferred if a coronal or sagittal marginal mandibulotomy is performed. For more extensive tumors that invade into the medullary cavity, segmental mandibulectomy is necessary. Preoperative radiographic evaluation of the mandible plays an important role in determining the type of bone resection required. For radiographic evaluation of the mandible, Panorex views demonstrate gross cortical invasion. MRI is the best modality for demonstrating invasion of the medullary cavity of the mandible. Sectional CT scanning with bone settings is the optimum modality for imaging subtle cortical invasion. Gross bony invasion involvement at the mandibular symphysis negatively impacts locoregional control.⁵¹

Anterior mandibulotomy with mandibular swing to approach a posterior lesion.

RETROMOLAR TRIGONE

The retromolar trigone is represented by tissue posterior to the posterior inferior alveolar ridge and ascends over the inner surface of the ramus of the mandible. Similar to alveolar lesions, early involvement of the mandible is common because of the lack of intervening soft tissue in the region. The clinical presentation of trismus represents involvement of the muscles of mastication and may indicate spread to the skull base. Tumors of the region may extend posteriorly into the oropharyngeal anatomy or laterally to invade the mandible. As a result, resection of retromolar trigone tumors usually requires a marginal or segmental mandibulectomy with a soft-tissue and/or osseous reconstruction to maximize a patient's postoperative ability for speech and swallowing. Ipsilateral neck dissection is performed because of the risk of metastasis to the regional lymphatics. Huang and associates demonstrated a 5-year, disease-free survival rate for T1 lesions of 76%, which declined to 54% for T4 disease. Patients with NO disease had a 5-year survival rate of 69%.⁵²

BUCCAL MUCOSA

The buccal mucosa includes all of the mucosal lining from the inner surface of the lips to the line of attachment of mucosa of the alveolar ridges and pterygomandibular raphe. The etiologies of malignancies in the buccal area include lichen planus, chronic dental trauma, and the habitual use of tobacco and alcohol. Tumors in this area have a propensity to spread locally and to metastasize to regional lymphatics. Local intraoral spread may necessitate resection of the alveolar ridge of the mandible or maxilla. Lymphatic drainage is to the facial and the submandibular nodes (level I). Small lesions can be excised surgically, but more advanced tumors require combined surgery and postoperative radiation.⁵³ Deep invasion into the cheek may require through-and-through resection. Reconstruction aimed at providing both internal and external lining may be accomplished with a folded fasciocutaneous free flap or a combination of pedicled and free tissue techniques.

PALATE

The hard palate is defined as the semilunar area between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones. It extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone. Most squamous cell carcinomas of the hard palate are caused by habitual tobacco and alcohol use. Chronic irritation from ill-fitting dentures also may play a causal role. Inflammatory lesions arising on the palate may mimic malignancy and can be differentiated by biopsy. Necrotizing

sialometaplasia appears on the palate as a butterfly-shaped ulcer that clinically appears similar to a neoplasm. Treatment is symptomatic and biopsy confirms its benign nature. Torus palatini are bony outgrowths of the midline palate and do not specifically require surgical treatment unless symptomatic.

Squamous cell carcinoma and minor salivary gland tumors are the most common malignancies of the palate.⁵⁴ The latter include adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and polymorphous low-grade adenocarcinoma. Mucosal melanoma may occur on the palate and presents as a nonulcerated, pigmented plaque. Kaposi's sarcoma of the palate is the most common intraoral site for this tumor. Tumors may present as either an ulcerative, exophytic, or submucosal mass. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate. Direct infiltration of bone leads to extension into the floor of the nasal cavity and/or maxillary sinus. Squamous cell carcinoma of the hard palate is treated surgically. Adjuvant radiation is indicated for advanced staged tumors. Because the periosteum of the palate can act as a barrier to spread of tumor, mucosal excision may be adequate for very superficial lesions. Involvement of the periosteum requires removal of a portion of the bony palate. Partial palatotomy of infrastructure maxillectomy may be required for larger lesions involving the palate or maxillary antrum. Malignancies may extend along the greater palatine nerve making biopsy important for identifying neurotropic spread. Through-and-through defects of the palate require a dental prosthesis for rehabilitation of swallowing and speech.

OROPHARYNX

The oropharynx extends from the soft palate to the superior surface of the hyoid bone (or floor of the vallecula) and includes the base of tongue, the inferior surface of the soft palate and uvula, the anterior and posterior tonsillar pillars, the glossotonsillar sulci, tonsils, and the lateral and posterior pharyngeal walls. Laterally, the borders of this region are the pharyngeal constrictors and the medial aspect of the mandible. Direct extension of tumors from the oropharynx into these lateral tissues may involve spread into the parapharyngeal space. The ascending ramus of the mandible can be involved when tumors invade the medial pterygoid muscle.

As was true of the oral cavity, the histology of the majority of tumors in this region is squamous cell carcinoma. Although less common, minor salivary gland tumors may present as submucosal masses in the tongue base and soft palate. Additionally, the tonsils and tongue base may be the presenting site for a lymphoma noted clinically as asymmetrical enlargement.

Oropharyngeal cancer may present as an ulcerative lesion or an exophytic mass. Tumor fetor from necrosis is common. A muffled or "hot potato" voice is seen with large tongue base tumors. Dysphagia and weight loss are common symptoms. Referred otalgia, mediated by the tympanic branches of cranial nerve (CN) IX and CN X, is a common complaint. Trismus may indicate advanced disease and usually results from involvement of the pterygoid musculature. The incidence of regional metastases from cancers of the oropharynx is high. Consequently, ipsilateral or bilateral nontender cervical lymphadenopathy is a common presenting sign.

Imaging studies are important for adequate staging and should assess for extension to the larynx, parapharyngeal space, pterygoid musculature, mandible, and nasopharynx. Lymph node metastasis from oropharyngeal cancer most commonly occurs in the subdigastic area of level II. Metastases also are found in levels III, IV, and V, in addition to the retropharyngeal and parapharyngeal lymph nodes. Approximately one half of patients have metastases at the time of presentation. Bilateral metastases are common from tumors arising in the tongue base and soft palate.⁵⁵

The treatment goals for patients with oropharyngeal cancer include maximizing survival and preserving function. Management of squamous cell cancers of this region includes surgery alone, primary radiation alone, surgery with postoperative radiation, and combined chemotherapy with radiation therapy.⁵⁶ Tumors of the oropharynx tend to be radiosensitive.⁵⁷ Patients with early stage lesions may be candidates for monomodality radiation alone. Adequate treatment of the neck is important with oropharyngeal squamous cancer because of the high risk of regional metastasis. Concomitant chemoradiation is used in patients with advanced stage (III, IV) oropharyngeal carcinoma.⁵⁸ This approach has been effectively demonstrated to preserve function and is associated with survivorship comparable to surgery with postoperative radiation.

Tumors of the soft palate and tonsil extending to the tongue base are associated with poor survival. Extensive oropharyngeal cancers may require surgical resection and postoperative radiotherapy.⁵⁹ Lesions that involve the mandible require composite resections, such as the classic jaw-neck resection or "commando" procedure. Surgical management of the tongue base may require total glossectomy for extensive lesions crossing the anatomic midline. The potential need for synchronous performance of total laryngectomy at the time of tongue base resection should be explained to the patient. Preservation of the larynx after total glossectomy is associated with a significant risk of postoperative dysphagia and aspiration.⁶⁰

Swallowing rehabilitation in patients with oropharyngeal carcinoma is an important aspect of posttreatment care. For soft palate defects, palatal obturators may assist in providing a seal between the nasopharynx and the posterior pharyngeal wall.⁶¹ Nasal regurgitation of air and liquids can be decreased with use. Close cooperation between the head and neck surgeon and the maxillofacial prosthodontist is essential to provide patients with the optimum prosthetic rehabilitation. Preoperative planning can result in the creation of a defect that better tolerates obturation. For patients with postglossectomy defects, palatal augmentation prostheses can provide bulk extending inferiorly from the palate. The prosthesis decreases the volume of the oral cavity and allows the remaining tongue or soft tissue to articulate with the palate. It also facilitates posterior projection of the food bolus during the oral and pharyngeal phases of swallowing.

HYPOPHARYNX AND CERVICAL ESOPHAGUS

The hypopharynx extends from the vallecula to the lower border of the cricoid cartilage and includes the pyriform sinuses, the lateral and posterior pharyngeal walls, and the postcricoid region (Fig. 18-31). Squamous cancers of the hypopharynx frequently present at an advanced stage. Clinical findings are similar to those of lower oropharyngeal lesions and include a neck mass, muffled or hoarse voice, referred otalgia, dysphagia, and weight loss. A common symptom is dysphagia, starting with solids and progressing to liquids, leaving patients malnourished at the time of presentation. Invasion of the larynx by direct extension can result in vocal cord paralysis and may lead to airway compromise.

Fig. 18-31.

Relationship of nasopharynx, oropharynx, and hypopharynx.

Routine office examination should include flexible fiber-optic laryngoscopy to properly assess the extent of tumor. During examination, the patient should be instructed to perform a Valsalva's maneuver, which will result in passive opening of the pyriform sinuses and postcricoid

regions, providing improved visualization. Decreased laryngeal mobility or fixation may indicate invasion of the prevertebral fascia and unresectability. Barium swallow can provide information regarding postcricoid and upper esophageal extension, potential multifocality within the esophagus, and document the presence of aspiration. CT and/or MRI imaging should be obtained through the neck and upper chest to assess for invasion of the laryngeal framework and to identify for regional metastases, with special attention given to the paratracheal and upper mediastinal lymph nodes (Fig. 18-32). Bilateral metastatic adenopathy in the paratracheal chain is common and the majority of patients present with nodal disease at the time of diagnosis.

View of the hypopharynx demonstrating the potential pathways of spread of tumor and pertinent anatomy.

Tumors of the hypopharynx and cervical esophagus are associated with poorer survival rates than are other sites in the head and neck because of advanced stage and lymph node metastasis at presentation. Surgery with postoperative radiation therapy improves locoregional control compared to single-modality therapy in the treatment of advanced stage tumors.⁶² Definitive radiation therapy may be effective for limited T1 tumors, whereas concomitant chemoradiation is generally used for T2 and T3 tumors.⁶³ Surgical salvage after radiation failure has a success rate of less than 50% and can be associated with significant wound-healing complications.

Larynx-preserving surgical procedures for tumors of the hypopharynx are possible for only a limited number of lesions. Tumors of the medial pyriform wall or pharyngoepiglottic fold may be resected with partial laryngopharyngectomy. In this circumstance, the tumor must not involve the apex of the pyriform sinus, vocal cord mobility must be unimpaired, and the patient must have adequate pulmonary reserve. Given the increased risk for postoperative aspiration associated with various forms of partial laryngectomy, a history significant for pulmonary disease is a contraindication for performing the procedures. Because the majority of patients with tumors of the hypopharynx present with large lesions with significant submucosal spread, total laryngectomy often is required to achieve negative resection margins. Resection of the primary tumor and surrounding pharyngeal tissue is performed en bloc. Bilateral neck dissection is frequently indicated given the elevated risk of nodal metastases found with these lesions.

When laryngopharyngectomy is performed for hypopharyngeal tumors the surgical defect is repaired by primary closure when possible. Generally, 4 cm or more of pharyngeal mucosa is necessary for primary closure to provide an adequate lumen for swallowing and to minimize the risk of stricture formation. Larger surgical defects require closure with the aid of pedicled myocutaneous flaps or microvascular reconstruction with radial forearm or jejunal free flap. When total laryngopharyngoesophagectomy is necessary, gastric pull-up is performed.

Cervical esophageal cancer may be managed surgically or by concomitant chemoradiation. Preservation of the larynx is possible if the cricopharyngeus muscle demonstrates limited involvement. Unfortunately, this is not often the case and many patients with cervical esophageal cancer require laryngectomy. Total esophagectomy is performed because of the tendency for multiple primary tumors and skip lesions seen with esophageal cancers.

Despite aggressive treatment strategies, the 5-year survival rate for cervical esophageal cancer is less than 20%. Given the presence of paratracheal lymphatic spread, surgical treatment for tumors of this area must include paratracheal lymph node dissection, in addition to treatment of the lateral cervical lymphatics.

LARYNX

Laryngeal carcinoma is a diagnosis typically entertained in individuals with prominent smoking histories and the complaint of a change in vocal quality (Fig. 18-33). The borders of the larynx span from the epiglottis superiorly to the cricoid cartilage inferiorly. The lateral limits of the larynx are the aryepiglottic folds. The larynx is composed of three regions: the supraglottis, the glottis, and the subglottis (Fig. 18-34).

Sagittal view of the larynx with the divisions of the supraglottis, glottis, and subglottis demonstrated.

The supraglottis includes the epiglottis, aryepiglottic folds, arytenoids, and ventricular bands (false vocal folds). The inferior boundary of the supraglottis is a horizontal plane passing through the lateral margin of the ventricle. The glottis is composed of the true vocal cords (superior and inferior surfaces) and includes the anterior and posterior commissures. The subglottis extends from the inferior surface of the glottis to the lower margin of the cricoid cartilage. The soft-tissue compartments of the larynx are separated by fibroelastic membranes, which can act as barriers to the spread of cancer. These membranes thicken medially to form the false vocal fold and the vocal ligament (the true vocal cord).

The supraglottic larynx contains pseudostratified, ciliated respiratory epithelium that covers the false vocal cords. The epiglottis and the vocal cords are lined by stratified, nonkeratinizing squamous epithelium. The subglottic mucosa is pseudostratified, ciliated respiratory epithelium. Minor salivary glands are also found in the supraglottis and subglottis. Tumor types that arise in the larynx are primarily squamous cell carcinoma but also include tumors of neuroendocrine origin, squamous papillomas, granular cell tumors, and tumors of salivary origin. Several histologic variants of squamous cell carcinoma exist and include verrucous, basaloid squamous cell, adenosquamous, and spindle cell carcinoma. Tumors of the laryngeal framework include synovial sarcoma, chondroma, and chondrosarcoma.

The normal functions of the larynx are airway patency, protection of the tracheobronchial tree during swallowing, and phonation. Patients with tumors of the supraglottic larynx may present with symptoms of chronic sore throat, dysphonia ("hot potato" voice), dysphagia, or a neck mass secondary to regional metastasis. Supraglottic tumors may cause vocal cord fixation by inferior extension in the paraglottic space or direct invasion of the cricoarytenoid joint. Anterior extension of tumors arising on the laryngeal surface of the epiglottis into the pre-epiglottic space produces a muffled quality to the voice. Referred otalgia or odynophagia is encountered with advanced supraglottic cancers. Bulky tumors of the supraglottis may result in airway compromise. In contrast to most supraglottic lesions, hoarseness is an early symptom in patients with tumors of the glottis.⁶⁴ Airway obstruction from a glottic tumor is usually a late symptom and is the result of tumor bulk or impaired vocal cord mobility. Decreased vocal cord mobility may be caused by direct muscle invasion or involvement of the RLN. Fixation of the vocal cord indicates invasion into the vocalis muscle, paraglottic space, or cricoarytenoid joint. Superficial tumors that are bulky may appear to cause cord fixation

through mass effect. Subglottic cancers are relatively uncommon and typically present with vocal cord paralysis (usually unilateral) and/or airway compromise.

The staging classification for squamous cell cancers of the larynx includes assessment of vocal cord mobility as well as local tumor extension. Accurate clinical staging of laryngeal tumors requires flexible fiber-optic endoscopy in the office and direct microlaryngoscopy under general anesthesia. Direct laryngoscopy, used to assess the extent of local spread, may be combined with esophagoscopy or bronchoscopy to adequately stage the primary tumor and to exclude the presence of a synchronous lesion. Key areas to note for tumor extension in supraglottic tumors are the vallecula, base of tongue, ventricle, arytenoid, and anterior commissure. For glottic cancers, it is important to determine extension to the false cords, anterior commissure, arytenoid, and subglottis.

Radiographic imaging by CT and/or MRI provides important staging information and is crucial for identifying cartilage erosion or invasion and extension into the pre-epiglottic or paraglottic spaces. High quality, thin-section images through the larynx should be obtained in patients with laryngeal tumors and used with clinical assessment to arrive at a final disease pretreatment staging. Lymph node metastasis may be defined more readily with the use of imaging studies.

Lymphatic drainage of the larynx is distinct for each subsite. Two major groups of laryngeal lymphatic pathways exist: those that drain areas superior to the ventricle, and those that drain areas inferior to it. Supraglottic drainage routes pierce the thyrohyoid membrane with the superior laryngeal artery, vein, and nerve, and drain mainly to the subdigastric and superior jugular nodes.⁶⁴ Those from the glottic and subglottic areas exit via the cricothyroid ligament and end in the prelaryngeal node (the Delphian node), the paratracheal nodes, and the deep cervical nodes along the inferior thyroid artery. Limited glottic cancers typically do not spread to regional lymphatics (1 to 4%). However, there is a high incidence of lymphatic spread from supraglottic (30 to 50%) and subglottic cancers (40%).

When considering treatment for laryngeal tumors, it is useful to categorize them as a continuum from early tumors (those with a small area of involvement resulting in minimal functional impairment) to advanced tumors (those with significant airway compromise and local extension). For example, severe dysplasia and carcinoma in situ often can be treated successfully with CO₂ laser resection or conservative surgical approaches. In contrast, more advanced tumors may require partial laryngectomy⁶⁵ (Fig. 18-35) or even total laryngectomy (Fig. 18-36). Further complicating the treatment paradigm is the role of radiotherapy, with or without chemotherapy, with the goal of laryngeal preservation.⁶⁶

Total laryngectomy specimen featuring a glottic squamous carcinoma.

Prognostic factors for patients with cancer of the larynx are tumor size, nodal metastasis, perineural invasion, and extracapsular spread of disease in cervical lymph nodes. Patient comorbidities are important to consider when arriving at a treatment plan for patients with laryngeal cancer.

For severe dysplasia or carcinoma in situ of the vocal cord, complete removal of the involved mucosa with microlaryngoscopy is an effective treatment. Patients with limited involvement of the arytenoid or anterior commissure are the best candidates for a good posttreatment vocal quality result with this approach. Multiple procedures may be necessary to control the disease and to prevent progression to an invasive cancer. Close follow-up examinations and smoking cessation are mandatory adjuncts of therapy. For early stage cancers of the glottis and the supraglottis, radiation therapy is equally as effective as surgery in controlling disease.

Critical factors in determining the appropriate treatment modality are comorbid conditions (chronic obstructive pulmonary disease, cardiovascular, and renal disease) and tumor extension. Voice preservation and maintenance of quality of life are key issues and significantly impact therapeutic decisions. The use of radiation therapy for early stage disease of the glottis and supraglottis provides excellent disease control with reasonable, if not excellent, preservation of vocal quality. Partial laryngectomy for small glottic cancers provides excellent tumor control, but vocal quality can vary. For supraglottic cancers without arytenoid or vocal cord extension, standard supraglottic laryngectomy results in excellent disease control with good voice function. For advanced tumors with extension beyond the endolarynx or with cartilage destruction, total laryngectomy followed by postoperative radiation is still considered the standard of care.⁶⁷ In this setting, reconstruction by means of a pectoralis major flap (Fig. 18-37) or free flap reconstruction is required for lesions with pharyngeal extension.

Fig. 18-37.

Pectoralis flap reconstruction of a laryngectomy patient requires soft-tissue augmentation for pharynx closure.

Subglottic cancers, constituting only 1% of laryngeal tumors, are typically treated with total laryngectomy. Because these tumors present with adenopathy in 40% of patients, special attention must be given to the treatment of paratracheal lymph nodes.⁶⁸

LARYNGEAL PRESERVATION TECHNIQUES

Superficial cancers confined to the true vocal cord can be treated with a variety of surgical options. These include endoscopic vocal cord stripping, microflap dissection, partial cordectomy, and CO₂ laser resection. Although using a CO₂ laser can provide excellent hemostasis and minimize damage to the adjacent uninvolved tissue, scarring associated with its use is considered more significant than with conventional "cold" techniques. Microflap dissection, using a subepithelial infusion of a saline-epinephrine solution into Reinke's space, allows for assessment of depth of invasion and the ability to resect the lesion as a single unit. Use of an operative microscope aids the precision of such dissections. Open laryngofissure and cordectomy may be reserved for more invasive tumors.

For larger tumors of the glottis with impaired vocal cord mobility, a variety of partial resections exist that permit preservation of reasonable vocal quality. For lesions involving the anterior commissure with limited subglottic extension, an anterofrontal partial laryngectomy is indicated. For lateralized T2 or T3 glottic tumors without cartilage destruction, a vertical partial laryngectomy is feasible. In this circumstance, reconstruction is accomplished by means of a false vocal cord imbrication to simulate a true vocal cord on the side of the resection.

For T3 glottic lesions not involving the pre-epiglottic space or cricoarytenoid joint, a supracricoid laryngectomy with cricohyoidopexy or cricohyoidoepiglottopexy (CHEP) are options.⁶⁵ The supracricoid laryngectomy technique uses the remaining arytenoids as the phonatory structures, which come into apposition with epiglottic remnant in the CHEP, or with the tongue base in the cricohyoidopexy. Oncologic advantages of this procedure include the complete removal of the paraglottic spaces and thyroid cartilage. The supracricoid laryngectomy with CHEP is associated with excellent disease control and a high rate of tracheostomy decannulation. Favorable deglutition rates and a breathy vocal quality are seen postoperatively with this procedure. For lesions with involvement of the cricoarytenoid joint and/or extension to the level of the cricoid, total laryngectomy is required.

The risk for aspiration is high following certain partial laryngectomies. Patient selection is vital to successful application of these techniques. Presurgical pulmonary assessment may be necessary. One simple measurement of functional reserve is to have the patient climb two flights of stairs. Those able to do so without stopping are more likely to be candidates for conservation surgical procedures. For patients that are not candidates for partial laryngectomy, total laryngectomy is considered the best surgical option for locoregional control. Total laryngectomy may also be the preferred treatment for those patients who are noncompliant, given the importance of postoperative follow-up and monitoring for recurrence.

The approach to the treatment for patients with advanced tumors of the larynx and hypopharynx has evolved over time. Chemoradiation has demonstrated the ability for comparable locoregional disease control and overall survival similar to open surgical approaches. The Radiation Therapy Oncology Group 91-11 trial demonstrated a higher laryngeal preservation rate among patients receiving concomitant chemotherapy and radiotherapy than in those patients receiving radiation alone or sequential chemotherapy followed by radiation therapy.⁶⁹ A randomized laryngeal preservation trial of neoadjuvant induction chemotherapy followed by radiation therapy has yielded survival rates similar to those of

laryngectomy, with the benefit of preservation of the larynx in 65% of patients.⁶⁶ Surgical salvage is available in cases of treatment failure or recurrent disease.

SPEECH AND SWALLOWING REHABILITATION

Involvement of a speech and swallowing therapist is critical in the preoperative counseling and postoperative rehabilitation of patients with laryngeal cancer. Speech rehabilitation options after total laryngectomy include esophageal speech, tracheoesophageal puncture, and use of an electrolarynx. Esophageal speech is produced by actively swallowing and releasing air from the esophagus resulting in vibrations of the esophageal walls and pharynx. The sounds produced can be articulated into words. The ability to create esophageal speech depends on the motivation of patients and their ability to control the upper esophageal sphincter, allowing injection and expulsion of air in a controlled fashion. Unfortunately, less than 20% of postlaryngectomy patients develop fluent esophageal speech.

A tracheoesophageal puncture is a fistula created between the trachea and esophagus that permits placement of a one-way valve that allows air from the trachea to enter the upper esophagus. The valve prevents retrograde passage of food or saliva into the trachea. Patients that undergo placement of a tracheoesophageal puncture have a success rate of greater than 80% in achieving functional speech.

For patients unable to develop esophageal speech, the electrolarynx creates vibratory sound waves when held against the neck or cheek. The vibrations create sound waves that the patient articulates into words. A disadvantage of the electrolarynx is the mechanical quality of the sound produced. This device is most useful in the postoperative period before training for esophageal speech.

Postoperative swallowing rehabilitation is another important task performed by the speech and swallowing team. Patient instruction in various swallowing techniques and evaluation for the appropriate diet consistency allow a patient to initiate oral intake of nutrition while minimizing the risk of aspirating. Flexible fiber-optic laryngoscopy can be performed transnasally and provides valuable information to assist in the assessment of dysphagia. The oral intake of various consistencies of liquids and solids can be observed with endoscopic assessment of laryngeal penetration. A similar assessment may be performed with a modified barium swallow allowing the analysis of the various phases of swallowing.

UNKNOWN PRIMARY TUMORS

When patients present with cervical nodal metastases without clinical or radiologic evidence of an upper aerodigestive tract primary tumor, they are referred to as having an unknown primary. Given the difficulty in performing a detailed examination in the clinical setting of the base of tongue, the tonsillar fossa, and the nasopharynx, examination under anesthesia with directed tissue biopsies has been advocated. Ipsilateral tonsillectomy, direct laryngoscopy with base of tongue and pyriform biopsies, examination of the nasopharynx, and bimanual examination can allow for identification of a primary site in a portion of patients previously considered to have an unknown primary. In those individuals in whom a primary site cannot be ascertained, empiric treatment of the mucosal sources of the upper aerodigestive tract at risk (from nasopharynx to hypopharynx) and the cervical lymphatics with concomitant chemoradiation is advocated. For patients with advanced neck disease (N2a or greater) or with persistent lymphadenopathy after radiation, a postradiation neck dissection may be necessary. For patients in whom the primary lesion is identified, a more limited radiation treatment field may be used.

Nose and Paranasal Sinuses

The nose and paranasal sinuses are the sites of a great deal of infectious and inflammatory pathology. The diagnosis of tumors within this region is frequently made after a patient has been unsuccessfully treated for recurrent sinusitis and undergoes diagnostic imaging. Symptoms associated with sinonasal tumors are subtle and insidious. They include chronic nasal obstruction, facial pain, headache, epistaxis, and facial numbness. As such, tumors of the paranasal sinuses frequently present at an advanced stage. Orbital invasion can result in proptosis, diplopia, epiphora, and vision loss. Paresthesia within the distribution of CN V2 is suggestive of pterygopalatine fossa or skull base invasion and is generally a poor prognostic factor. Maxillary sinus tumors can present with loose dentition indicating erosion of the alveolar and/or palatal bones. Tumors found to arise posterior to Ohngren's line are associated with a worse prognosis than are more anteriorly based lesions (Fig. 18-38).⁷⁰

Fig. 18-38.

A variety of benign tumors arise in the nasal cavity and paranasal sinuses and include inverted papillomas, hemangiomas, hemangiopericytomas, angiofibromas, minor salivary tumors, and benign fibrous histiocytomas. Fibro-osseous and osseous lesions, such as fibrous dysplasias, ossifying fibromas, osteomas, and myxomas, can also arise in this region. Additionally, herniation of intracranial contents into the nasal cavity can occur with the erosion of the anterior skull base with the resultant presentation of a sinonasal mass on clinical examination.

Malignant tumors of the sinuses are predominantly squamous cell carcinomas. Sinonasal undifferentiated carcinoma,⁷¹ adenocarcinoma, mucosal melanoma, lymphoma, olfactory neuroblastoma, rhabdomyosarcoma, and angiosarcoma are some of the other malignancies that have been described. Metastases from the kidney, breast, lung, and thyroid may also present as an intranasal mass. Regional metastasis is uncommon with tumors of the paranasal sinuses (14 to 16%) and occurs in the parapharyngeal, retropharyngeal, and subdiaphragmatic nodes of the jugular chain.

The diagnosis of an intranasal mass is made with the assistance of a headlight and nasal speculum or nasal endoscopy. The site of origin, involved bony structures, and the presence of vascularity should be assessed. For paranasal sinus tumors, MRI and CT scanning often are complementary studies in determining orbital and intracranial extension.⁷² Benign processes frequently present as slow-growing expansile tumors with limited erosion of surrounding bone, as compared to the lytic destruction typically associated with malignancies. Skull base foramen should be closely examined for enlargement that may be suggestive of perineural invasion. Examination for cavernous sinus extension, cribriform plate erosion, and dural enhancement is necessary to assess for resectability and the type of surgical approach that is possible. A meningocele or encephalocele will present as a unilateral pulsatile mass. Biopsy of a unilateral nasal mass should be deferred until imaging studies are obtained. Untimely biopsy can result in a CSF leak. If hypervascularity is suspected, biopsy should be performed under controlled conditions in the operating room.

The standard treatment for malignant tumors of the paranasal sinuses is surgical resection with postoperative radiation therapy. Tumors arising along the medial wall of the maxillary sinus may be treated by means of a medial maxillectomy. The treatment of advanced tumors of the paranasal sinuses frequently involves a multispecialty approach. Members of this team include the head and neck surgeon, neurosurgeon, prosthodontist, ophthalmologist, and reconstructive surgeon. Each team member is necessary to facilitate the goal of safe and complete tumor removal. For vascular tumors, preoperative embolization performed within 24 hours of the planned surgical resection may reduce intraoperative

hemorrhage.

Prognosis is dependent on tumor location and extension to the surrounding anatomy. Infrastructure maxillectomy, which includes removal of the hard palate and the lower maxillary sinus, is necessary for inferiorly based tumors of the maxillary sinus. For tumors in the upper portion of the maxillary sinus, complete maxillectomy (including removal of the orbital floor) is performed. If there is invasion of the orbital fat, exenteration of the orbital contents is required. Removal of the bony floor of the orbit and preservation of the globe are possible where there is absence of invasion through the orbital periosteum. However, reconstruction of the orbital floor to recreate a stable support for the orbital contents is essential. Removal of anterior cheek skin is indicated when there is tumor extension into the overlying subcutaneous fat and dermis.

For tumors involving the ethmoid sinuses, the integrity of the cribriform plate is assessed with preoperative imaging. Complete sphenoethmoidectomy or medial maxillectomy may suffice if the tumor is localized to the lateral nasal wall. Endoscopic resection with the assistance of image-guidance technology is gaining increasing acceptance for low-grade resectable lesions such as inverted papilloma.

If erosion of the cribriform has occurred, an anterior craniofacial resection is the standard operative approach. The head and neck surgeon and neurosurgeon work in concert to perform this procedure. The neurosurgeon performs a frontal craniotomy for exposure of the anterior cranial fossa floor, whereas the head and neck surgeon proceeds through a transfacial or endoscopic approach to resect the inferior bony attachments. Paranasal sinus malignancies that are deemed unresectable are those with bilateral optic nerve involvement, massive brain invasion, or carotid encasement.⁷³ Postoperative rehabilitation after orbital exenteration is accomplished by soft-tissue reconstruction and placement of a maxillofacial prosthesis. Combined treatment with surgery and postoperative radiotherapy for squamous cell carcinoma of the sinuses results in survival superior to either radiation or surgery alone. Chemotherapy has a limited application and may be used for specific indications. Rhabdomyosarcoma is primarily treated with chemotherapy followed by radiation therapy. Surgery is reserved for persistent disease after chemoradiation. Sinonasal undifferentiated carcinoma is highly aggressive and typically is not adequately controlled with standard therapy. Chemotherapy in this setting may help to reduce the tumor bulk and allow for orbital preservation.

Nasopharynx

The nasopharynx extends in a plane superior to the hard palate from the choana, to the posterior nasal cavity, to the posterior pharyngeal wall. It includes the fossa of Rosenmüller, the eustachian tube orifices (torus tubarius), and the site of the adenoid pad. Tumors arising in the nasopharynx are usually of squamous cell origin and range from lymphoepithelioma to well-differentiated carcinoma. However, the differential diagnosis for nasopharyngeal tumors is broad and also includes lymphoma, chordoma, chondroma, nasopharyngeal cyst (Tornwaldt's cyst), angiofibroma, minor salivary gland tumor, paraganglioma, rhabdomyosarcoma, extramedullary plasmacytoma, and sarcoma.

Risk factors for nasopharyngeal carcinoma include area of habitation, ethnicity, and tobacco use. There is an increased incidence of nasopharyngeal cancer in southern China, Africa, Alaska, and in Greenland Eskimos. A strong correlation exists between nasopharyngeal cancer and the presence of EBV infection, such that EBV titers may be used as a means to follow a patient's response to treatment.

Symptoms associated with nasopharyngeal tumors include nasal obstruction, posterior (level V) neck mass, epistaxis, headache, serous otitis media with hearing loss, and otalgia. Cranial nerve involvement is indicative of skull base extension and advanced disease. Lymphatic spread occurs to the posterior cervical, upper jugular, and retropharyngeal nodes. Bilateral regional metastatic spread is common. Distant metastasis is present in 5% of patients at presentation.

Examination of the nasopharynx is facilitated by the use of the flexible or rigid fiber-optic endoscope. Evaluation with imaging studies is important for staging and treatment planning. CT with contrast is used for determining bone destruction, while MRI is used to assess for intracranial and soft-tissue extension. Erosion or enlargement of neural foramina (on CT imaging) or enhancement of cranial nerves (on MRI) is indicative of perineural spread of disease and portends a worse prognosis. The status of the cavernous sinus and optic chiasm should also be assessed. The standard treatment for nasopharyngeal carcinoma is chemoradiation. Combination therapy produces superior survival rates for nasopharyngeal carcinoma in comparison to radiation alone.⁷⁴ Intracavitary radiation boost with implants to the tumor may be included as an adjunct to external beam radiotherapy to improve local control of advanced tumors. Surgical treatment for nasopharyngeal carcinoma is rarely feasible, but may be considered in selected cases as salvage therapy for patients with localized recurrences.

For minor salivary gland and low-grade tumors of the nasopharynx, resection can be performed via a variety of approaches. Lateral rhinotomy or midface degloving approaches can provide good access for removal of tumors in the posterior nasal cavity extending into the nasopharynx.

Endoscopic removal is also possible in selected cases. A variety of surgical approaches also exist for more posteriorly located tumors extending to the sphenoid and clivus. Transpalatal approaches used in combination with transmaxillary and transcervical routes can provide good surgical access in addition to providing adequate control of the carotid artery. The emergence of endoscopic techniques has provided a significant advancement in the surgical management of lesions in these two sites.

Ear and Temporal Bone

Tumors of the ear and temporal bone are uncommon and account for less than 1% of all head and neck malignancies. Primary sites include the external ear (pinna), EAC, middle ear, mastoid, or petrous portion of the temporal bone. The most common histology is squamous cell carcinoma. Minor salivary gland tumors, including adenoid cystic carcinoma and adenocarcinoma, may also present in this region. The pinna, because of its exposure to ultraviolet light, is a common site for basal cell and squamous cell carcinoma to arise. Direct extension of tumors from the parotid gland and periauricular skin may occur in this region. Metastases from distant sites occur primarily to the petrous bone and arise in the breast, kidney, lung, and prostate. In the pediatric population, tumors of the temporal bone are most commonly soft-tissue sarcomas. For advanced stage tumors with extensive temporal bone extension, the complex anatomy of the temporal bone makes removal of tumors with functional preservation challenging.

The diagnosis of tumors of the ear and temporal bone is frequently delayed because the initial presentation of these patients is mistaken for benign infectious disease. When patients fail to improve with conservative care and symptoms evolve to potentially include facial nerve paralysis or worsening hearing loss, the need for imaging and biopsy become obvious. Granulation tissue in the EAC or middle ear should be biopsied in patients with atypical presentations or histories consistent with chronic otologic disease.⁷⁵ The complexity of the temporal bone anatomy makes the use of imaging studies of paramount importance in the staging and treatment of tumors in this region.

Small skin cancers on the helix of the ear can be readily treated with simple excision and primary closure. Mohs' microsurgery with frozen section margin control also can be used for cancer of the external ear. In lesions that are recurrent or invade the underlying perichondrium and cartilage, rapid spread through tissue planes can occur. Tumors may extend from the cartilaginous external canal to the bony canal and invade the parotid, temporomandibular joint, and skull base. For extensive, pinna-based lesions, procedures such as auriclectomy may be required. Postoperative radiation therapy may be required for advanced skin cancer with positive margins, perineural spread, or multiple involved lymph nodes.

Tumors involving the EAC and middle ear may present with persistent otorrhea, otalgia, EAC or periauricular mass, hearing loss, and facial nerve weakness or paralysis. The patient resembles the presentation of an external otitis unresponsive to standard medical therapy. Sleeve resections are reserved for small superficial tumors involving the cartilaginous external canal. Tumors involving the petrous apex or intracranial structures may present with headache and palsies of CN V and VI. The optimal treatment for tumors of the middle ear and bony external canal is en bloc resection followed by radiation therapy. Management of the regional lymphatics is determined by the site and stage of the tumor at presentation. Temporal bone resections are classified as lateral or subtotal (Fig. 18-39). The lateral temporal bone resection removes the bony and cartilaginous canal, tympanic membrane, and ossicles. The subtotal temporal bone resection includes the removal of the ear canal, middle ear, inner ear, and facial nerve. It is indicated for malignant tumors extending into the middle ear.

Examples of resection specimens for lateral temporal bone resection, subtotal temporal bone resection, and total temporal bone resection.

Postoperative radiation therapy in the treatment of malignancies of the temporal bone usually is indicated and improves local control over surgery alone. Five-year survival rates are approximately 50% for patients with tumors confined to the external canal and decrease with medial tumor extension. Prognosis is poor when tumor involves the petrous apex.⁷⁶

The purpose of reconstruction after temporal bone resection is to provide vascularized tissue and bulk to the site of resection. Prevention of CSF leak by watertight dural closure and prevention of meningitis are important goals of repair. Additionally, the reconstruction enables protection of vascular structures and the surrounding bone to prepare the patient for postoperative radiation therapy. Commonly used reconstruction methods are regional pedicle myocutaneous flaps (e.g., pectoralis major) and free flaps (rectus abdominis, radial forearm, or latissimus dorsi). The loss of the pinna produces significant external deformity; however, a prosthetic ear may produce acceptable rehabilitation. When the facial nerve is sacrificed, rehabilitation is necessary and includes the use of interposition nerve grafts, hypoglossal to facial nerve anastomosis, and static or dynamic sling techniques. In patients with poor eye closure, taping of the eyelids and the liberal use of eye lubrication can prevent exposure keratitis. Additionally, tarsorrhaphy, lid-shortening procedures, and the use of gold weight implants can provide upper eyelid closure and protect the cornea.

Neck

The diagnostic evaluation of a neck mass requires a planned approach that does not compromise the effectiveness of future treatment options. A neck mass in a 50-year-old smoker/drinker with a synchronous oral ulcer is different from cystic neck mass in an 18-year-old that enlarges with an upper respiratory infection. As with all diagnoses, a complete history with full head and neck exam, including flexible laryngoscopy, are critical to complete evaluation. The differential diagnosis of a neck mass is dependent on its location and the patient's age. In children, most neck masses are inflammatory or congenital. However, in the adult population, a neck mass greater than 2 cm in diameter has a greater than 80% probability of being malignant. Once the physician has developed a differential diagnosis, interventions to confirm or dispute diagnoses are initiated. Fine-needle aspiration (FNA), with or without the assistance of ultrasound or CT guidance, can provide valuable information for early treatment planning. The use of imaging (CT and/or MRI) is dictated by the patient's clinical presentation. Imaging enables the physician to evaluate the anatomic relationships of the mass to the surrounding anatomy of the neck and sharpen the differential. A cystic lesion may represent benign pathology such as a branchial cleft cyst; however, it may also represent a regional metastasis of a tonsil/base of tongue

squamous cell carcinoma or a papillary thyroid carcinoma. In this circumstance, evaluation of these potential primary sites can alter the planned operative intervention.

If a variety of diagnoses are still being entertained after FNA and imaging, an open biopsy may be necessary. For patients with the potential diagnosis of lymphoma, a biopsy sacrificing normal anatomical structures is not necessary. Ensuring appropriate processing of biopsied materials, sent in saline or in formalin, and sparing undue trauma to tissues can decrease the need for rebiopsy. Appropriate placement of the incision for an open biopsy should be considered if the need for neck dissection or composite resection is later required.

PATTERNS OF LYMPH NODE METASTASIS

The regional lymphatic drainage of the neck is divided into seven levels. These levels allow for a standardized format for radiologists, surgeons, pathologists, and radiation oncologists to communicate concerning specific sites within the neck (Fig. 18-40). The levels are defined as the following:

Fig. 18-40.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Levels of the neck denoting lymph node bearing regions.

Level I—the submental and submandibular nodes

Level Ia—the submental nodes; medial to the anterior belly of the digastric muscle bilaterally, symphysis of mandible superiorly, and hyoid inferiorly

Level Ib—the submandibular nodes and gland; posterior to the anterior belly of digastric, anterior to the posterior belly of digastric, and inferior to the body of the mandible

Level II—upper jugular chain nodes

Level IIa—jugulodigastric nodes; deep to sternocleidomastoid (SCM) muscle, anterior to the posterior border of the muscle, posterior to the posterior aspect of the posterior belly of digastric, superior to the level of the hyoid, inferior to spinal accessory nerve (CN XI)

Level IIb—submuscular recess; superior to spinal accessory nerve to the level of the skull base

Level III—middle jugular chain nodes; inferior to the hyoid, superior to the level of the cricoid, deep to SCM muscle from posterior border of the muscle to the strap muscles medially

Level IV—lower jugular chain nodes; inferior to the level of the cricoid, superior to the clavicle, deep to SCM muscle from posterior border of the muscle to the strap muscles medially

Level V—posterior triangle nodes

Level Va—lateral to the posterior aspect of the SCM muscle, inferior and medial to splenius capitis and trapezius, superior to the spinal accessory nerve

Level Vb—lateral to the posterior aspect of SCM muscle, medial to trapezius, inferior to the spinal accessory nerve, superior to the clavicle

Level VI—anterior compartment nodes; inferior to the hyoid, superior to suprasternal notch, medial to the lateral extent of the strap muscles bilaterally

Level VII—paratracheal nodes; inferior to the suprasternal notch in the upper mediastinum

Patterns of spread from primary tumor sites in the head and neck to cervical lymphatics are well described.⁷⁷ The location and incidence of metastasis vary according to the primary site. Primary tumors within the oral cavity and lip metastasize to the nodes in levels I, II, and III. Skip metastases may occur with oral tongue cancers such that involvement of nodes in level III or IV may occur without involvement of higher echelon nodes (levels I & II). Tumors arising in the oropharynx, hypopharynx, and larynx most commonly spread to the lymph nodes of the lateral neck in levels II, III, and IV. Isolated level V lymphadenopathy is uncommon with oral cavity, pharyngeal, and laryngeal primaries. Malignancies of the nasopharynx and thyroid commonly spread to level V nodes in addition to the jugular chain nodes. Retropharyngeal lymph nodes are sites for metastasis from tumors of the nasopharynx, soft palate, and lateral and posterior walls of the oropharynx and hypopharynx. Tumors of the hypopharynx, cervical esophagus, and thyroid frequently involve the paratracheal nodal compartment, and may extend to the lymphatics in the upper mediastinum (level VII). The Delphian node, a pretracheal lymph node, may become involved by advanced tumors of the glottis with subglottic spread.

The philosophy for the treatment of the cervical lymphatics in head and neck cancer has evolved significantly since the mid-1970s. The presence of cervical metastasis decreases the 5-year survival rate in patients with upper aerodigestive malignancies by approximately 50%. As such, adequate treatment of the N₀ and N₊ neck in these patients has always been viewed as a priority in an effort to increase disease-free survival rates. Traditionally, the gold standard for control of cervical metastasis has been the radical neck dissection (RND) first described by Crile. The classic RND removes levels I to V of the cervical lymphatics in addition to the SCM, internal jugular vein, and the spinal accessory nerve (CN XI). Any modification of the RND that preserves nonlymphatic structures (i.e., CN XI, SCM muscle, or internal jugular vein) is defined as a *modified radical neck dissection* (MRND). A neck dissection that preserves lymphatic compartments normally removed as part of a classic RND is termed a *selective neck dissection* (SND). Bocca⁷⁸ and colleagues demonstrated that the MRND, or "functional neck dissection," was equally effective in controlling regional metastasis as the RND, in addition to noting that the functional results in patients were superior. With outcome data supporting the use of SND and MRND, these procedures have become the preferred alternative for the treatment of cervical metastases when indicated.^{79,80}

SND options have become increasingly popular given the benefits of improved shoulder function and cosmetic impact on neck contour when compared to MRND. The principle behind preservation of certain nodal groups is that specific primary sites preferentially drain their lymphatics in a predictable pattern. Types of SND include the supraomohyoid neck dissection, the lateral neck dissection, and the posterolateral neck dissection.⁸¹ The supraomohyoid dissection, typically used with oral cavity malignancies, removes lymph nodes in levels I to III (Fig. 18-41). The lateral neck dissection, frequently used for laryngeal malignancies, removes those nodes in levels II through IV (Fig. 18-42). The posterolateral neck dissection, used with thyroid cancer, removes the lymphatics in levels II to V (Fig. 18-43). In the clinically negative neck (N₀), if the risk for occult metastasis is greater than 20%, elective treatment of the nodes at risk is generally advocated. This may be in the form of elective neck irradiation or elective neck dissection. An additional role of SND is as a staging tool to determine the need for postoperative radiation therapy. Regional control after selective dissection has been shown to be as effective for controlling regional disease as the MRND in the N₀ patient. Awareness of the potential for "skip metastases," in particular with lateral oral tongue lesions, may require extension of a standard SND to include additional levels for selected lesions.⁸² The treatment option selected for the primary site cancer is a significant factor in determining which therapeutic modality will be selected for the treatment of the regional lymphatics.

Shaded region indicates the region included in a posterolateral neck dissection.

For clinically N₊ necks, frequently the surgical treatment of choice is the MRND or RND. SND options have been advocated by some authors for treatment of limited N1 disease, however, they do not have a role in the treatment of advanced N stage disease. When extracapsular spread, perineural invasion, vascular invasion, and the presence of multiple involved lymph nodes are noted, surgical management of the neck alone is not adequate.⁸³ Adjuvant radiation therapy, and possibly chemoradiation, is indicated in these cases.

A planned postradiation neck dissection for patients undergoing radiation as a primary therapy is another indication for the use of neck dissection. In patients with existing advanced N stage disease (N2a or greater) or in patients with a partial response in the neck to therapy, neck dissection is performed 6 to 8 weeks after completion of radiation.

Regional metastases that encase the carotid artery or that demonstrate fixation of nodes to surrounding structures (e.g., prevertebral muscles) decrease 5-year survival rates significantly, to the range of 15 to 22%. The associated morbidity is high with procedures involving carotid resection (cerebrovascular accident and death) and must be weighed carefully when deciding if surgery is to be pursued. Surgically debulking metastatic disease does not improve survival and is not advocated. Recurrent neck metastasis after comprehensive neck dissection or radiation is associated with very poor survival.

PARAPHARYNGEAL SPACE MASSES

The parapharyngeal space is a potential space, shaped like an inverted pyramid spanning the skull base to the hyoid. The boundaries of the space are separated by the styloid process and its associated fascial attachments into the "prestyloid" and "poststyloid" compartments.⁸⁴ The contents of the prestyloid space are the parotid, fat, and lymph nodes. The poststyloid compartment is composed of CNs IX to XII, the carotid space contents, cervical sympathetic chain, fat, and lymph nodes. Tumors in this space can produce displacement of the lateral pharyngeal wall medially into the oropharynx (Fig. 18-44), dysphagia, cranial nerve dysfunction, Horner's syndrome, or vascular compression.

Parapharyngeal mass—prestyloid with prominent oropharyngeal presentation typical of a dumbbell tumor.

Of the masses found in the parapharyngeal space, 40 to 50% of the tumors are of salivary gland origin. Tumors of neurogenic origin such as paragangliomas (glomus vagale, carotid body tumor), schwannomas, and neurofibromas are responsible for 20 to 25% of parapharyngeal masses. Lymph node metastases and primary lymphoma represent 15% of lesions. With this in mind, when reviewing preoperative imaging, one can assume that tumors arising anterior to the styloid process are most likely of salivary gland origin, whereas those of the poststyloid compartment are vascular or neurogenic. This is helpful in that angiography is not as necessary for prestyloid lesions as it may be for vascular poststyloid tumors. If a paraganglioma is suspected, a 24-hour urinary catecholamine collection should be obtained to allow for optimal premedication for patients with functional tumors. Embolization may be considered for vascular tumors before surgery in an attempt to decrease intraoperative blood loss.

Surgical access to these tumors may require a transmandibular and/or lateral cervical approach. It is inadvisable to approach parapharyngeal

space tumors transorally without having the necessary exposure and control of the associated vasculature that is afforded by these approaches. Some tumors of the parapharyngeal space (e.g., dumbbell tumors of deep parotid origin) are amenable to removal by a combined transparotid and transcervical approach while allowing for dissection and displacement of the facial nerve to assist removal of tumor.

BENIGN NECK MASSES

A number of benign masses of the neck occur that require surgical management. Many of these masses are seen in the pediatric population. The differential diagnosis includes thyroglossal duct cyst, branchial cleft cyst, lymphangioma (cystic hygroma), hemangioma, and dermoid cyst.

Thyroglossal duct cysts represent the vestigial remainder of the tract of the descending thyroid gland from the foramen cecum, at the tongue base, into the lower anterior neck during fetal development. They present as a midline or paramedian cystic mass adjacent to the hyoid bone. After an upper respiratory infection, the cyst may enlarge or become infected. Surgical management of a thyroglossal duct cyst requires removal of the cyst, the tract, and the central portion of the hyoid bone (Sistrunk procedure), as well as a portion of the tongue base up to the foramen cecum. Before excision of a thyroglossal duct cyst, an imaging study such as ultrasound is performed to identify if normal thyroid tissue exists in the lower neck, and lab assay is performed to assess if the patient is euthyroid.

Congenital branchial cleft remnants are derived from the branchial cleft apparatus that persists after fetal development. There are several types, numbered according to their corresponding embryologic branchial cleft. First branchial cleft cysts and sinuses are associated intimately with the EAC and the parotid gland. Second and third branchial cleft cysts are found along the anterior border of the SCM muscle and can produce drainage via a sinus tract to the neck skin (Fig. 18-45). Secondary infections can occur, producing enlargement, cellulitis, and neck abscess that requires operative drainage. The removal of branchial cleft cysts and fistula requires removal of the fistula tract to the point of origin to decrease the risk of recurrence. The second branchial cleft remnant tract courses between the internal and external carotid arteries and proceeds into the tonsillar fossa. The third branchial cleft remnant courses posterior to the common carotid artery, ending in the pyriform sinus region. Cystic metastasis from squamous cell carcinoma of the tonsil or tongue base to a cervical lymph node can be confused for a branchial cleft cyst in an otherwise asymptomatic patient. Dermoid cysts tend to present as midline masses and represent trapped epithelium originating from the embryonic closure of the midline.

CT scan demonstrating a branchial cleft cyst with operative specimen.

Lymphatic malformations such as lymphangiomas and cystic hygromas can be difficult management problems. They typically present as mobile, fluid-filled masses. Because of their predisposition to track extensively into the surrounding soft tissues, complete removal of these lesions can be challenging. Recurrence and regrowth occur with incomplete removal. Cosmetic deformity and/or nerve injury can result when extensive surgical dissection is performed for large lesions. In newborns and infants, there is higher associated morbidity when cystic hygromas and

lymphangiomas become massive, require tracheostomy, and involve the deep neck and mediastinum.

DEEP-NECK FASCIAL PLANES

The fascial planes of the neck provide boundaries that are clinically applicable because they determine the pathway of spread of an infection. The deep cervical fascia is composed of three layers. These are the investing (superficial deep), pretracheal, and the prevertebral fascias. The superficial layer of the deep cervical fascia forms a cone around the neck and spans from skull base and mandible to the clavicle and manubrium. This layer surrounds the SCM muscle and covers the anterior and posterior triangles of the neck. The pretracheal fascia is found within the anterior compartment, deep to the strap muscles and surrounds the thyroid gland, trachea, and esophagus. This fascia blends laterally to the carotid sheath. Infections in this region may track along the trachea or esophagus into the mediastinum. The prevertebral fascia extends from the skull base to the thoracic vertebra and covers the prevertebral musculature and cervical spine. If an infection were to communicate anteriorly through the prevertebral fascia, it would enter the retropharyngeal space. Infectious extension into this space is complicated by the fact that this region, located posterior to the buccopharyngeal fascia, extends from the skull base to the mediastinum.

Salivary Gland Tumors

Tumors of the salivary gland are relatively uncommon and represent less than 2% of all head and neck neoplasms. The major salivary glands are the parotid, submandibular, and sublingual glands. Minor salivary glands are found throughout the submucosa of the upper aerodigestive tract with the highest density found within the palate. Eighty-five percent of salivary gland neoplasms arise within the parotid gland (Fig. 18-46). The majority of these neoplasms are benign, with the most common histology being pleomorphic adenoma (benign mixed tumor). In contrast, approximately 50% of tumors arising in the submandibular and sublingual glands are malignant. Tumors arising from minor salivary gland tissue carry an even higher risk for malignancy (75%).

Fig. 18-46.

Example of a tumor in the parotid with the pattern of the facial nerve and associated anatomy. m. = muscle; n. = nerve; v. = vein.

Salivary gland tumors are usually slow growing and well circumscribed. Patients with a mass and findings of rapid growth, pain, paresthesias, and facial nerve weakness are at increased risk of harboring a malignancy. The facial nerve, which separates the superficial and deep lobes of the parotid, may be directly involved by tumors in 10 to 15% of patients. Additional findings ominous for malignancy include skin invasion and fixation to the mastoid tip. Trismus suggests invasion of the masseter or pterygoid muscles.⁸⁵

Submandibular and sublingual gland tumors present as a neck mass or floor of mouth swelling, respectively. Malignant tumors of the sublingual or submandibular gland may invade the lingual or hypoglossal nerves, causing paresthesias or paralysis.⁸⁶ Bimanual examination is important for determining the size of the tumor and possible fixation to the mandible or involvement of the tongue.

Minor salivary gland tumors present as painless submucosal masses and are most frequently seen at the junction of the hard and soft palate. Minor salivary gland tumors arising in the prestyloid parapharyngeal space may produce medial displacement of the lateral oropharyngeal wall and tonsil.

The incidence of metastatic spread to cervical lymphatics is variable and depends on the histology, primary site, and stage of the tumor. Parotid gland malignancies can metastasize to the intra- and periglandular nodes. The next echelon of lymphatics for the parotid is the upper jugular nodal chain. Although the risk of lymphatic metastasis is low for most salivary gland malignancies, lesions that are considered high grade or that demonstrate perineural invasion have a higher propensity for regional spread. Tumors arising in patients of advanced age also tend to have more aggressive behavior. Initial nodal drainage for the submandibular gland is the level Ia and Ib lymph nodes and submental nodes followed by the upper and midjugular nodes. Extraglandular extension of tumor and lymph node metastases are adverse prognostic factors for submandibular gland tumors.

Diagnostic imaging is standard for the evaluation of salivary gland tumors. MRI is the most sensitive study to determine soft-tissue extension and involvement of adjacent structures. Unfortunately, imaging studies lack the specificity for differentiating benign and malignant neoplasms. Diagnosis of salivary gland tumors is frequently aided by the use of FNA. In the hands of an experienced cytologist familiar with salivary gland pathology, FNA can provide an accurate preoperative diagnosis in 70 to 80% of cases. This can help the operative surgeon with treatment planning and patient counseling, but should be viewed in the context that a more extensive procedure may be ultimately required. The final histopathologic diagnosis is confirmed by surgical excision.

Benign and malignant tumors of the salivary glands are divided into epithelial, nonepithelial, and metastatic neoplasms. Benign epithelial tumors include pleomorphic adenoma (80%), monomorphic adenoma, Warthin's tumor, oncocytoma, or sebaceous neoplasm. Nonepithelial benign lesions include hemangioma, neural sheath tumor, and lipoma. Treatment of benign neoplasms is surgical excision of the affected gland or, in the case of the parotid, excision of the superficial lobe with facial nerve dissection and preservation. The minimal surgical procedure for neoplasms of the parotid is superficial parotidectomy with preservation of the facial nerve. Enucleation of the tumor mass is not recommended because of the risk of incomplete excision and tumor spillage. Tumor spillage of a pleomorphic adenoma during removal can lead to problematic recurrences.

Malignant epithelial tumors range in aggressiveness from low to high grade. Their behavior depends on tumor histology, degree of invasiveness, and the presence of regional metastasis. The most common malignant epithelial neoplasm of the salivary glands is mucoepidermoid carcinoma. The low-grade mucoepidermoid carcinoma is composed of largely mucin-secreting cells, whereas in high-grade tumors, the epidermoid cells predominate. High-grade mucoepidermoid carcinomas resemble nonkeratinizing squamous cell carcinoma in their histologic features and clinical behavior. Adenoid cystic carcinoma, which has a propensity for neural invasion, is the second most common malignancy in adults. Skip lesions along nerves are common and can lead to treatment failures because of the difficulty in treating the full extent of invasion. Adenoid cystic carcinomas have a high incidence of distant metastasis, but display indolent growth. It is not uncommon for patients to experience lengthy survival despite the presence of disseminated disease. The most common malignancies in the pediatric population are mucoepidermoid carcinoma and acinic cell carcinoma. For minor salivary glands, the most common malignancies are adenoid cystic carcinoma, mucoepidermoid carcinoma, and low-grade polymorphous adenocarcinoma. Carcinoma ex pleomorphic adenoma is an aggressive malignancy that arises from a pre-existing benign mixed tumor.

The primary treatment of salivary malignancies is surgical excision. In this setting, basic surgical principles include the en bloc removal of the involved gland with preservation of all nerves unless directly invaded by tumor. For parotid tumors that arise in the lateral lobe, superficial parotidectomy with preservation of CN VII is indicated. If the tumor extends into the deep lobe of the parotid, a total parotidectomy with nerve preservation is performed. Although malignant tumors may abut the facial nerve, if a plane of dissection can be developed without leaving gross tumor, it is preferable to preserve the nerve. If the nerve is encased by tumor (or is noted to be nonfunctional preoperatively) and preservation would result leaving gross residual disease, nerve sacrifice should be considered.

The removal of submandibular malignancies includes en bloc resection of the gland and submental and submandibular lymph nodes. Radical

resection is indicated with tumors that invade the mandible, tongue, or floor of mouth. Therapeutic removal of the regional lymphatics is indicated for clinical adenopathy or when the risk of occult regional metastasis exceeds 20%. High-grade mucoepidermoid carcinomas, for example, have a high risk of regional disease and require elective treatment of the regional lymphatics. When gross nerve invasion is found (lingual or hypoglossal), sacrifice of the nerve is indicated with retrograde frozen section biopsies to determine the extent of involvement. If the nerve is invaded at the level of the skull base foramina, a surgical clip may be left in place to mark the area for inclusion in postoperative radiation fields. The presence of skip metastases in the nerve with adenoid cystic carcinoma makes recurrence common with this pathology.

Postoperative radiation treatment plays an important role in the treatment of salivary malignancies. The presence of extraglandular disease, perineural invasion, direct invasion of regional structures, regional metastasis, and high-grade histology are all indications for radiation treatment.

RECONSTRUCTION IN HEAD AND NECK SURGERY

Defects of soft tissue and bony anatomy of the head and neck can occur after oncologic resection. Tumor surgery frequently necessitates removal of structures related to speech and swallowing. Loss of sensation and motor function can produce dysphagia through impairment of food bolus formation, manipulation, and propulsion. Removal of laryngeal, tongue base, and hypopharyngeal tumors can lead to impairment in airway protective reflexes and predispose to aspiration. Cosmetic deformities that result from surgery can also significantly impact the quality of life of a patient. Current surgical management of head and neck tumors requires restoration of form and function through application of contemporary reconstruction techniques.

Basic principles of reconstruction include attempting to replace resected tissue components (bone, skin, soft tissue) with tissue with similar qualities. However, restoring a patient's functional capacity does not always require strict observation of this rule. The head and neck reconstructive surgeon must consider a patient's preoperative comorbidities and anatomy when constructing a care plan.

A stepladder analogy has been used to describe the escalation in complexity of reconstructive options in the repair of head and neck defects. It is important to remember that the most complex procedure is not always the most appropriate. Progression for closure by secondary intention, primary closure, skin grafts, local flaps, regional flaps, and free-tissue transfer flaps (free flaps) run the gamut of options available. The most appropriate reconstructive technique used is based on the medical condition of the patient, the location and size of the defect to be repaired, and the functional impairment associated with the defect.

Small defects of the skin of the medial canthus, scalp, and nose may be allowed to heal by secondary intention with excellent cosmetic and functional results. When considering primary closure, the excision should be placed in the lines of relaxed skin tension and should attempt to not distort surrounding anatomy such as the hairline, eyelids, or lips.

Skin Grafts

Split and full-thickness skin grafts are used in the head and neck for a variety of defects. Following oral cavity resections, split-thickness grafts can provide adequate reconstruction of the mucosal surface if an adequate vascular tissue bed is available to support the blood supply needed for graft survival. These grafts start to incorporate into the recipient site in approximately 5 days and do not provide replacement of absent soft-tissue bulk; however, they are a simple low morbidity technique for covering mucosal defects that allow for monitoring for local recurrence. Full-thickness grafts are used on the face when local rotational flaps are not available. These grafts have less contracture over time than split-thickness grafts. Grafts can be harvested from the postauricular or supraclavicular areas to maximize the match of skin characteristics. Dermal grafts have been used to provide coverage for exposed vessels in the neck, reconstruct mucosal defects, and assist in providing soft-tissue bulk.

Local Flaps

Local flaps encompass a large number of mainly random-pattern flaps used to reconstruct defects in adjacent areas. It is beyond the scope of this chapter to enumerate all of these flaps, but they should be designed according to the relaxed skin tension lines of the face and neck skin. These lines are tension lines inherent in the facial regions and caused in part by the insertions of muscles of facial animation. Incisions paralleling the relaxed skin tension lines that respect the aesthetic subunits of the face heal with the least amount of tension and camouflage into a more appealing cosmetic result. Poorly designed incisions or flaps result in widened scars and distortion of important aesthetic units.

Regional Flaps

Regional flaps are those that are available as pedicled transfer of soft tissue from areas adjacent to the defect. These flaps have an axial blood supply that traverses the flap longitudinally from proximal to distal between the fascia and subcutaneous tissue. Single-stage reconstruction is possible, and harvest may occur simultaneously with the resection of primary disease resulting in a decrease in overall operative time.

The deltopectoral fasciocutaneous flap is a medially based flap from the anterior chest wall reliant on the perforators of the internal mammary artery. Its pliability permits folding, making it capable for use with reconstruction of pharyngoesophageal defects. A disadvantage is that use of the flap requires a second stage detaching the proximal chest component and completion of inseting approximately 3-4 weeks after the original procedure.

Several myocutaneous flaps exist for head and neck reconstruction. The vascular pedicle of these flaps permits a wide arc of rotation, making them ideal for a variety of different reconstructive needs. The trapezius muscle provides a number of soft-tissue flaps that can be rotated to reconstruct a number of defects in the head and neck. The superior trapezius flap is based on paraspinous perforators and is ideal for lateral neck defects. The lateral island trapezius flap, based on the transverse cervical and dorsal scapular vessels, allows for harvest of a soft-tissue paddle below the inferior border of the scapula. This flap is ideal for reconstruction of scalp and lateral skull base defects.

The pectoralis myocutaneous flap is based on the pectoral branch of the thoracoacromial artery (medial) and the lateral thoracic artery (lateral). The latter vessel may be sacrificed to increase the arc of rotation. This workhorse flap includes the pectoralis major muscle, either alone or with overlying anterior chest skin. The pectoralis myocutaneous flap has enjoyed tremendous popularity because of its ease of harvest, the ability to tailor its thickness to the defect, and limited donor site morbidity. It can be used for reconstruction of the oropharynx, oral cavity, and the hypopharynx and in some cases can be tubed to replace cervical esophageal defects. Bulk associated with this flap may make certain applications less practical, and this problem is exacerbated in obese patients. The arc of rotation limits the superior extent of this flap to the zygomatic arch externally and the superior pole of the tonsil internally.

The latissimus dorsi flap provides a large source of soft tissue and has a wide arc of rotation. The flap is based on the thoracodorsal vasculature. This flap can be used as a regional rotational flap or as a free flap. Lateral decubitus positioning is typically required for harvesting this flap, making it less attractive for simultaneous cancer ablation and reconstruction.

Free-Tissue Transfer

Free-tissue transfer with microvascular anastomosis affords the reconstructive surgeon unparalleled ability to replace tissue loss with tissues of similar characteristics. There are a number of donor sites available for various types of flaps, including osteomyocutaneous, myocutaneous, fasciocutaneous, fascial, and myosseous flaps. The flaps most popular in head and neck reconstructive armamentarium are those with ease of harvest from a standpoint of patient positioning and those that allow for a two-teamed approach for simultaneous flap harvesting and oncologic resection.⁸⁷

The radial forearm fasciocutaneous flap (Fig. 18-47) is a hardy flap with constant vascular anatomy and a long vascular pedicle, allowing for ease of inseting and choice in anastomotic vascular recipient sites. It is pliable and can be reinnervated as a sensate flap, making it ideal for repair of oral cavity and oropharyngeal defects. It can be tubed to repair hypopharyngeal and upper esophageal defects.^{88,89}

Radial forearm free flap before harvest from the arm.

The anterolateral thigh flap, based on the descending branch of the lateral circumflex femoral artery, has the capacity for a large pliable skin paddle with muscle that is capable of being tubed and is used to reconstruct similar defects as that of the radial forearm flap while providing more tissue bulk.

The fibular osteocutaneous or osteomyocutaneous flap allows for one-stage reconstruction of resected mandible. In the adult, up to 20 cm of bone can be harvested with a cuff of soleus and flexor hallucis longus muscle for additional soft-tissue bulk. The donor site defect is well tolerated as long as approximately 7 cm of bone are retained proximally and distally for knee and ankle stability.⁹⁰

Iliac crest osteocutaneous flaps are also used for the reconstruction of mandible defects. The natural shape of this donor site bone is similar to the mandibular angle. The thick stock of bone provided by the iliac crest allows for better vertical reconstruction of the mandible while spanning a segmental defect. However, for lengthy mandibular defects (greater than 10 cm), the fibular flap usually is chosen. Additionally, for shorter mandible defects, other free flaps, including osseous components such as scapular and radial forearm flaps, can be used. The scapular flap can provide approximately 12 cm of scapula bone and is based on the circumflex scapular artery. This flap can be combined with parascapular and scapular skin islands and portions of latissimus dorsi and serratus anterior muscle. The radial forearm osteocutaneous flap can provide a limited quantity of bone with the soft-tissue component of the flap but is associated with an increased risk of donor site fracture.

Large soft-tissue defects can result from trauma, excision of skull base tumors, and tumors involving large segments of skin. Furthermore, after extensive skull base resections in the anterior and lateral skull base, the need for separation of the oropharyngeal and sinonasal tracts from the dura requires soft-tissue interposition between the dura and the contaminated upper aerodigestive tract. The rectus abdominis flap, based on the deep inferior epigastric vessels, provides a large amount of soft tissue and is ideal for closure of wounds of the lateral skull base and dura.

For reconstruction of defects of the hypopharynx and cervical esophagus, both free flaps and regional pedicled flaps are available. The free transfer of a jejunal segment can be performed based on branches of the superior mesenteric artery. Other free flaps used in this area include fasciocutaneous flaps, such as tubed radial forearm flap. The gastric pull-up is a regional flap that is also in use for reconstruction of cervical esophageal defects. The stomach is mobilized and pedicled on the right gastric and gastroepiploic vessels into the defect via tunneling through the thoracic cavity.

TRACHEOSTOMY

Tracheostomy is indicated in the management of patients who require prolonged intubation, access for frequent pulmonary suctioning, and in those patients with neurologic deficits that impair protective airway reflexes. Its use in head and neck surgery is often for the temporary management of the airway in the perioperative period. After surgical resection of oral cavity and oropharyngeal cancers, edema of the upper

aerodigestive tract occurs necessitating perioperative tracheostomy to prevent loss of the airway.

The avoidance of prolonged orotracheal and nasotracheal intubation decreases the risk of laryngeal and subglottic injury and potential stenosis, facilitates oral and pulmonary suctioning, and decreases patient discomfort. When the tracheostomy is no longer needed, the tube is removed and closure of the opening usually occurs spontaneously over a 2-week period. Complications of tracheostomy include pneumothorax, RLN injury, tracheal stenosis, wound infection with large-vessel erosion, and failure to close after decannulation. The use of cricothyroidotomy as an alternative to tracheostomy for patients who require prolonged intubation is associated with a higher incidence of vocal cord dysfunction and subglottic stenosis. When cricothyroidotomy is used in the setting of establishing an emergency airway, conversion to a standard tracheostomy should be considered if decannulation is not anticipated within 5 to 7 days.

Placement of a tracheostomy does not obligate a patient to loss of speech. When a large cuffed tracheostomy tube is in place, expecting a patient to be capable of normal speech is impractical. However, after a patient is downsized to an uncuffed tracheostomy tube, intermittent finger occlusion or Passy-Muir valve placement will allow a patient to communicate while still using the tracheostomy to bypass the upper airway. When a patient no longer has the original indication for the tracheostomy and can tolerate capping of the tracheal tube for greater than 24 hours, decannulation is considered safe. If an upper airway mass or tissue reconstruction was the indication for the tracheostomy, pre-decannulation flexible laryngoscopic examination of the airway is recommended.⁹¹

LONG-TERM MANAGEMENT AND REHABILITATION

Palliative Care

For patients with unresectable disease or distant metastases, palliative care options exist. Palliative treatment is aimed at improving a patient's symptoms and may include radiation, chemotherapy, or consultation with a pain specialist. The head and neck surgeon has the options of tracheostomy and gastrostomy tube placement for patients progressing with worsening airway compromise and dysphagia, respectively. Hospice is also an option for patients with a limited short-term outlook; hospice allows a patient to retain dignity at the time of greatest adversity.

Follow-Up Care

Patients diagnosed and treated for a head and neck tumor require follow-up care aimed at monitoring for recurrence and the side effects of therapy. For malignancies of the upper aerodigestive tract, the American Head and Neck Society offers a formula for follow-up appointments (Table 18-4).⁹²

Table 18-4 American Head and Neck Society Follow-Up Appointment Formula	
Posttreatment	Follow-Up Period
1st y	Every 1–3 mo
2nd y	Every 2–4 mo
3rd y	Every 3–6 mo
4th y	Every 4–6 mo
5th y and after	Every 12 mo

In addition to a formal head and neck examination, patients should be questioned about any emerging symptoms related to their primary tumor. New-onset pain, otalgia, hoarseness, and dysphagia are some of the problems that may indicate the need to evaluate further for recurrence. Worsening dysphagia may also be a presenting symptom for a patient developing a pharyngeal stricture. Such a patient may require dilatation and/or placement of a gastrostomy tube for nutrition. Additionally, a number of patients who undergo head and neck radiation will develop hypothyroidism years after treatment. Patients with shoulder dysfunction after surgery should be considered for physical therapy consultation to minimize the long-term effects of their surgical care. Patients with chronic pain-related issues can benefit from consultation with a pain specialist to construct a treatment regimen to provide adequate control of long-term discomfort. Long-term follow-up with a dentist experienced in caring for patients with a history of therapeutic radiation therapy is vital if prevention of osteoradionecrosis is to be achieved.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 19. Chest Wall, Lung, Mediastinum, and Pleura >

KEY POINTS

1. Lung cancer continues to be a highly lethal and extremely common cancer, with 5-year survival of 15%. Lung cancer incidence is second only to the incidence of prostate cancer in men and breast cancer in women. Squamous cell carcinoma and adenocarcinoma of the lung are the most common subtypes and are rarely found in the absence of a smoking history. Nonsmokers who live with smokers have a 24% increased risk of lung cancer compared to nonsmokers who do not live with smokers.
2. Endoscopic bronchial ultrasound is a valuable new tool that can enhance the accuracy and safety of transbronchial biopsies of both the primary tumor (when it abuts the central airways) and the mediastinal lymph nodes and should become part of the surgeon's armamentarium for the diagnosis and treatment of lung cancer.
3. The assessment of patient risk before thoracic resection is based on clinical judgment and data.
4. Impaired exchange of carbon monoxide is associated with a significant increase in the risk of postoperative pulmonary complications, independent of the patient's smoking history. In patients undergoing pulmonary resection, the risk of any pulmonary complication increases by 42% for every 10% decline in the percent carbon monoxide diffusion capacity (%DLCO), and this measure may be a useful parameter in risk stratification of patients for surgery.
5. Maximum oxygen consumption ($\dot{V}O_2\text{max}$) values provide important additional information in those patients with severely impaired DLCO and forced expiratory volume in 1 second. Values of <10 mL/kg per minute generally prohibit any major pulmonary resection, because the mortality in patients with these levels is 26% compared with only 8.3% in patients whose $\dot{V}O_2\text{max}$ is ≥ 10 mL/kg per minute; values of >15 mL/kg per minute generally indicate the patient's ability to tolerate pneumonectomy.
6. Major changes in the tumor, node, and metastasis (TNM) staging system for lung cancer have been proposed. Tumor stage will be further subdivided into T1a and T1b, T2a and T2b, T3, and T4. Satellite nodules in the same lobe will be considered T3 and malignant pleural and pericardial effusions will be considered metastatic disease rather than T4 disease.
7. Increasing evidence suggests a significant role for gastroesophageal reflux disease in the pathogenesis of chronic lung diseases such as bronchiectasis and idiopathic pulmonary fibrosis, and it may also contribute to bronchiolitis obliterans syndrome in lung transplant patients.
8. Multidrug-resistant tuberculosis (MDRTB) organisms are present in approximately 10% of new tuberculosis cases and 40% of recurrent cases. Another rare disease variant termed *extensively drug-resistant tuberculosis* has also been identified. The causative organisms are resistant not only to isoniazid and rifampin, as are the MDRTB organisms, but also to at least one of the injectable second-line drugs such as capreomycin, amikacin, and kanamycin.
9. Treatment of pulmonary aspergilloma is individualized. Asymptomatic patients can be observed without any additional therapy. Similarly, mild hemoptysis, which is not life-threatening, can be managed with medical therapy, including antifungals and cough suppressant. Amphotericin B is the drug of choice, although voriconazole has recently been used for treatment of aspergillosis, with fewer side effects and equivalent efficacy. Massive hemoptysis had traditionally been an indication for urgent or emergent operative intervention. However, with the advancement of endovascular techniques, bronchial artery embolization in select centers with experience in these techniques has been effective.
10. Treatment for candidal infection, like that for other fungal infections, has changed dramatically in the past decade. The availability of multiple effective therapies allows for specific tailoring of treatment, including combination regimens, based on the patient's ability to tolerate associated toxicities, the microbiologic information for the specific candidal species, and the route of administration. Although their demonstrated efficacy is similar to that of other classes of antifungal drugs, the triazoles and echinocandins appear to have fewer side effects and are better tolerated than these other drug classes.
11. In patients with malignant pleural effusion, poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result with pleurodesis and is the primary indication for placement of indwelling pleural catheters. These catheters have dramatically changed the management of end-stage cancer treatment, because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.

TRACHEA

Anatomy

An understanding of the relevant anatomy of the trachea is essential for surgeons of all specialties (Fig. 19-1).¹ The trachea is composed of cartilaginous and

membranous portions, beginning with the cricoid cartilage, the first complete cartilaginous ring of the airway. The cricoid cartilage consists of an anterior arch and a posterior broad-based plate. Articulating with the posterior cricoid plate are the arytenoid cartilages. The vocal cords originate from the arytenoid cartilages and then attach to the thyroid cartilage. The subglottic space, the narrowest part of the trachea with an internal diameter of approximately 2 cm, begins at the inferior surface of the vocal cords and extends to the first tracheal ring. The remainder of the distal trachea is 10.0 to 13.0 cm long, consists of 18 to 22 rings, and has an internal diameter of 2.3 cm.

Fig. 19-1.

Anatomy of the larynx and upper trachea. m. = muscle; n. = nerve.

The tracheal blood supply enters the airway near the junction of the membranous and cartilaginous portions of the airway (Fig. 19-2). It is segmental, which means that each entering small branch supplies a segment of 1.0 to 2.0 cm, which limits circumferential mobilization to that same distance. The arteries supplying the trachea include the inferior thyroid, subclavian, supreme intercostal, internal thoracic, innominate, and superior and middle bronchial arteries. The vessels are interconnected along the lateral surface of the trachea by an important longitudinal vascular anastomosis that feeds transverse segmental vessels to the soft tissues between the cartilages.

Fig. 19-2.

Tracheal Injury

Injury secondary to endotracheal intubation is most commonly the result of overinflation of the cuff. Although high-volume/low-pressure cuffs are now ubiquitous, they can easily be overinflated, and pressures can be generated that are high enough to cause ischemia of the contiguous airway wall. In some patients, periods of ischemia as short as 4 hours may be all that is required to induce an ischemic event significant enough to lead to scarring and stricture. With prolonged overinflation and consequent full-thickness destruction of the airway, fistula development between the innominate artery and esophagus may ensue. For these reasons, it is good practice in all intubations, no matter how brief, to inflate the cuff only to the level necessary to prevent air leakage around the cuff. In circumstances of prolonged ventilatory support and high airway pressures, cuff pressure monitoring (to maintain pressures below 20 mmHg) is advisable.

Tracheal stenosis is nearly always iatrogenic. It is secondary to either endotracheal intubation or tracheostomy. Collectively, such tracheal injuries are referred to as *postintubation injuries*. Clinically significant tracheal stenosis is common after tracheostomy due to scarring and local injury, and occurs in 3 to 12% of cases.² Factors associated with an increased risk of tracheal stenosis include incorrect placement of the tracheostomy through the first tracheal ring or the cricothyroid membrane where the airway is narrowest, use of a large tracheostomy tube, and transverse incision on the trachea. However, even a properly placed tracheostomy can lead to tracheal stenosis secondary to scarring and local injury, and mild ulceration and stenosis frequently are seen after tracheostomy removal. The rate of stomal stenosis can be minimized by using the smallest tracheostomy tube possible and downsizing as soon as the patient will tolerate it, and by using a vertical tracheal incision without removing cartilage.

Clinically, stridor and dyspnea on exertion are the primary symptoms of tracheal stenosis. The length of time to onset of symptoms after extubation or after tracheostomy decannulation varies, usually ranging from 2 to 12 weeks; however, symptoms can appear immediately or as long as 1 to 2 years later. Frequently, patients are misdiagnosed as having asthma or bronchitis, and treatment for such illnesses can persist for some time before the correct diagnosis is discovered. Generally, the intensity of symptoms experienced is related to the degree of stenosis and to the patient's underlying pulmonary disease.

ACUTE MANAGEMENT

The treatment of tracheal stenosis is resection and primary anastomosis. In nearly all postintubation injuries the injury is transmural, and significant portions of the cartilaginous structural support are destroyed (Fig. 19-3). Measures such as laser ablation are temporizing. In the early phase of evaluating patients, dilation using a rigid bronchoscope is useful to gain immediate relief of dyspnea and to allow full assessment of the lesion. It is important to carefully document the length and position of the stenosis as well as the location in relation to the vocal cords. Rarely, if ever, is a tracheostomy necessary. For patients who are not operative candidates due to associated comorbidities, internal stents, typically silicone T tubes, are useful. Wire mesh stents should not be used, given their known propensity to erode through the wall of the airway. The use of balloon dilation and tracheoplasty also has been described, although their efficacy is marginal. Efforts focused on tissue engineering may provide suitable material for tracheal replacement in long-segment tracheal stenosis in the future.

Fig. 19-3.

Diagram of the principal postintubation lesions. **A.** A circumferential lesion at the cuff site after the use of an endotracheal tube. **B.** Potential lesions after the use of tracheostomy tubes. Anterolateral stenosis can be seen at the stomal level. Circumferential stenosis can be seen at the cuff level (lower than with an endotracheal tube). The segment in between is often inflamed and malacotic. **C.** Damage to the subglottic larynx. **D.** Tracheoesophageal fistula occurring at the level of the tracheostomy cuff. Circumferential damage is usual at this level. **E.** Tracheoinnominate artery fistula.

(Adapted with permission from Grillo.²)

Most intubation injuries are located in the upper third of the trachea, so tracheal resection usually is done through a collar incision. Resection typically involves 2 to 4 cm of trachea for benign stenosis. However, a primary anastomosis can still be performed without undue tension, even if up to one half of the trachea needs to be resected.² When resection for a postintubation injury is performed, it is critical to fully resect all inflamed and scarred tissue. Tracheostomies and stents are not required postoperatively, and the patient often is extubated in the operating room or shortly thereafter.

Tracheal Fistulas

TRACHEOINNOMINATE ARTERY FISTULA

Tracheoinnominate artery fistula has two causes: too low a placement of the tracheostomy and hyperinflation of the tracheal cuff. When performing a tracheostomy, the surgeon must be diligent about proper identification of the tracheal rings. Tracheostomies should be placed through the second to fourth tracheal rings without reference to the location of the sternal notch. When they are placed below the fourth tracheal ring, the inner curve of the tracheostomy cannula will be positioned to exert pressure on the upper surface of the innominate artery, which will lead to arterial erosion. Similarly, the tracheal cuff, when hyperinflated, will cause ischemic injury to the airway and subsequent erosion into the artery and fistula development. Most cuff-induced fistulas develop within 2 weeks after placement of the tracheostomy.

Clinically, tracheoinnominate artery fistulas present with bleeding. A premonitory hemorrhage often occurs, and although it usually is not massive, it must not be ignored or simply attributed to general airway irritation or wound bleeding. With significant bleeding, the tracheostomy cuff can be hyperinflated to temporarily occlude the arterial injury. If such an effort is unsuccessful, the tracheostomy incision should immediately be opened widely and a finger inserted to compress the artery against the manubrium (Fig. 19-4). The patient can then be orally intubated, and the airway suctioned free of blood. Emergent surgical resection of the involved segment of artery is performed, usually without reconstruction.

Fig. 19-4.

TRACHEOESOPHAGEAL FISTULA

Tracheoesophageal fistulas (TEFs) occur primarily in patients with an indwelling nasogastric tube who are also receiving prolonged mechanical ventilatory support.³ Cuff compression of the membranous trachea against the nasogastric tube leads to airway and esophageal injury and fistula development. Clinically, saliva, gastric contents, or tube feeding contents are noted in the material suctioned from the airway. Distention of the stomach secondary to positive pressure ventilation can occur. Diagnosis of a suspected TEF is by bronchoscopy. Withdrawal of the endotracheal tube with the bronchoscope inserted allows the fistula at the cuff site to be seen. Alternatively, esophagoscopy will enable visualization of the cuff of the endotracheal tube in the esophagus.

First and foremost, treatment of a TEF requires weaning the patient from the ventilator and then extubating as soon as possible. During the weaning period, the nasogastric tube should be removed, with attention given to ensuring that the cuff of the endotracheal tube is placed below the fistula and that it is not overinflated. Then a gastrostomy tube should be placed for aspiration (to prevent reflux) and a jejunostomy tube for feeding. If aspiration is relentless and is not managed by the aforementioned steps, esophageal diversion with esophagostomy can be performed. Once the patient is weaned from the ventilator, a single-stage operation should be done, consisting of tracheal resection and primary anastomosis, repair of the esophageal defect, and interposition of a muscle flap between the trachea and esophagus (Fig. 19-5).⁴

Single-stage operation for closure of a tracheoesophageal fistula and tracheal resection. **A.** The fistula is divided and the trachea is transected below the level of damage. **B.** The fistula is closed on the tracheal side in a single layer and on the esophageal side in a double layer. **C.** The damaged trachea segment is resected. **D.** View of completed tracheal anastomosis. m. = muscle.

Tracheal Neoplasms

Primary tracheal neoplasms are exceedingly rare, and the diagnosis frequently is delayed. The most common primary tracheal neoplasms are squamous cell carcinomas (related to smoking) and adenoid cystic carcinomas. Clinically, tracheal tumors present with cough, dyspnea, hemoptysis, stridor, or symptoms of invasion of contiguous structures (such as the recurrent laryngeal nerve or the esophagus). The most common radiologic finding of tracheal malignancy is tracheal stenosis, but it is seen in only 50% of cases. With tumors other than squamous cell carcinomas, symptoms may persist for months because of slow tumor growth rates. Stage of presentation is advanced, with approximately 50% of patients presenting with stage IV disease. Overall 5-year survival for patients with tracheal neoplasms is 40%, but survival falls to 15% for those with stage IV disease.⁵

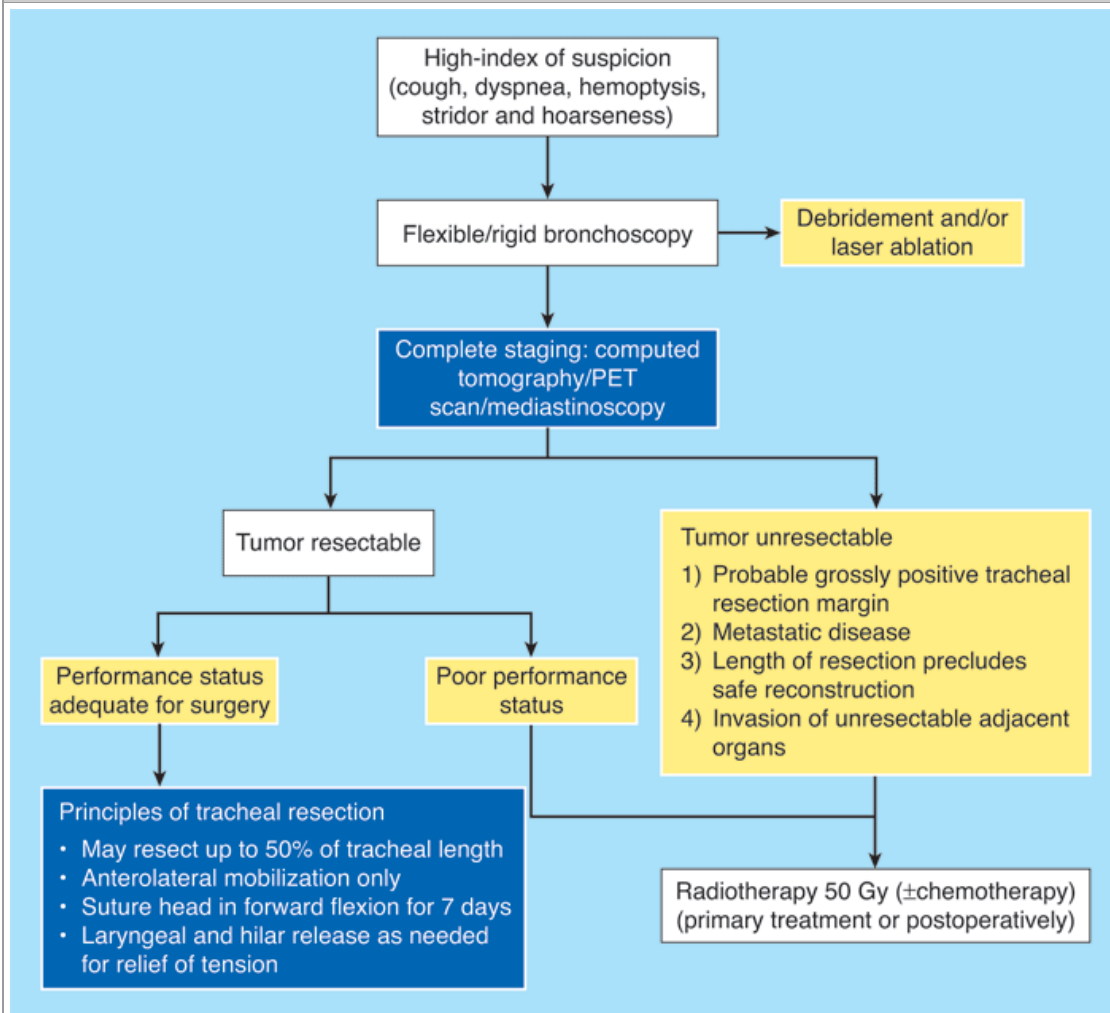

Squamous cell carcinomas often present with regional lymph node metastases and are frequently not resectable at the time of presentation. Their biologic behavior is similar to that of squamous cell carcinomas of the lung. Adenoid cystic carcinomas, which are a type of salivary gland tumor, are generally slow

growing, spread submucosally, and tend to infiltrate along nerve sheaths and within the tracheal wall. Spread to regional lymph nodes can occur. Although indolent in nature, adenoid cystic carcinomas are malignant and can spread to the lungs and bones. Squamous cell carcinomas and adenoid cystic carcinomas represent approximately 65% of all tracheal neoplasms. The remaining 35% is composed of small cell carcinomas, mucoepidermoid carcinomas, adenocarcinomas, lymphomas, and others.⁶

THERAPY

A treatment algorithm for tracheal neoplasms is presented in Fig. 19-6. Evaluation and treatment of patients with tracheal tumors should include neck and chest computed tomography (CT) and rigid bronchoscopy. Rigid bronchoscopy permits general assessment of the airway and tumor; it also allows débridement or laser ablation of the tumor to provide relief of dyspnea. If the tumor is judged to be completely resectable, primary resection and anastomosis is the treatment of choice.⁷

Fig. 19-6.

Algorithm for evaluation and treatment of tracheal neoplasm. PET = positron emission tomography.

The length limit of tracheal resection is roughly 50% of the trachea. To prevent tension on the anastomosis postoperatively, specialized maneuvers are necessary, such as anterolateral tracheal mobilization, suturing of the chin to the sternum with the head flexed forward for 7 days, laryngeal release, and right hilar release. For most tracheal resections (which involve much less than 50% of the airway), anterolateral tracheal mobilization and suturing of the chin to the sternum for 7 days are done routinely. Use of laryngeal and hilar release is determined at the time of surgery, based on the surgeon's judgment of the degree of tension present.

Radiotherapy is frequently given postoperatively after resection of both adenoid cystic carcinomas and squamous cell carcinomas, due to their radiosensitivity.⁸ A dose of 50 Gy or higher is usual. For patients with unresectable tumors, radiation may be given as the primary therapy with the expectation of temporary local control, but it is rarely curative. For recurrent airway compromise, stenting or laser therapies should be considered part of the

treatment algorithm.

LUNG

Anatomy

SEGMENTAL ANATOMY

The segmental anatomy of the lungs and bronchial tree is illustrated in Fig. 19-7.⁹ Note the continuity of the pulmonary parenchyma between adjacent segments of each lobe. In contrast, separation of the bronchial and vascular stalks allows subsegmental and segmental resections, if the clinical situation requires it or if lung tissue can be preserved.

LYMPHATIC DRAINAGE

Many lymphatic vessels are located beneath the visceral pleura of each lung, in the interlobular septa, in the submucosa of the bronchi, and in the perivascular and peribronchial connective tissue. Lymph nodes that drain the lungs are divided into two groups according to the tumor, node, and metastasis (TNM) staging system for lung cancer: the pulmonary lymph nodes, N1; and the mediastinal nodes, N2 (Fig. 19-8).

Fig. 19-8.

The location of regional lymph node stations for lung cancer staging. Station, Description: 1, highest mediastinal lymph nodes; 2, upper paratracheal nodes; 3, prevascular, precarinal and retrotracheal nodes; 4, lower paratracheal nodes; 5, aorto-pulmonary nodes; 6, pre-aortic nodes; 7, subcarinal nodes; 8, paraesophageal nodes; 9, pulmonary ligament nodes; 10, tracheobronchial nodes; 11, interlobular nodes; 12, lobar bronchial nodes; 13, segmental nodes; 14, subsegmental nodes. Note: Stations 12, 13, and 14 are not shown in their entirety.

(Reproduced with permission from Ferguson, MK: *Thoracic Surgery Atlas*. W.B. Saunders, Inc., Philadelphia, PA, 2007. Copyright Elsevier.)

The N1 lymph nodes consist of the following: (a) intrapulmonary or segmental nodes that lie at points of division of segmental bronchi or in the bifurcations of the pulmonary artery; (b) lobar nodes that lie along the upper, middle, and lower lobe bronchi; (c) interlobar nodes that are located in the angles formed by the bifurcation of the main bronchi into the lobar bronchi; and (d) hilar nodes that are located along the main bronchi. The interlobar lymph nodes lie in the depths of the interlobar fissure on each side and constitute a lymphatic sump for each lung, referred to as the *lymphatic sump of Borrie*; all of the pulmonary lobes of the corresponding lung drain into this group of nodes (Fig. 19-9). On the right side, the nodes of the lymphatic sump lie around the bronchus intermedius (bounded above by the right upper lobe bronchus and below by the middle lobe and superior segmental bronchi). On the left side, the lymphatic sump is confined to the interlobar fissure, with the lymph nodes in the angle between the lingular and lower lobe bronchi and in apposition to the pulmonary artery branches.

The lymphatic sump of Borrie includes the groups of lymph nodes that receive lymphatic drainage from all pulmonary lobes of the corresponding lung.

The N2 lymph nodes consist of four main groups: (a) anterior mediastinal, (b) posterior mediastinal, (c) tracheobronchial, and (d) paratracheal. The anterior mediastinal nodes are located in association with the upper surface of the pericardium, the phrenic nerves, the ligamentum arteriosum, and the left innominate vein. Within the inferior pulmonary ligament on each side are the paraesophageal lymph nodes, which are part of the posterior mediastinal group. Additional paraesophageal nodes can be located more superiorly, between the esophagus and trachea near the arch of the azygos vein. The tracheobronchial lymph nodes are made up of three subgroups that are located near the bifurcation of the trachea: the subcarinal nodes, the lymph nodes that lie in the obtuse angle between the trachea and each main stem bronchus, and nodes that lie anterior to the lower end of the trachea. The paratracheal lymph nodes are located in proximity to the trachea in the superior mediastinum. Those on the right side form a chain with the tracheobronchial nodes inferiorly and with some of the deep cervical nodes above (scalene lymph nodes). Lymphatic drainage of the right lung is ipsilateral, except for occasional bilateral drainage to the superior mediastinum. Ipsilateral and contralateral drainage from the left lung, particularly the left lower lobe, to the superior mediastinum occur with the same frequency.

COMPUTED TOMOGRAPHY

Spiral (helical) CT allows continuous scanning as the patient is moved through a scanning gantry so that an x-ray beam can trace a helical curve in relation to the patient's position. The entire thorax can be imaged during a solitary breath hold, so motion artifacts are eliminated, which results in superior image quality (compared with conventional CT scanning), particularly in the detection of pulmonary nodules and central airway abnormalities.¹⁰ The shorter acquisition time of spiral CT allows for consistent contrast filling of the great vessels, which results in markedly improved visualization of pathologic states and anatomic variation contiguous to vascular structures. In addition, three-dimensional spiral CT images can be reconstructed for enhanced visualization of spatial anatomic relationships.¹¹

In general, slice thickness is proportional to image resolution; as slice thickness increases, volume averaging increases, which results in a decline in image resolution. Slice thickness is determined by the structure being imaged as well as by the indication for the study. Thin sections (1- to 2-mm collimation) at 1-cm intervals should be used to evaluate pulmonary parenchyma and peripheral bronchi. If the goal is to find any pulmonary metastases, thin sections at intervals of 5- to 7-mm collimation are recommended. For assessing the trachea and central bronchi, collimation of 3 to 5 mm is recommended. Virtually all institutions have protocols for spiral CT scanning. Providing accurate clinical history and data is of paramount importance to obtaining appropriate imaging. In addition, the astute clinician must be well versed in normal thoracic anatomy to appreciate pathologic changes and management strategies (Fig. 19-10).

Spiral computed tomographic scan showing normal transverse chest anatomy at four levels. **A.** At the level of the tracheal bifurcation, the aortopulmonary window (APW) can be seen. **B.** The origin of the left pulmonary artery (LPA) can be seen at a level 1 cm inferior to **A.** **C.** The origin and course of the right pulmonary artery (RPA) can be seen at this next most cephalad level. The left upper lobe bronchus can be seen at its origin from the left main bronchus (LMB). **D.** Cardiac chambers and pulmonary veins are seen in the lower thorax. AA = ascending aorta; DA = descending aorta; LA = left atrium; LV = left ventricle; MPA = main pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava; T = trachea.

Thoracic Surgical Approaches

Thoracic surgical approaches have changed over recent years with advancements in minimally invasive approaches. A surgeon trained in advanced minimally invasive techniques can now perform sympathectomy, segmental lung resections, lobectomies, and mediastinal resections through multiple thoroscopic ports and small access incisions without the need for a substantial, rib-spreading incision. Although there has not been a documented change in mortality using these approaches, subjective measures of quality of life after video-assisted thoracic surgery (VATS), such as pain level (Fig. 19-11) and perceived functional recovery, consistently and reproducibly favor VATS over thoracotomy. Objective measures such as functional status as measured by 6-minute walk, return to work, and ability to tolerate chemotherapy also favor VATS over thoracotomy. Finally, recovery of respiratory function occurs earlier in patients undergoing VATS. These findings are pronounced in patients with chronic obstructive pulmonary disease (COPD) and in the elderly, populations whose quality of life can be dramatically impacted by changes in their respiratory symptoms and function, thoracic pain, and physical performance.¹² Table 19-1 provides a summary of populations that may benefit from VATS approaches.

Table 19-1 Special Circumstances under Which Lobectomy by Video-Assisted Thoracic Surgery May Be Preferable

Condition	Examples
Pulmonary compromise	Poor FEV ₁ /DLCO, heavy smoking, sleep apnea, recent pneumonia
Cardiac dysfunction	Congestive heart failure, severe coronary artery disease, recent myocardial infarction, valvular disease
Extrathoracic malignancy	Solitary brain metastasis from lung cancer, deep pulmonary metastases requiring lobectomy
Poor physical performance	Performance status equivalent to a Zubrod score of 2 or 3, morbid obesity
Rheumatologic/orthopedic condition	Spinal disease, severe rheumatoid arthritis, severe kyphosis, lupus erythematosus, osteomyelitis
Advanced age	Age >70 y
Vascular problems	Aneurysm, severe peripheral vascular disease
Recent or impending major operation	Urgent abdominal operation, joint replacement requiring use of crutches, need for contralateral thoracotomy
Psychologic/neurologic conditions	Substance abuse, poor command following, pain syndromes
Immunosuppression/impaired wound healing	Recent transplantation, diabetes

DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 s.

Mediastinoscopy is generally used for diagnostic assessment of mediastinal lymphadenopathy and staging of lung cancer. Mediastinoscopy is performed via a transverse 2- to 3-cm incision approximately 1 cm above the suprasternal notch. The incision is carried through the platysma. The midline of the strap muscles is identified and dissected laterally. Care is taken to avoid any venous structures that may overlie these muscles, which are highly variable in size and position. The pretracheal fascia is incised. Blunt dissection along the anterior trachea is performed to the level of the carina with careful note of the position of the innominate artery. The innominate artery can be located close to the suprasternal notch, particularly in women; therefore, blind use of electrocautery is to be avoided. The mediastinoscope is inserted, and anatomic definition of the trachea, carina, and lateral aspect of both proximal bronchi is achieved with blunt dissection using a long suction catheter. Long biopsy forceps can be inserted through the scope for sampling. The standard staging procedure for lung cancer includes biopsies of the paratracheal (stations 4R and 4L) and subcarinal lymph nodes (station 7).

Before the widespread use of VATS and CT-guided biopsy, a modified Chamberlain procedure was used for evaluation of aortopulmonary window lymph nodes. In this procedure a 4- to 5-cm incision is made over the left second costal cartilage, which, on occasion, is excised. The internal mammary vessels may be ligated or preserved. The dissection proceeds into the mediastinum along the aortic arch. Biopsy of the aortopulmonary window lymph nodes and anterior mediastinal lymphomas just beneath the second and third costal cartilage can then be performed. Improved techniques in CT-guided biopsy, positron emission tomography (PET), and VATS have significantly reduced the need for this operative approach.

The most frequently used incision for an open procedure in thoracic surgery is the posterolateral thoracotomy. The posterolateral thoracotomy incision can be

used for most pulmonary resections, for esophageal operations, and for the approach to the posterior mediastinum and vertebral column (Fig. 19-12). The patient is placed in the lateral decubitus position. A pitfall of thoracic incisions in a lateral decubitus position is the potential for injury to the brachial plexus and axillary vascular structures secondary to displacement of the shoulder. Therefore careful attention must be paid to positioning the patient on the operating table after anesthesia has been induced. The skin incision typically starts at the anterior axillary line just below the nipple level and extends posteriorly below the tip of the scapula. The incision then proceeds in a cranial direction halfway between the vertebral border of the scapula and the spinous processes of the vertebrae. The latissimus dorsi is divided and the serratus anterior is retracted. Before entering the pleural space, the surgeon confirms that the anesthesiologist has excluded ventilation to the operative lung by clamping the proper lumen of a double-lumen endotracheal tube. The pleural space is then entered at the fifth interspace by dividing the intercostal muscles with electrocautery above the sixth rib. A rib spreader is placed into the thoracic cavity and minimally opened. The division of the intercostal muscles anteriorly (to the level of the internal mammary artery) and posteriorly (to the level of the paraspinous tendons) is continued using electrocautery from the inside of the thoracic cavity as an internal thoracotomy. The internal thoracotomy will prevent rib fracture during subsequent spreading of the retractor. If necessary, a portion of rib can be removed posteriorly to improve visibility and prevent injury to a rib, which can lead to increased postoperative pain and prolong restricted motion of the rib cage. Should a rib fracture occur, resection of any broken edges is recommended to help reduce postoperative pain.

The posterolateral thoracotomy incision. **A**. Skin incision from the anterior axillary line to the lower extent of the scapula tip. **B** and **C**. Division of the latissimus dorsi and shoulder girdle musculature. **D**. The pleural cavity is entered after dividing the intercostal muscles along the lower margin of the interspace, with care taken not to injure the neurovascular bundle lying below each rib.

The anterolateral thoracotomy has traditionally been used in trauma victims. This approach allows quick entry into the chest with the patient supine. When hemodynamic instability is present, the lateral decubitus position significantly compromises control over the patient's cardiopulmonary system and

resuscitation efforts, whereas the supine position allows the anesthesiologist full access to the patient. The incision is submammary, beginning at the sternal border overlying the fourth intercostal space and extending to the midaxillary line. The pectoralis major muscle and some of the pectoralis minor are divided, and the incision is carried through the serratus anterior muscle. The intercostal muscles are divided with cautery over the top of the subjacent rib. Should more exposure be necessary, the sternum can be transected and the incision carried to the contralateral thoracic cavity ("clamshell" thoracotomy). A bilateral anterior thoracotomy incision with a transverse sternotomy (clamshell thoracotomy) is a standard operative approach to the heart and mediastinum in certain elective circumstances. It is the preferred incision for double-lung transplantation. A partial median sternotomy also can be added to an anterior thoracotomy ("trap door" or "hemiclam" thoracotomy) for access to mediastinal structures. A hypesthetic nipple is a frequent complication of this approach.

The median sternotomy incision allows exposure of anterior mediastinal structures and is principally used for cardiac operations. The surgeon has access to both pleural cavities and can avoid incision into the pleural cavity if it is unnecessary. The skin incision extends from the suprasternal notch to the xiphoid process (Fig. 19-13). A sternal saw is used to split the sternum. Advantages of this approach include decreased postoperative pain and less compromise of pulmonary function than with a lateral thoracotomy. Disadvantages of the incision include an increased risk of infection if a tracheostomy is needed concomitantly or before the sternotomy is completely healed.

Video-Assisted Thoracoscopic Surgery

VATS has become an accepted approach for diagnosis and treatment of pleural effusions and recurrent pneumothorax, and for lung biopsy, lobectomy or segmental resection, resection of bronchogenic and mediastinal cysts, esophageal myotomy, and intrathoracic esophageal mobilization for esophagectomy.¹³ VATS is performed via two to four incisions measuring 0.5 to 1.2 cm in length to allow insertion of the thoracoscope and instruments. The incision location varies according to the procedure. For VATS lobectomy, port placement varies according to the lobe being resected and is highly variable among surgeons.¹⁴ The basic principle is to position the ports high enough on the thoracic cage to have access to the hilar structures (Fig. 19-14). Endoscopic staplers are used to divide the major vascular structures and bronchus.

Fig. 19-14.

Selected video-assisted thoracic surgery lobectomy maneuvers. All the maneuvers are shown with the patient positioned in the left lateral decubitus position. The same maneuvers can be performed in mirror image for left-sided work. **A.** Medial viewing and inferior holding of lung to allow dissection through the access incision. Example shows division of the apical hilum. **B.** Medial viewing and access holding of lung to allow stapling of hilar structures from below. Example shows division of the apical pulmonary artery trunk to the right upper lobe (upper lobe branch of vein divided and reflected away). **C.** Standard viewing and use of working port to dissect and divide structures while lung is retracted through access incision. Example shows use of stapler to divide pulmonary artery to right lower lobe. **D.** Standard viewing and use of working port to retract lung and access incision to dissect structures. This method is commonly used to dissect the pulmonary artery in the major fissure. Example shows inferior pulmonary vein after the pulmonary ligament was divided using this maneuver. **E.** Standard viewing and use of access incision to deliver stapler to divide fissures. Example shows division of the posterior fissure between the right lower lobe and the upper lobe.

At the conclusion of a thoracic operation, the pleural cavity typically is drained with one or more chest tubes. Each chest tube is brought out through a separate stab incision in the chest wall below the level of the thoracotomy or through a VATS port site. If the visceral pleura has not been violated and there is no concern of pneumothorax or hemothorax (i.e., after VATS sympathectomies), a chest tube is unnecessary. The lung is then ventilated and placed under positive pressure ventilation to assist with re-expansion of atelectatic segments. Thoracic incisions should be closed in layers: the intercostal space with three to four interrupted sutures, two running sutures for musculofascial layers, and a running subcuticular suture or staples for the skin closure.

Postoperative Care

CHEST TUBE MANAGEMENT

Chest tubes are routinely placed into the pleural space at the conclusion of all operations involving resection or manipulation of lung tissue. The reason for pleural tube placement is twofold: first, the tube allows evacuation of air if an air leak is present. Second, blood and pleural fluid can be drained, which prevents accumulations within the pleural space that would compromise the patient's respiratory status. The tube is removed when the air leak is resolved and when the volume of drainage decreases below an acceptable level over 24 hours. The ideal volume of drainage over a 24-hour period that predicts safe chest tube removal is unknown. The ability of the pleural lymphatics to absorb fluid is substantial. It can be as high as 0.40 mL/kg per hour in a healthy individual, possibly resulting in the absorption of up to 500 mL of fluid over a 24-hour period. The capacity of the pleural space to manage and absorb fluid is high if the pleural lining and lymphatics are healthy.

In the past, many surgeons required a drainage volume of <150 mL over 24 hours before removing a chest tube. Recently, however, it has been shown that pleural tubes can be removed after VATS lobectomy or thoracotomy with 24-hour drainage volumes as high as 400 mL without subsequent development of pleural effusions.¹⁵ Currently, it is the practice of these authors to remove chest tubes when 24-hour output is ≤400 mL after lobectomy or lesser pulmonary resections.

If the pleural space is altered (e.g., malignant pleural effusion, pleural space infections or inflammation, or pleurodesis), strict adherence to a volume requirement before tube removal is appropriate (typically 100 to 150 mL over 24 hours). Such circumstances alter normal pleural fluid dynamics.

The use of suction and the management of air leaks vary. Suction levels of –20 cm H₂O have been routinely used after pulmonary surgery in an effort to eradicate residual air spaces and to control postoperative parenchymal air leaks. However, it has been shown that the routine use of a water seal (with the patient off suction) actually promotes more rapid healing of parenchymal air leaks.¹⁶ The main factors guiding the use of a water seal are the degree of air leakage and the degree of expansion of the remaining lung. If the leak is significant enough to induce atelectasis or collapse of the lung during use of a water seal (off suction), suction should be used to achieve lung re-expansion.

A systematic approach to the evaluation of an air leak and/or incompletely drained pneumothorax with associated pulmonary collapse is important. The chest tube and its attached tubing should be examined to ensure that the chest tube is patent and that the attached tubing is not kinked or mechanically obstructed, such as occurs when the patient is lying on the tube. Once the surgeon has confirmed that the chest tube is patent, the patient is asked to voluntarily cough or perform Valsalva's maneuver. This maneuver increases the intrathoracic pressure and will push air contained in the hemithorax out of the chest tube. During the cough, the water seal chamber is observed. If bubbles pass through the water seal chamber, an air leak is presumed. Occasionally, if the chest tube is not secured snugly at the skin surface, air can enter into the hemithorax around the tube with respiration; thus an air leak will be present, although not emanating from the lung itself. During the voluntary cough, the fluid level in the water seal chamber should move up and down with the cough and with deep respiration, reflecting the pleural pressure changes occurring with these maneuvers. A stationary fluid level implies a mechanical blockage, either due to external tube compression or to a clot or debris within the tube.

PAIN CONTROL

Good pain control after posterolateral thoracotomy is critical. It permits the patient to actively participate in breathing maneuvers designed to clear and manage secretions, and promotes ambulation and a feeling of well-being. The most common routes for pain medication are epidural, paravertebral, and IV. To maximize efficacy, epidural catheters should be inserted at about the T6 level, roughly at the level of the scapular tip. Lower placement risks inadequate pain control, and higher placement may provoke hand and arm numbness. Typically, a combination of fentanyl at 0.3 µg/mL and either bupivacaine (0.125%) or ropivacaine (0.1%) is used. Ropivacaine has less cardiotoxicity than bupivacaine; thus, in the event of inadvertent IV injection, the potential for refractory complete heart block as is seen with bupivacaine is significantly less. Paravertebral anesthesia can be initiated using the same epidural catheter kit with placement 2.5 cm lateral to the spinous process at T4 to T6. Combinations of narcotics and topical analgesics are then infused as with epidural catheters.

When the catheter is properly placed, well-managed epidural anesthesia can provide outstanding pain control without significant systemic sedation.¹⁷ Urinary retention is a frequent side effect, particularly in males, who require an indwelling urinary catheter. In addition, the use of local anesthetics may cause sympathetic outflow blockade, leading to vasodilation and hypotension that often require IV administration of vasoconstrictors (an alpha agonist such as phenylephrine) and/or fluid administration. In such circumstances, fluid administration for hypotension may be undesirable in pulmonary surgery patients, particularly after pneumonectomy. Paravertebral anesthesia provides equivalent pain control with less effect on hemodynamics.¹⁸

Alternatively, IV narcotics delivered via a patient-controlled analgesia device can be used, often in conjunction with ketorolac. Titration of basal and intermittent dosing often is necessary to balance the degree of pain relief with the degree of sedation. Oversedation and narcotization of patients is as undesirable as failure to provide adequate pain control, because of the significant risk of secretion retention and development of atelectasis or pneumonia. Proper pain control with IV narcotics is a balance of pain relief and sedation.

Whether receiving pain control medication via the epidural, paravertebral, or IV route, the patient typically is transitioned to oral pain medication on the third or fourth postoperative day. During both the parenteral and oral phase of pain management, use of a standardized regimen of stool softeners and laxatives is advisable to prevent severe constipation.

RESPIRATORY CARE

Good respiratory care is the result of a commitment by the surgeon and by all other health care professionals involved. The team should be educated about the techniques of good respiratory care. The best respiratory care is achieved when the patient is able to deliver an effective cough to clear secretions. The process ideally begins preoperatively, with clear instructions on using pillows (or other support devices) over the wound and then applying pressure. Postoperatively, proper pain control without oversedation (as outlined earlier) is essential. Multiple studies have shown that a variety of adjunct respiratory care techniques (e.g., intermittent positive pressure breathing and incentive spirometry) may not be of benefit. These findings are consistent with the impression of these authors that routine respiratory care is best accomplished by a dedicated team and educated patients.

In patients whose pulmonary function is significantly impaired preoperatively, generating an effective cough postoperatively may be nearly impossible. In this setting, routine nasotracheal suctioning can be used but is uncomfortable for the patient. A better alternative is placement of a percutaneous transtracheal suction catheter at the time of surgery. This catheter is comfortable for the patient and allows regular and convenient suctioning.

POSTOPERATIVE COMPLICATIONS

Postpneumonectomy pulmonary edema occurs in 1 to 5% of patients undergoing pneumonectomy, with a higher incidence after right pneumonectomy. Clinically, symptoms of respiratory distress manifest hours to days after surgery. Radiographically, diffuse interstitial infiltration or frank alveolar edema is seen. The pathophysiologic causes remain poorly understood but are related to factors that increase permeability and filtration pressure and decrease lymphatic drainage from the affected lung. The syndrome reportedly is associated with a nearly 100% mortality rate even with aggressive therapy. Treatment consists of ventilatory support, fluid restriction, and diuretics.

Other postoperative complications include air leak and bronchopleural fistula. Although these are two very different problems, distinguishing between them may be difficult. Postoperative air leaks are common after pulmonary resection, particularly in patients with emphysematous changes, because the fibrotic changes and destroyed blood supply impair healing of surface injuries. Prolonged air leaks—that is, those lasting over 5 days—may be treated by diminishing or discontinuing suction (if used), by continuing chest drainage, or by instilling a pleurodesic agent, usually talcum powder.

If the leak is moderate to large, a high index of suspicion should be maintained for bronchopleural fistula from the resected bronchial stump, particularly if the patient is immunocompromised or received induction chemotherapy and/or radiation therapy. If a bronchopleural fistula is suspected, flexible bronchoscopy is performed. Management options include continued prolonged chest tube drainage, reoperation and reclosure (with stump reinforcement with intercostals or a serratus muscle pedicle flap), or, for fistulas <4 mm, bronchoscopic fibrin glue application. Patients often have concomitant empyemas, and open drainage may be necessary.

Solitary Pulmonary Nodule

A solitary pulmonary nodule is typically described as a single, well-circumscribed, spherical lesion. It is ≤ 3 cm in diameter and is completely surrounded by normal aerated lung parenchyma.¹⁹ There are no associated changes of atelectasis, hilar enlargement, or pleural effusion. The American College of Chest Physicians discourages use of the term *coin lesion* because these lesions are spherical. The majority are detected incidentally on chest radiographs or CT scans obtained for some other purpose. Originally defined by findings on chest radiographs, solitary pulmonary nodules were identified on 0.09 to 0.2% of all chest radiographs in large screening studies as early as 1950.^{20,21} With the advent of low-dose screening CT, however, many of these lesions are ultimately found to be associated with multiple (one to six) other, usually subcentimeter, nodules. In the Early Lung Cancer Action project, 23% (233/1000) of healthy volunteers were found to have between 1 to 6 nodules on screening CT. Notably, 12% (27/233) had nodule-associated malignant disease.²² Approximately 150,000 solitary nodules are found incidentally each year. The clinical significance of such a lesion depends on whether or not it represents a malignancy.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a solitary pulmonary nodule can be distilled down to a differentiation between malignancy and other numerous benign conditions. Ideally, diagnostic approaches would provide a clear distinction between the two, so that definitive surgical resection could be reserved for the malignant nodule and resection avoided when the nodule is benign. In unselected patient populations, a new solitary pulmonary nodule observed on a chest radiograph has a 20 to 40% likelihood of being malignant, with the risk approximately 50% or higher in smokers. Factors influencing the probability of cancer in a solitary pulmonary nodule include evidence for growth over time, density of the lesion on CT scan (with 40 to 50% of partial solid nodules cancerous compared with

only 15% of solid nodules <1 cm and nonsolid nodules), associated symptoms, patient age, sex, cigarette smoking history, occupational history, and the prevalence of endemic granulomatous disease.

Infectious granulomas arising in response to a variety of organisms comprise 70 to 80% of this type of benign solitary nodule; hamartomas are the next most common single cause, accounting for approximately 10%. The differential diagnosis of a solitary pulmonary nodule should include a broad variety of congenital, neoplastic, inflammatory, vascular, and traumatic disorders.

IMAGING

Chest thin section CT scanning is critical in characterizing nodule location, size, margin morphology, calcification pattern, and growth rate.²³ Because of the increased sensitivity of CT (compared with radiography) for detection of small nodules, CT often reveals more than a single pulmonary nodule; up to 50% of patients thought to have a single lesion based on chest radiograph are proven to harbor multiple nodules when examined by CT. Beyond a certain number, multiple nodules more likely represent metastases or granulomatous disease, which alters work-up. Lesions >3 cm are regarded as masses and are more likely malignant. Irregular, lobulated, or spiculated edges strongly suggest malignancy. The corona radiata sign (consisting of fine linear strands extending 4 to 5 mm outward and appearing spiculated on radiographs) is highly cancer specific (Fig. 19-15).

Computed tomographic scan images of solitary pulmonary nodules. **A.** The corona radiata sign demonstrated by a solitary nodule. Multiple fine striations extend perpendicularly from the surface of the nodule like the spokes of a wheel. **B.** A biopsy-proven adenocarcinoma demonstrating spiculation. **C.** A lesion with a scalloped border, an indeterminate finding suggesting an intermediate probability of malignancy.

Calcification within a nodule suggests a benign lesion. Four patterns of benign calcification are common: diffuse, solid, central, and laminated or "popcorn." Granulomatous infections such as tuberculosis can demonstrate the first three patterns, whereas the popcorn pattern is most common in hamartomas.

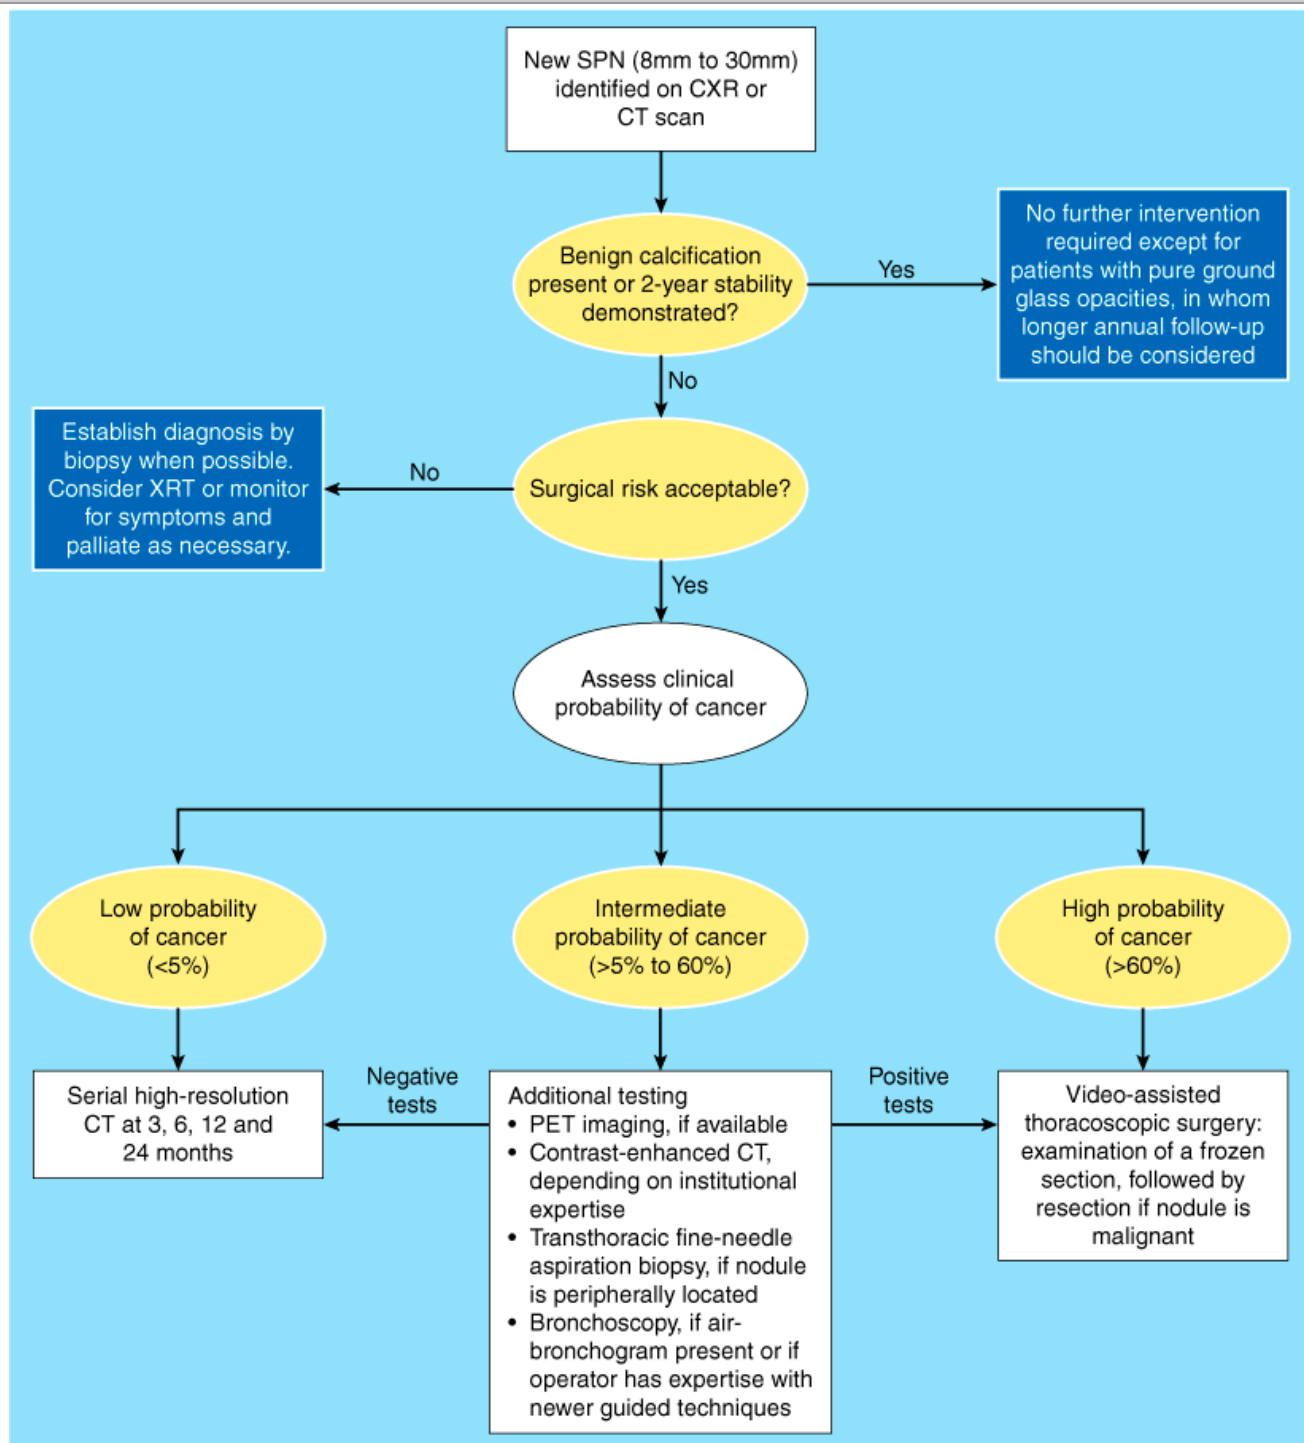

Calcification that is stippled, amorphous, or eccentric usually is associated with cancer. Characteristically neoplasms grow, and several studies have confirmed that lung cancers have volume-doubling times of 20 to 400 days.²⁴ Lesions with shorter doubling times are likely due to infection, and longer doubling times suggest benign tumors but can indicate slower-growing lung cancer. Traditionally, size stability over 2 years on chest radiographs has been considered a sign of a benign tumor. However, this long-held notion has been challenged by recent investigations, which demonstrated only a 65% positive predictive value for chest radiographs.²⁵ Thus size stability of a pulmonary mass on chest films is a relatively unreliable indicator of a benign lesion that must be interpreted with caution.

PET scanning takes advantage of another biologic property of neoplasms: increased glucose uptake commensurate with increased metabolic activity.¹⁸ F-fluorodeoxyglucose (FDG) is used to measure glucose metabolism in cells imaged by PET. Most lung tumors have increased signatures of glucose uptake, compared with healthy tissues. PET is becoming widely used to help differentiate benign from malignant nodules.²⁶ One meta-analysis estimated its sensitivity for identifying neoplasms as 97% and its specificity as 78%.²⁷ False-negative results can occur (especially in patients who have bronchoalveolar carcinomas (BACs), carcinoids, and tumors <1 cm in diameter), as can false-positive results (because of confusion with other infectious or inflammatory processes).

BIOPSY VS. RESECTION

The surgeon must have an evidence-based algorithm for approaching the diagnosis and treatment of a pulmonary nodule. Guidelines have been developed based on a systematic literature review and consensus of clinical experts in the field¹⁹ (Fig. 19-16). Only through biopsy can a pulmonary nodule be definitively diagnosed. Bronchoscopy has a 20 to 80% sensitivity for detecting a neoplastic process within a solitary pulmonary nodule, depending on the nodule size, its proximity to the bronchial tree, and the prevalence of cancer in the population being sampled. Transthoracic fine-needle aspiration (FNA) biopsy can accurately identify the status of peripheral pulmonary lesions in up to 95% of patients; the false-negative rate ranges from 3 to 29%.²⁸ Complications may occur at a relatively high rate (e.g., a 30% rate of pneumothorax). VATS often is used for excising and diagnosing indeterminate pulmonary nodules. Lesions most suitable for VATS are those that are located in the outer one third of the lung and those that are <3 cm in diameter. Certain principles must be followed when excising potentially malignant lesions via VATS. The nodule must not be directly manipulated with instruments, the visceral pleura overlying the nodule must not be violated, and the excised nodule must be extracted from the chest within a bag to prevent seeding of the chest wall. Some groups advocate proceeding directly to VATS in the work-up of a solitary pulmonary nodule in appropriate clinical circumstances, citing superior diagnostic accuracy and low surgical risks.²⁹

Lung Neoplasms

Lung cancer is the leading cancer killer in the United States. Every year, it accounts for 30% of all cancer deaths—more than cancers of the breast, prostate, and ovary combined. It is the second most frequently diagnosed cancer in the United States, behind prostate cancer in men and breast cancer in women (Fig. 19-17). In the annual report to the nation on the status of cancer in 2007, it was noted that the incidence of lung cancer in men has begun to decrease, while incidence has remained stable in women. Annual death rates for men also have declined. Annual death rates for women continue to increase, although at a

significantly slower pace than noted in previous reports.³⁰ Most patients are diagnosed at an advanced stage of disease, so therapy is rarely curative. The overall 5-year survival for all patients with lung cancer is 15%, which makes lung cancer the most lethal of the leading four cancers (Fig. 19-18).

Survival of patients with lung cancer varies according to several demographic and social factors. Positive survival factors are female sex (5-year survival of 18.3% for women vs. 13.8% for men), younger age (5-year survival of 22.8% for those <45 years vs. 13.7% for those >65 years), and white race (5-year survival of 16.1% for whites vs. 12.2% for African Americans). When access to advanced medical care is unrestricted, as for the military population, the racial difference in survival disappears, which suggests that these differences in survival may be explained, at least in part, by less access to advanced medical care and later diagnosis for African Americans.³¹

EPIDEMIOLOGY

Cigarette smoking is the primary cause of lung cancer, with smoking-related cancers accounting for approximately 75% of all lung cancers worldwide in 2007. Two lung cancer types, squamous cell carcinoma and small cell carcinoma, are extraordinarily rare in the absence of cigarette smoking. The risk of developing lung cancer escalates with the number of cigarettes smoked and the number of years of smoking, and is higher when unfiltered cigarettes are used. Conversely, the risk of lung cancer declines with smoking cessation (Table 19-2).³² Even after smoking cessation, however, the risk never drops to that of people who never smoked, regardless of the length of abstinence. Approximately 25% of all lung cancers worldwide and 53% of cancers in women are not related to smoking, and the majority of these (62%) are adenocarcinomas. Table 19-3 summarizes the existing data regarding the etiology of lung cancer in nonsmokers.³³

Table 19-2 Relative Risk of Lung Cancer in Smokers

Smoking Category	Relative Risk
Never smoked	1.0
Currently smoke	15.8–16.3
Formerly smoked	
Years of abstinence	

1–9	5.9–19.5
10–19	2.0–6.1
>20	1.9–3.7

Secondhand (or passive) smoke exposure has been shown to confer an excess risk of developing lung cancer of 24% when a nonsmoker lives with a smoker.³⁴ Pre-existing lung disease confers an increased risk of lung cancer—up to 13%—for individuals who have never smoked. This increase is thought to be related to poor clearance of inhaled carcinogens and/or to the effects of chronic inflammation.

Other causes of lung cancer include exposure to a number of industrial compounds, including asbestos, arsenic, and chromium compounds. Of particular note is the ominous combination of asbestos exposure and cigarette smoking, which together have a multiplicative effect on risk, as opposed to an additive effect. Patients with COPD are at higher risk for lung cancer than would be predicted based on smoking risk alone. A previous history of tuberculosis with secondary

scar formation also leads to a higher risk of primary lung carcinoma.

Over 3000 chemicals have been identified in tobacco smoke, but the main chemical carcinogens are polycyclic aromatic hydrocarbons. Once inhaled and absorbed, these compounds become mutagenic through their activation by specific enzymes, binding to macromolecules such as DNA and then inducing mutations.

In treating any patient with a history of smoking, it is important to remember that field cancerization of the entire aerodigestive tract has likely occurred. The patient's risk is increased for cancers of the oral cavity, pharynx, larynx, tracheobronchial tree and lung, and esophagus. In examining such patients, a detailed history must be taken and physical examination of these organ systems performed.

NORMAL LUNG HISTOLOGY

The lung can be conveniently viewed as two linked components: the tracheobronchial tree (or conducting airways component) and the alveolar spaces (or gas exchange component). The tracheobronchial tree consists of approximately 23 airway divisions to the level of the alveoli. It includes the main bronchi, lobar bronchi, segmental bronchi (to designated bronchopulmonary segments), and terminal bronchioles (i.e., the smallest airway vessels, which lack alveoli and are lined by bronchial epithelium). The tracheobronchial tree is normally lined by pseudostratified ciliated columnar cells and mucous (or goblet) cells, both of which derive from basal cells (Fig. 19-19). Ciliated cells predominate. Goblet cells, which release mucus, can significantly increase in number in acute bronchial injury, such as exposure to cigarette smoke. The normal bronchial epithelium also contains bronchial submucosal glands, which are mixed salivary-type glands containing mucous cells, serous cells, and Kulchitsky cells. Kulchitsky cells are neuroendocrine cells; they also are found within the surface epithelium (see Fig. 19-19). The bronchial submucosal glands can give rise to salivary gland-type tumors (previously referred to as *bronchial gland tumors*), including mucoepidermoid carcinomas and adenoid cystic carcinomas.

Normal lung histology. **A.** Pseudostratified ciliated columnar cells and mucous cells normally line the tracheobronchial tree. **B.** A Kulchitsky cell is depicted

(arrow).

The alveolar spaces or alveoli have two primary cell types, referred to as *type I and II pneumocytes*. Type I pneumocytes cover 95% of the surface area of the alveolar wall but constitute only 40% of the total number of alveolar epithelial cells. These cells are not capable of regeneration because they have no mitotic potential. Type II pneumocytes cover only 3% of the alveolar surface but constitute 60% of the alveolar epithelial cells. In addition, clusters of neuroendocrine cells are seen in the alveolar spaces.

PREINVASIVE LESIONS

As with epithelial tumors in other organs, precancerous changes can be seen in the respiratory tract. Three precancerous lesions are currently recognized: squamous dysplasia and carcinoma in situ, atypical adenomatous hyperplasia, and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. The term *precancerous* does not mean that an inevitable progression to invasive carcinoma will occur, but such lesions, particularly those with high-grade dysplasia,^{35,36} do constitute a clear marker of the potential for later development of invasive cancer.

Squamous Dysplasia and Carcinoma In Situ

Cigarette smoke can induce a metaplastic change of the tracheobronchial pseudostratified epithelium to squamous mucosa, which is a normal response to injury. With the development of cellular abnormalities in the metaplastic squamous mucosa, squamous dysplasia evolves. It involves increased cell size, an increased number of cell layers, an increased nucleus:cytoplasm ratio, increased mitoses, and changes in cellular polarity. Gradations are considered mild, moderate, or severe. Carcinoma in situ represents carcinoma still confined by the basement membrane. Once the in situ tumor invades beyond the basement membrane, invasive squamous cell carcinoma is present.

Atypical Adenomatous Hyperplasia

Atypical adenomatous hyperplasia is defined as a lesion <5.0 mm consisting of epithelial cells lining the alveoli that are similar to type II pneumocytes. Histologically, atypical adenomatous hyperplasia is similar to BAC. It represents the beginning stage of a stepwise evolution to BAC and then to adenocarcinoma.

Diffuse Idiopathic Pulmonary Neuroendocrine Cell Hyperplasia

Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia is a rare lesion representing a diffuse proliferation of neuroendocrine cells but without invasion of the basement membrane. It can exist as a diffuse increase in the number of single neuroendocrine cells or as small lesions <5.0 mm in diameter. Lesions that are >5.0 mm in size or that breach the basement membrane are carcinoid tumors.

INVASIVE OR MALIGNANT LESIONS

The term *bronchial carcinoma* is synonymous with lung cancer in general. Both terms refer to any epithelial carcinoma occurring in the bronchopulmonary tree. Currently, the pathologic diagnosis of lung cancer is based on light microscopic criteria, and cancers are broadly divided into two main groups: non–small cell lung carcinomas and neuroendocrine tumors (typical carcinoid, atypical carcinoid, large cell neuroendocrine carcinoma, and small cell carcinoma).³⁷ Immunohistochemical staining and electron microscopy are used as adjuncts in diagnosis, particularly in the assessment of potential neuroendocrine tumors.

Non–Small Cell Lung Carcinoma

The term *non–small cell lung carcinoma (NSCLC)* encompasses many tumor cell types, including large cell carcinoma, squamous cell carcinoma, adenocarcinoma, and BAC, and is used to distinguish these tumors from small cell carcinoma. Although they differ in appearance histologically, their clinical behavior and treatment options are similar. Because of this, they are usually thought of as a uniform group. Each type, however, has unique features that affect its clinical presentation and findings.

Squamous Cell Carcinoma

Squamous cell carcinomas account for 30 to 40% of lung cancers. Squamous cell carcinoma is the cancer most frequently found in men and is highly correlated with cigarette smoking. Histologically, cells develop a pattern of clusters with intracellular bridges and keratin pearls. Importantly, squamous cell carcinoma is primarily located centrally and arises in the major bronchi, often causing the typical symptoms of centrally located tumors, such as hemoptysis, bronchial obstruction with atelectasis, dyspnea, and pneumonia. Occasionally a more peripherally based squamous cell carcinoma will develop in a tuberculosis scar or in the wall of a bronchiectatic cavity. Central necrosis is frequent and may lead to the radiographic findings of a cavity (possibly with an air-fluid level). Such cavities may become infected, with resultant abscess formation.

Adenocarcinoma

The incidence of adenocarcinoma has increased over the last several decades, and adenocarcinomas now account for 25 to 40% of all lung cancers. Adenocarcinoma is the most frequent histologic type found in women and occurs more frequently in females than in males.³⁸ Unlike squamous cell carcinoma, adenocarcinoma is most often a peripherally based tumor; thus it frequently is discovered incidentally on routine chest radiographs. Symptoms of chest wall

invasion or malignant pleural effusions dominate. Histologically, adenocarcinoma is composed of glands with or without mucin production, combined with destruction of contiguous lung architecture.

Bronchoalveolar Carcinoma

BAC is a relatively unusual (5% of all lung cancers) subtype of adenocarcinoma. BAC has a unique growth pattern and differs from adenocarcinoma in that, rather than invading and destroying contiguous lung parenchyma, tumor cells multiply and fill the alveolar spaces. For a tumor to be classified as a pure BAC, there can be no evidence of destruction of surrounding lung parenchyma. When sites of classic BAC are demonstrated within glandular destruction of contiguous lung architecture, the tumor is classified as adenocarcinoma with BAC features.

Because of their growth within alveoli, BAC tumor cells from one site can aerogenously seed other parts of the same lobe or lung, or the contralateral lung. This growth pattern and tendency to seed can produce three radiographic presentations: a single nodule, multiple nodules (in single or multiple lobes), or a diffuse form with an appearance mimicking that of a lobar pneumonia. Because tumor cells fill the alveolar spaces and envelop small airways rather than destroying them, air bronchograms can be seen, unlike with other carcinomas.

Large Cell Carcinoma

Large cell carcinomas account for 10 to 20% of lung cancers and may be located centrally or peripherally. As implied by the name, the cells are large, with diameters of 30 to 50 μm . They are often admixed with other cell types such as squamous cells or adenocarcinoma. Large cell carcinoma can be confused with a large cell variant of neuroendocrine carcinoma, with immunohistochemical staining usually allowing diagnostic distinction between the two.

Neuroendocrine Neoplasms

Neuroendocrine tumors of the lung have been plagued by a confusing array of differing classifications. Over the last decade, progress in immunohistochemical and electron microscopic techniques have significantly improved the understanding and classification of these tumors.³⁹ In particular, immunohistochemical staining for neuroendocrine markers (including chromogranins, synaptophysin, CD57, and neuron-specific enolase) is essential to accurate diagnosis of most tumors.

Recently, neuroendocrine lung tumors have been reclassified into neuroendocrine hyperplasia and three separate grades of neuroendocrine carcinoma (NEC).³⁹ Listed below is the grading system now applied to NEC (left column), with the previously used common name (right column):

Grade I NEC	Classic or typical carcinoid
Grade II NEC	Atypical carcinoid
Grade III NEC	Large cell type
	Small cell type

Grade I NEC (classic or typical carcinoid) is a low-grade NEC. An epithelial tumor, it arises primarily in the central airways, although 20% of the time it occurs peripherally. It occurs primarily in younger patients. Because of the central location, it classically presents with hemoptysis, with or without airway obstruction and pneumonia. Histologically, tumor cells are arranged in cords and clusters with a rich vascular stroma. This vascularity can lead to life-threatening hemorrhage with even simple bronchoscopic biopsy maneuvers. Regional lymph node metastases are seen in 15% of patients but rarely spread systemically or cause death.

Grade II NEC (atypical carcinoid) comprises a group of tumors with a degree of aggressive clinical behavior. Unlike Grade I NEC, these tumors are etiologically linked to cigarette smoking and are more likely to be peripherally located. Histologic findings may include areas of necrosis, nuclear pleomorphism, and higher mitotic rates. These tumors have a much higher malignant potential. Lymph node metastases are found in 30 to 50% of patients. At the time of their diagnosis, 25% of patients already have remote metastases.

Grade III NEC large cell–type tumors occur primarily in heavy smokers. These tumors tend to be found in the middle to peripheral lung fields. They are often large with central necrosis and a high mitotic rate. Their neuroendocrine nature is revealed by positive immunohistochemical staining for at least one neuroendocrine marker.

Grade III NEC small cell type [small cell lung carcinoma (SCLC)] is the most malignant NEC and accounts for 25% of all lung cancers. These tumors are centrally located and consist of smaller cells with a diameter of 10 to 20 μm that have little cytoplasm and very dark nuclei. The tumors also have a high mitotic rate and areas of extensive necrosis. Multiple mitoses are easily seen. Importantly, examination of very small bronchoscopic biopsy specimens can distinguish NSCLC from SCLC, but crush artifact may make NSCLC appear similar to SCLC. If uncertainty exists, special immunohistochemical staining or rebiopsy (or both) are necessary. These tumors are the leading producer of paraneoplastic syndromes.

Salivary Gland–Type Neoplasms

The tracheobronchial tree has salivary-type submucosal bronchial glands interspersed throughout. These glands can give rise to tumors that are histologically

identical to those seen in the salivary glands. The two most common are adenoid cystic carcinoma and mucoepidermoid carcinoma. Both tumors occur centrally due to their site of origin. Adenoid cystic carcinoma is a slow-growing tumor that is locally and systemically invasive. It tends to grow submucosally and infiltrate along perineural sheaths. Mucoepidermoid carcinoma consists of squamous and mucous cells and is graded as low or high grade, depending on the mitotic rate and degree of necrosis.

CLINICAL PRESENTATION

Lung cancer displays one of the most diverse presentation patterns of all human maladies (Table 19-4). The wide range of symptoms and signs is related to (a) histologic features, which often help determine the anatomic site of origin in the lung; (b) the specific tumor location in the lung and its relationship to surrounding structures; (c) biologic features, and the production of a variety of paraneoplastic syndromes; and (d) the presence or absence of metastatic disease.

Table 19-4 Clinical Presentation of Lung Cancer		
Category	Symptom	Cause
Pulmonary symptoms	Cough	Bronchus irritation or compression
	Dyspnea	Airway obstruction or compression
	Wheezing	>50% airway obstruction
	Hemoptysis	Tumor erosion or irritation
	Pneumonia	Airway obstruction
Nonpulmonary thoracic symptoms	Pleuritic pain	Parietal pleural irritation or invasion
	Local chest wall pain	Rib and/or muscle involvement
	Radicular chest pain	Intercostal nerve involvement
	Pancoast's syndrome	Stellate ganglion, chest wall, brachial plexus involvement
	Hoarseness	Recurrent laryngeal nerve involvement
	Swelling of head and arms	Bulky involved mediastinal lymph nodes
		Medially based right upper lobe tumor

TUMOR HISTOLOGY

Squamous cell and small cell carcinomas frequently arise in main, lobar, or first segmental bronchi, which are collectively referred to as the *central airways*. Symptoms of airway irritation or obstruction are common and include cough, hemoptysis, wheezing (due to high-grade airway obstruction), dyspnea (due to bronchial obstruction with or without postobstructive atelectasis), and pneumonia (caused by airway obstruction with secretion retention and atelectasis).

In contrast, adenocarcinomas often are located peripherally. For this reason, they are often discovered incidentally as an asymptomatic peripheral lesion on chest radiograph. When symptoms occur, they are due to pleural or chest wall invasion (pleuritic or chest wall pain) or pleural seeding with malignant pleural effusion.

BAC (a variant of adenocarcinoma) may present as a solitary nodule, as multifocal nodules, or as a diffuse infiltrate mimicking an infectious pneumonia (pneumonic form). In the pneumonic form, severe dyspnea and hypoxia may occur, sometimes with expectoration of large volumes (over 1 L/d) of light tan fluid, with resultant dehydration and electrolyte imbalance. Because BAC tends to fill the alveolar spaces as it grows (as opposed to the typical invasion, destruction, and compression of lung architecture seen with other cell types), air bronchograms may be seen radiographically within the tumor.

TUMOR LOCATION

Symptoms related to the local intrathoracic effect of the primary tumor can be conveniently divided into two groups: pulmonary and nonpulmonary thoracic symptoms.

Pulmonary Symptoms

Pulmonary symptoms result from the direct effect of the tumor on the bronchus or lung tissue. Symptoms (in order of frequency) include cough (secondary to irritation or compression of a bronchus), dyspnea (usually due to central airway obstruction or compression, with or without atelectasis), wheezing (with narrowing of a central airway by >50%), hemoptysis (typically, blood streaking of mucus that rarely is massive and indicates a central airway location), pneumonia (usually due to airway obstruction by the tumor), and lung abscess (due to necrosis and cavitation, with subsequent infection).

Nonpulmonary Thoracic Symptoms

Nonpulmonary thoracic symptoms result from invasion of the primary tumor directly into a contiguous structure (e.g., chest wall, diaphragm, pericardium, phrenic nerve, recurrent laryngeal nerve, superior vena cava, and esophagus) or from mechanical compression of a structure (e.g., esophagus or superior

vena cava) by enlarged tumor-bearing lymph nodes.

Peripherally located tumors (often adenocarcinomas) extending through the visceral pleura lead to irritation or growth into the parietal pleura and potentially to continued growth into the chest wall structures. Three types of symptoms are possible, depending on the extent of chest wall involvement: (a) pleuritic pain, from noninvasive contact of the parietal pleura with inflammatory irritation and from direct parietal pleural invasion; (b) localized chest wall pain, with deeper invasion and involvement of the rib and/or intercostal muscles; and (c) radicular pain, from involvement of the intercostal nerve(s). Radicular pain may be mistaken for renal colic in the case of lower lobe tumors that invade the posterior chest wall.

Tumors (usually adenocarcinomas) originating in the posterior apex of the chest, referred to as *superior sulcus tumors*, may produce Pancoast's syndrome. Depending on the exact tumor location, symptoms can include apical chest wall and/or shoulder pain (from involvement of the first rib and chest wall), Horner syndrome (unilateral enophthalmos, ptosis, miosis, and facial anhidrosis from invasion of the stellate sympathetic ganglion), and radicular arm pain (from invasion of T1, and occasionally C8, brachial plexus nerve roots).

Invasion of the primary tumor into the mediastinum may lead to involvement of the phrenic or recurrent laryngeal nerves. The phrenic nerve traverses the thoracic cavity along the superior vena cava and anterior to the pulmonary hilum. Direct invasion of the nerve occurs with tumors of the medial surface of the lung or with anterior hilar tumors. Symptoms may include shoulder pain (referred), hiccups, and dyspnea with exertion because of diaphragm paralysis. Radiographically, the diagnosis is suggested by unilateral diaphragm elevation on chest radiograph and can be confirmed by fluoroscopic examination of the diaphragm with breathing and sniffing (the sniff test).

Recurrent laryngeal nerve involvement most commonly occurs on the left side, given the hilar location of the left recurrent laryngeal nerve as it passes under the aortic arch. Paralysis may occur from invasion of the vagus nerve above the aortic arch by a medially based left upper lobe tumor, from invasion of the recurrent laryngeal nerve directly by a hilar tumor, or from invasion by hilar or aortopulmonary lymph nodes involved with metastatic tumor. Symptoms include voice change, often referred to as *hoarseness* but more typically a loss of tone associated with a breathy quality, and coughing, particularly when drinking liquids.

Superior vena caval syndrome most frequently occurs with small cell carcinoma, with bulky enlargement of involved mediastinal lymph nodes and compression of the superior vena cava. Occasionally, a medially based right upper lobe tumor can produce the syndrome with direct invasion. Symptoms include variable degrees of swelling of the head, neck, and arms; headache; and conjunctival edema. Pericardial invasion may lead to pericardial effusions (benign or malignant), associated with increasing levels of dyspnea and/or arrhythmias, and with the potential to develop pericardial tamponade. Diagnosis requires a high index of suspicion in the setting of a medially based tumor with symptoms of dyspnea and is confirmed by CT scan or echocardiography.

Direct invasion of a vertebral body produces symptoms of back pain, which is often localized and severe. If the neural foramina are involved, radicular pain may also be present. Involvement of the esophagus is usually secondary to external compression by enlarged lymph nodes involved with metastatic disease, usually with lower lobe tumors. Finally, invasion of the diaphragm by a tumor at the base of a lower lobe may produce dyspnea, pleural effusion, or referred shoulder pain.

TUMOR BIOLOGY

Lung cancers, both non–small cell and small cell, are capable of producing a variety of paraneoplastic syndromes, most often from tumor production and release of biologically active materials systemically (Table 19-5). The majority of such syndromes are caused by small cell carcinomas, including many endocrinopathies. Paraneoplastic syndromes may produce symptoms even before symptoms are produced by the primary tumor, thereby leading to early diagnosis. Their presence does not influence resectability or the potential to successfully treat the tumor. Symptoms of the syndrome often will abate with successful treatment, and recurrence may be heralded by recurrent paraneoplastic symptoms. Many of the symptoms induced by these syndromes mimic those of the generalized debility caused by metastatic disease.

Table 19-5 Paraneoplastic Syndromes in Patients with Lung Cancer
Endocrine
Hypercalcemia (ectopic parathyroid hormone)
Cushing’s syndrome
Syndrome of inappropriate secretion of antidiuretic hormone
Carcinoid syndrome
Gynecomastia
Hypercalcitoninemia
Elevated growth hormone level
Elevated levels of prolactin, follicle-stimulating hormone, luteinizing hormone
Hypoglycemia

Hyperthyroidism
Neurologic
Encephalopathy
Subacute cerebellar degeneration
Progressive multifocal leukoencephalopathy
Peripheral neuropathy
Polymyositis
Autonomic neuropathy
Eaton-Lambert syndrome
Optic neuritis
Skeletal
Clubbing
Pulmonary hypertrophic osteoarthropathy
Hematologic
Anemia
Leukemoid reactions
Thrombocytosis
Thrombocytopenia
Eosinophilia
Pure red cell aplasia
Leukoerythroblastosis
Disseminated intravascular coagulation
Cutaneous
Hyperkeratosis
Dermatomyositis
Acanthosis nigricans
Hyperpigmentation
Erythema gyratum repens
Hypertrichosis lanuginosa acquista
Other
Nephrotic syndrome
Hypouricemia
Secretion of vasoactive intestinal peptide with diarrhea
Hyperamylasemia
Anorexia or cachexia

One of the more common paraneoplastic syndromes in patients with SCLC is hypertrophic pulmonary osteoarthropathy (HPO). Clinically, the syndrome is characterized by tenderness and swelling of the ankles, feet, forearms, and hands. It is due to periostitis of the fibula, tibia, radius, metacarpals, and metatarsals. Symptoms may be severe and debilitating. Clubbing of the digits occurs with or independently of HPO in up to 30% of patients with SCLC (Fig. 19-20). Symptoms of HPO may antedate the diagnosis of cancer by months. Radiographically, plain films of the affected areas show periosteal inflammation and elevation. A bone scan demonstrates intense but symmetric uptake of radiotracer in the long bones. Relief is afforded by treatment with aspirin or NSAIDs and by successful surgical or medical eradication of the tumor.

Hypercalcemia occurs in up to 10% of patients with lung cancer and is most often due to metastatic disease. However, 15% of cases are caused by secretion of ectopic parathyroid hormone–related peptide, most often with squamous cell carcinoma. A diagnosis of ectopic parathyroid hormone secretion can be made by measurement of elevated serum levels of parathyroid hormone; however, the clinician must also rule out concurrent metastatic bone disease by a bone scan. Symptoms of hypercalcemia include lethargy, depressed level of consciousness, nausea, vomiting, and dehydration. Most patients have resectable tumors, and after complete resection the calcium level will normalize. Unfortunately, tumor recurrence is extremely common and may manifest as recurrent hypercalcemia.

Endocrinopathies are caused by the release of hormones or hormone analogues into the systemic circulation. Most occur with SCLCs. The syndrome of inappropriate secretion of antidiuretic hormone occurs in 10 to 45% of patients with SCLC. Characterized by confusion, lethargy, and possible seizures, it is diagnosed by the presence of hyponatremia, low serum osmolality, and high urinary sodium and osmolality. Another cause of hyponatremia can be the ectopic secretion of atrial natriuretic peptide.

Cushing's syndrome is due to production of an adrenocorticotrophic hormone (ACTH)–like molecule and occurs principally in patients with SCLC. ACTH production is autonomous and not suppressible by dexamethasone. Immunoreactive ACTH is present in nearly all extracts of SCLC. A high percentage of patients with SCLC have elevated ACTH levels by radioimmunoassay, yet <5% have symptoms of Cushing's syndrome. Because the serum elevation of ACTH is rapid, appearance of the physical signs of Cushing's syndrome (e.g., truncal obesity, buffalo hump, striae) is unusual. Symptoms are primarily related to the metabolic consequences of severe hypokalemia, metabolic alkalosis, and hyperglycemia. Diagnosis is made by demonstrating hypokalemia (potassium level of <3.0 mmol/L), nonsuppressible elevated plasma levels of cortisol that lack the normal diurnal variation, elevated blood ACTH levels, or elevated urinary levels of 17-hydroxycorticosteroids, all of which are not suppressible by administration of exogenous dexamethasone.

Peripheral and central neuropathies are among the most common paraneoplastic syndromes in lung cancer, particularly in SCLC and squamous cell carcinoma. Unlike other paraneoplastic syndromes, which are usually due to ectopic secretion of an active substance, these syndromes are felt to be immune mediated. Antigens normally expressed only by the nervous system are believed to be aberrantly expressed by the cancer cells, generating antibodies leading either to interference with neurologic function or to immune neurologic destruction. Up to 16% of patients with lung cancer have evidence of neuromuscular disability, and of these patients, half have small cell carcinomas and 25% have squamous cell carcinomas. In patients with neurologic or muscular symptoms, central nervous system (CNS) metastases must be ruled out with CT or magnetic resonance imaging (MRI) of the head. Other metastatic disease leading to disability must also be excluded.

Lambert-Eaton syndrome is a myasthenia-like syndrome usually seen in patients with SCLC. It is caused by a neuromuscular conduction defect. Gait abnormalities are due to proximal muscle weakness and fatigability, and particularly affect the thighs. Symptoms can occur before symptoms of the primary

tumor and may actually precede radiographic evidence of the tumor. The syndrome is produced by immunoglobulin G antibodies targeting voltage-gated calcium channels, which function in the release of acetylcholine from presynaptic sites at the motor end plate. Therapy is directed at the primary tumor with resection, radiation, and/or chemotherapy. Many patients have dramatic improvement after resection or successful medical therapy. For patients with refractory symptoms, treatment consists of administration of guanidine hydrochloride, immunosuppressive agents such as prednisone and azathioprine, and occasionally plasma exchange. Unlike in myasthenia gravis patients, neostigmine is usually ineffective.

METASTATIC SYMPTOMS

Lung cancer metastases occur most commonly to the CNS, vertebral bodies, bone, liver, adrenal glands, lungs, skin, and soft tissues. At diagnosis, 10% of patients with primary lung cancer have CNS metastases; another 10 to 15% will go on to develop CNS metastases after diagnosis. Focal symptoms are most common and include headache, nausea and vomiting, seizures, hemiplegia, and speech difficulty. Lung cancer is the most common cause of spinal cord compression, which may occur by invasion of an intervertebral foramen from a primary tumor contiguous with the spine or from direct extension of a vertebral metastasis. Bony metastases, such as to the vertebral bodies or ribs, are identified in 25% of all patients with lung cancer. They are primarily lytic and produce pain locally; thus any new and localized skeletal symptoms must be evaluated radiographically. Liver metastases are most often an incidental finding on CT scan. Adrenal metastases are also typically asymptomatic and are usually discovered by routine CT scan. They may lead to adrenal hypofunction. Skin and soft tissue metastases occur in 8% of patients dying of lung cancer and generally present as painless subcutaneous or intramuscular masses. Occasionally, the tumor erodes through the overlying skin, with necrosis and creation of a chronic wound. Excision may then be necessary for both mental and physical palliation.

NONSPECIFIC SYMPTOMS

Lung cancer often produces a variety of nonspecific symptoms such as anorexia, weight loss, fatigue, and malaise. The cause of these symptoms is often unclear, but their presence should raise concern about possible metastatic disease.

DIAGNOSIS, EVALUATION, AND STAGING

In a patient with either a histologically confirmed lung cancer or a pulmonary lesion suspected to be a lung cancer, assessment encompasses three areas: the primary tumor, presence of metastatic disease, and functional status (the patient's ability to tolerate a pulmonary resection). A discrete approach to each of these three areas allows the surgeon to systematically evaluate the patient, perform accurate clinical stage assignment, and assess the patient's functional suitability for pulmonary resection (Table 19-6).

Table 19-6 Evaluation of Patients with Lung Cancer			
	Primary Tumor	Metastatic Disease	Functional Assessment
History	Pulmonary	Weight loss	Ability to walk up two flights of stairs
	Nonpulmonary thoracic	Malaise	Ability to walk on a flat surface indefinitely
	Paraneoplastic	New bone pain	
		Neurologic signs or symptoms	
Physical examination		Skin lesions	
	Voice	Supraclavicular node palpation	Accessory muscle usage
		Skin examination	Air flow by auscultation
		Neurologic examination	Force of cough
Radiographic examination	Chest CT	Chest CT, PET	Chest CT: tumor anatomy, atelectasis
Tissue analysis	Bronchoscopy	Bone scan, head MRI, abdominal CT	Quantitative perfusion scan
	Transthoracic needle aspiration and biopsy	Bronchoscopic lymph node FNA	
		Endoscopic ultrasound	
		Mediastinoscopy	
		Biopsy of suspected metastasis	
Other	Thoracoscopy	—	Pulmonary function tests (FEV ₁ , DLCO, O ₂ consumption)

CT = computed tomography; DLCO = carbon monoxide diffusion capacity; FEV₁ = forced expiratory volume in 1 s; FNA = fine-needle aspiration; MRI = magnetic resonance imaging; PET = positron emission tomography.

Assessment of the Primary Tumor

Assessment of the primary tumor begins with the history and directed questions regarding the presence or absence of pulmonary, nonpulmonary, thoracic, and paraneoplastic symptoms. Because patients often come to the surgeon with a chest radiograph or CT scan demonstrating the lesion, the location of the tumor can help direct the clinician in taking the history and performing the physical examination.

If the patient does not already have a chest CT scan, CT should be performed expeditiously as the next stage in evaluating a new patient. Routine chest CT should include IV administration of a contrast agent to enable delineation of mediastinal lymph nodes relative to normal mediastinal structures. Chest CT allows assessment of the primary tumor and its relationship to surrounding and contiguous structures. It also indicates whether invasion of contiguous structures has occurred. Recommendations for treatment and options for obtaining a tissue diagnosis require a thorough assessment of these CT findings.

The determination of invasion often is made from the patient's history and the location of the primary tumor. For example, a tumor abutting the chest wall with underlying rib destruction provides clear evidence of local invasion. It is common to see the primary tumor abutting the chest wall without evidence of rib destruction. In this circumstance, a history of the presence or absence of pain in the area is an accurate guide to the likelihood of parietal pleural, rib, or intercostal nerve involvement. Similar observations apply to tumors abutting the recurrent laryngeal nerve, phrenic nerve, diaphragm, vertebral bodies, and chest apex. Thoracotomy should not be denied because of presumptive evidence of invasion of the chest wall, vertebral body, or mediastinal structures; proof of invasion may require thoracoscopy or even thoracotomy.

MRI of pulmonary lesions and mediastinal nodes has been disappointing; overall, it offers no real improvement over CT scanning. There may be an important role for MRI, however, in defining a tumor's relationship to a major vessel due to its excellent imaging of vascular structures. This is especially true if the use of a contrast agent is contraindicated. Thus routine use of MRI in lung cancer patients is reserved for those with allergies to contrast agents or with suspected mediastinal, vascular, or vertebral body invasion.

Tissue diagnosis of the primary tumor can be made from specimens obtained through bronchoscopy or needle biopsy. Bronchoscopy provides additional useful information regarding tumor location within the airway and may guide operative planning. It is particularly useful for centrally located tumors, which have a higher probability of being visualized and being within reach of endobronchial biopsy forceps. In addition, bronchoscopy enables visualization of the entire tracheobronchial tree and thus allows the surgeon to identify the presence of additional unsuspected endobronchial lesions.

Diagnostic tissue can be obtained from bronchoscopy by one of four methods: (a) brushings and washings for cytologic analysis, (b) direct forceps biopsy of a visualized lesion, (c) fine-needle aspiration (FNA) with a Wang needle of an externally compressing lesion without a visualized endobronchial tumor, and (d) transbronchial biopsy with the use of forceps guided to the lesion by fluoroscopy. For peripheral lesions (roughly the outer half of the lung), transbronchial fluoroscopic biopsy often is performed first, followed by collection of brushings and washings. The intent is to improve the yield of the biopsy by picking up additional cells after disruption of the lesion by the biopsy forceps. For central lesions, direct forceps biopsy by bronchoscopic visualization often is possible, and again is followed by collection of brushings and washings. For central lesions with external airway compression but no visible endobronchial lesions, Wang needle FNA through the bronchoscope is performed. Endoscopic bronchial ultrasound (EBUS) is a valuable new tool that can facilitate the accuracy and safety of these transbronchial biopsies of both the primary tumor (when it abuts the central airways) and the mediastinal lymph nodes,⁴⁰ and should become part of the surgeon's armamentarium for the diagnosis and treatment of lung cancer.

Transthoracic needle aspiration is ideally suited for peripheral lesions not easily accessible by bronchoscopy. Under imaging guidance (fluoroscopy or CT), either an FNA or core-needle biopsy is performed. The primary complication is pneumothorax (occurring in up to 50% of patients), which is usually minor and requires no treatment. Three biopsy results are possible: malignancy, a specific benign process, or indeterminate findings. The overall false-negative rate is 20 to 30%; therefore, unless a specific benign diagnosis (such as granulomatous inflammation or hamartoma) is made, malignancy is not ruled out and further efforts at diagnosis are warranted.

Thoracoscopy is a valuable staging tool for assessing the primary tumor's relationship to other intrathoracic structures, because it is frequently difficult to discern whether the primary tumor has invaded a contiguous structure (such as the chest wall or mediastinum). It is also useful for obtaining tissue diagnoses for tumors that are inaccessible by imaging-guided procedures or for which the biopsy results were indeterminate. Peripheral lesions are readily accessible by thoracoscopic wedge excision of the lesion, and if the patient's pulmonary reserve is adequate, the surgeon can then proceed to lobectomy (either VATS or open) after frozen-section diagnosis.

A thoracotomy is occasionally necessary to diagnose and stage a primary tumor. Although this occurs in <5% of patients, two circumstances may require such an approach: (a) the presence of a deep-seated lesion that yielded an indeterminate needle biopsy result or that could not be biopsied for technical reasons, or (b) inability to determine invasion of a mediastinal structure by any method short of palpation. In the case of a deep-seated lesion without a diagnosis, FNA, biopsy using a core needle, or preferably an excisional biopsy can be performed with frozen-section analysis. If the biopsy result is indeterminate, a lobectomy may instead be necessary. When a pneumonectomy is required, a tissue diagnosis of cancer must be made before proceeding.

Assessment of Metastatic Disease

Distant metastases are found in approximately 40% of patients with newly diagnosed lung cancer. The presence of lymph node or systemic metastases may

imply inoperability. A patient's risk of harboring metastatic disease must be carefully considered by the surgeon.

As with assessment of the primary tumor, assessment for the presence of metastatic disease should begin with the history taking and physical examination, with a focus on the presence or absence of new bone pain, neurologic symptoms, and new skin lesions. In addition, constitutional symptoms (e.g., anorexia, malaise, and unintentional weight loss of >5% of body weight) suggest either a large tumor burden or the presence of metastases. Physical examination should focus on the patient's overall appearance, and any evidence of weight loss such as redundant skin or muscle wasting should be noted. A complete examination of the head and neck, including evaluation of cervical and supraclavicular lymph nodes and the oropharynx, should be performed because of the strong association of oropharyngeal primary tumors and lung cancer. This is particularly true for patients with a significant history of tobacco use. The skin should be thoroughly examined. Routine laboratory studies include serum levels of hepatic enzymes (e.g., serum glutamic oxaloacetic transaminase and alkaline phosphatase), as well as serum calcium level (to detect bone metastases or the ectopic parathyroid syndrome). Elevation of either hepatic enzyme levels or serum calcium levels typically occurs with extensive metastases.

Mediastinal Lymph Nodes

Chest CT scanning permits assessment of possible metastatic spread to the mediastinal lymph nodes. It continues to be the most effective noninvasive method available to assess the mediastinal and hilar nodes for enlargement. However, a positive CT finding (i.e., nodal diameter >1.0 cm) predicts actual metastatic involvement in only approximately 70% of lung cancer patients. Thus even when enlarged mediastinal lymph nodes are noted on CT scan, up to 30% of such nodes are enlarged due to noncancerous reactive causes such as inflammation related to atelectasis or pneumonia secondary to the tumor. Therefore, no patient should be denied an attempt at curative resection just because of a positive CT finding of mediastinal lymph node enlargement. Any CT finding of metastatic nodal involvement must be confirmed histologically. The negative predictive value of normal-appearing lymph nodes by CT (lymph nodes <1.0 cm) is better than the positive predictive value of a suspicious-appearing lymph node, particularly with small squamous cell tumors. With normal-size lymph nodes and a T1 tumor, the false-negative rate is <10%, which leads many surgeons to omit mediastinoscopy. However, the false-negative rate increases to nearly 30% with centrally located and T3 tumors. In this situation, mediastinoscopy is routinely recommended, because it has been demonstrated that T3 adenocarcinomas or large cell carcinomas have a higher rate of early micrometastasis. Therefore, all such patients should undergo mediastinoscopy.

PET scanning for metastatic disease is based on the detection of positrons emitted by FDG, a D-glucose analogue labeled with positron-emitting fluorine. After cellular uptake and phosphorylation, FDG is not metabolized further, which leads to intracellular accumulation. This accumulation, combined with a cancer's intrinsically higher rate of glucose metabolism, results in accumulation and potential visualization. A significant advantage of PET scanning is the ability to image the whole body after a single FDG injection, which allows simultaneous evaluation of the primary lung lesion, mediastinal lymph nodes, and distant organs.

Mediastinal lymph node staging by PET scanning appears to have greater accuracy than staging by CT scanning. PET staging of mediastinal lymph nodes has been evaluated in two meta-analyses. The overall sensitivity of PET for detection of mediastinal lymph node metastases was 0.79 [95% confidence interval (CI) = 0.76 to 0.82], with a specificity of 0.91 (95% CI = 0.89 to 0.93), and an accuracy of 0.92 (95% CI = 0.90 to 0.94).^{41,42}

When results of PET and CT scans were compared in patients who also underwent lymph node biopsies, PET had a sensitivity of 88% and a specificity of 91%, whereas CT scanning had a sensitivity of 63% and a specificity of 76%. Combining CT and PET scanning may lead to even greater accuracy.⁴³ In one study of CT, PET, and mediastinoscopy in 68 patients with potentially operable, non-small cell lung carcinoma (NSCLC), CT correctly identified the nodal stage in 40 patients (59%). It understaged the tumor in 12 patients and overstaged it in 16. PET correctly identified the nodal stage in 59 patients (87%). It understaged the tumor in five patients and overstaged it in four. For detecting N2 and N3 disease, the combination of PET and CT scanning yielded a sensitivity, specificity, and accuracy of 93%, 95%, and 94%, respectively. The values for CT scan alone were 75%, 63%, and 68%, respectively. With the recent development of combined PET-CT scanners, continued improvement in accuracy may be anticipated. However, with mediastinal lymph nodes, mediastinoscopy is recommended for histologic verification of disease in nodes determined to be cancerous by PET.

Endoesophageal ultrasound (EUS) has recently emerged as a method of staging in NSCLC. EUS can accurately visualize mediastinal paratracheal lymph nodes (stations 4R, 7, and 4L) and other lymph node stations (stations 8 and 9). It is able to visualize primary lung lesions contiguous with or near the esophagus (see Fig. 19-8). Using FNA techniques and, more recently, core-needle biopsy, samples of lymph nodes or primary lesions can be obtained. Diagnostic yield is improved with intraoperative cytologic evaluation, which can be performed with the cytopathologist in the operating room. Limitations of EUS include the inability to visualize the anterior (pretracheal) mediastinum, and thus it does not replace mediastinoscopy for complete mediastinal nodal staging. However, it may not be necessary to perform mediastinoscopy if findings on EUS are positive for N2 nodal disease, particularly if more than one station is found to harbor metastases.

Bronchoscopic FNA of paratracheal lymph nodes (primarily stations 4R, 7, and 4L) also can be performed. A significant disadvantage is the relatively blind nature of the aspiration. Station 7 can be reliably accessed, but other paratracheal lymph node locations must be estimated and aspiration attempted; therefore bronchoscopic FNA has limited usefulness. Both EUS and bronchoscopic FNA lack the ability for complete staging afforded by mediastinoscopy, which enables sampling of all upper mediastinal nodal stations and determination of the degree of lymph node involvement (from microscopic to complete nodal

replacement). The addition of EBUS-guided lymph node FNA is currently under study at many institutions. Because the biopsy is image guided and the biopsy needed is directed at an angle from the scope, the limitations of the transbronchial biopsy are overcome. Using this technology, it is possible to obtain FNA cytologic samples from level 4, level 7, level 10, and level 11 lymph nodes. Accuracy of the technique compared to the gold standard of mediastinoscopy is still being determined. Like mediastinoscopy, it does not allow assessment of level 3, 5, or 6 nodal stations. With this additional modality, it may be possible to use a combination of EUS and EBUS to determine clinical stage, with mediastinoscopy reserved for restaging after induction chemotherapy and/or radiation therapy. Further studies are needed, including determination of appropriate training and credentialing for those performing the procedure, before this approach can be considered a replacement for mediastinoscopy. For the foreseeable future, therefore, mediastinoscopy remains the standard method of tissue staging of the mediastinum.

Cervical mediastinoscopy has several advantages over other techniques of mediastinal lymph node staging (Fig. 19-21). It can provide a tissue diagnosis, allows sampling of all paratracheal and subcarinal lymph nodes, and permits visual determination of the presence of extracapsular extension of nodal metastases. With complex hilar or right paratracheal primary tumors, it allows direct biopsies and assessment of invasion into the mediastinum.

Fig. 19-21.

Cervical mediastinoscopy. Paratracheal and subcarinal lymph node tissues (within the pretracheal space) can be sampled using a mediastinoscope introduced through a suprasternal skin incision.

An absolute indication for obtaining a tissue diagnosis is mediastinal lymph node enlargement of >1.0 cm by CT scan. As stated earlier, EUS, EBUS, or transbronchial biopsy all can be used for this diagnosis. If the results are negative from these less invasive means, mediastinoscopy is mandatory, because the rates of false-negative biopsy results in this setting are high and the likelihood of metastatic disease is significant. When the size of mediastinal lymph nodes is normal, mediastinoscopy generally is recommended for centrally located tumors, for T2 and T3 primary tumors, and occasionally for T1 adenocarcinomas or large cell carcinomas (due to their higher rate of metastatic spread). Some surgeons perform mediastinoscopy in all lung cancer patients because of the poor survival associated with surgical resection of N2 disease.

Patients with left upper lobe tumors may have localized regional spread to station 5 and 6 lymph nodes, without mediastinal paratracheal involvement (see Fig. 19-8). Traditionally, such patients have undergone left anterior mediastinotomy (Chamberlain procedure). A left parasternal transverse incision is made with reflection of the mediastinal pleura laterally. The anterior mediastinal tissue is entered, which allows biopsy of station 5 and 6 lymph nodes and of primary tumors of the left hilum. More recently, left thoracoscopic (VATS) biopsy of these nodal stations is performed, particularly in centers experienced with VATS lobectomy. If there is a low index of suspicion, the patient can be scheduled for VATS biopsy and lobectomy under the same anesthesia if the nodes are negative. If the index of suspicion is high, the VATS biopsy is performed as a separate procedure. Cervical mediastinoscopy should precede both anterior mediastinotomy and VATS biopsy, even if the patient has normal paratracheal lymph nodes. Additional diagnostic evaluation of the lymph nodes in station 5 and 6 may be unnecessary if the cervical lymph nodes are proven to be benign via biopsy during cervical mediastinoscopy and the preoperative CT scan suggests complete resectability of the tumor and potentially involved mediastinal lymphadenopathy. There are, however, several indications for prethoracotomy biopsy of station 5 and 6 lymph nodes, which are listed in Table 19-7. It is particularly important to prove pathologically that mediastinal lymph nodes are involved before deciding that the patient is *not* a candidate for resection.

Table 19-7 Indications for Prethoracotomy Biopsy of Station 5 and 6 Lymph Nodes

1. Enrollment criteria for induction therapy protocol require pathologic confirmation of N2 disease.
2. Computed tomographic scan shows evidence of bulky nodal metastases or extracapsular spread that could prevent complete resection.
3. Tissue diagnosis of a hilar mass or of lymph nodes causing recurrent laryngeal nerve paralysis is needed.

Pleural Effusion

A pleural effusion found on a CT scan (or chest radiograph) is not automatically a malignant effusion. Malignant pleural effusion can be diagnosed only by finding malignant cells in a sample of pleural fluid examined microscopically. Pleural effusion is often secondary to the atelectasis or consolidation seen with central tumors, or it can be reactive or secondary to cardiac dysfunction. However, pleural effusion associated with a peripherally based tumor, particularly one that abuts the visceral or parietal pleural surface, does have a higher probability of being malignant. Regardless, no pleural effusion should be assumed to be malignant. Cytologic proof of the presence of malignant cells is required. Thoracoscopy may be indicated to rule out pleural metastases in selected patients. It can be performed as part of a separate staging procedure, often with mediastinoscopy, or immediately before a planned thoracotomy.

Distant Metastases

Until recently, detection of distant metastases outside the thorax was performed with a combination of chest CT scan and multiorgan scanning (e.g., brain CT or MRI, abdominal CT, and bone scan). Chest CT scans always include the upper abdomen and allow visualization of the liver and adrenal glands. Liver abnormalities that are not clearly simple cysts or hemangiomas need to be further evaluated, typically by MRI scanning. Adrenal enlargement, nodules, or masses also should be further evaluated by MRI and occasionally by needle biopsy. It must be remembered that adrenal adenomas, which are found in 2% of the general population and in up to 8% of patients with hypertension, may be mistakenly assumed to represent metastases. Adrenal adenomas have a high lipid content (secondary to steroid production), but metastases and most primary adrenal malignancies contain little if any lipid; thus MRI usually is able to distinguish the two.

In the absence of neurologic symptoms or signs, the probability of negative results on a CT scan of the head is 95%. Bone scans are notorious for their high sensitivity but low specificity and have a known overall false-positive rate of 40%. False-positive findings for any organ often lead to further noninvasive and invasive evaluation, and may even lead to denial of surgical resection. For these reasons, routine preoperative multiorgan scanning is not recommended for patients with a negative clinical evaluation and clinical stage I disease. However, it is recommended for patients with regionally advanced (clinical stage II, IIIA, and IIIB) disease. Any patient with a clinical evaluation suggestive of metastases, regardless of clinical stage, should undergo radiographic evaluation for metastatic disease.

PET scanning has supplanted multiorgan scanning in the search for distant metastases to the liver, adrenal glands, and bones. Currently, chest CT and PET are routine in the evaluation of patients with lung cancer. Brain MRI should be performed when the suspicion or risk of brain metastases is increased. Several reports have shown that PET scanning appears to detect an additional 10 to 15% of distant metastases not detected by routine chest or abdominal CT and bone scans.^{44–46} The PET finding of FDG uptake at a distant site must be proven not to be a metastasis. This often is accomplished with MRI and/or biopsies.

Integrated PET-CT scanners recently have become available. Early reports have demonstrated better accuracy in detection and localization of lymph node and distant metastases than with independently performed PET and CT scans (Fig. 19-22). This technology appears to overcome the problem of imprecise information on the exact location of focal abnormalities seen on PET scans and will likely become the standard imaging modality for lung cancer.

With any radiologic assessment for cancer, a common problem faced by surgeons is whether the results are true-positive or false-positive. Because a false-positive result can have a dramatic impact on the therapeutic course for a patient, the accuracy of a given scan must be ensured. The patient must be given the benefit of any doubt about the accuracy of a scan; the result must be proven, most often by a biopsy, to be true-positive.

Assessment of Functional Status

For patients with a potentially resectable primary tumor, the patient's functional status and ability to tolerate either lobectomy or pneumonectomy needs to be carefully assessed. The surgeon should first estimate the likelihood of pneumonectomy, lobectomy, or possibly sleeve resection, given the CT scan results (see discussion of surgical resection in "Treatment"). A sequential process of evaluation then unfolds.

A patient's history is the most important tool for gauging risk. It must be emphasized that numbers alone [e.g., forced expiratory volume in 1 second (FEV₁) and carbon monoxide diffusion capacity (DLCO)] do not supplant the clinician's assessment. The clinical assessment entails the observation of the patient's general vigor and attitude. The late Dr. Robert Ginsberg best summarized the impact of a patient's vigor and attitude:

Other factors that may predict a poor outcome from surgical intervention are difficult to classify. It has been my distinct impression that the patient's attitude toward the disease, the desire to have a favorable outcome, and confidence in the doctor is predictive of success. A prospective analysis of quality of life following lung cancer treatment, performed by the Lung Cancer Study Group, confirmed that the patient's attitude toward the disease was the best indicator of long-term survival. Except in life-threatening situations, patients should never be cajoled or forced into accepting surgery. In most cases, this led to disastrous results. At times, it is best to defer surgical intervention to the patient with a significant negative outlook, especially if other curative options (e.g., radiotherapy for cancer) are available. [Personal communication to author (JDL).]

When obtaining the patient's history, specific questions should be routinely asked that help determine the amount of lung that the patient will likely tolerate having resected. Can the patient walk on a flat surface indefinitely, without oxygen and without having to stop and rest secondary to dyspnea? If so, the patient will be very likely to tolerate thoracotomy and lobectomy. Can the patient walk up two flights of stairs (up two standard levels), without having to stop and rest secondary to dyspnea? If so, the patient will likely tolerate pneumonectomy. Finally, nearly all patients, except those who show carbon dioxide retention on arterial blood gas analysis, will be able to tolerate periods of single-lung ventilation and wedge resection.

Other pertinent elements of the history are current smoking status and sputum production. Current smokers have a significantly increased risk of postoperative pulmonary complications, defined as respiratory failure requiring intensive care unit care or reintubation, pneumonia, atelectasis requiring bronchoscopy, pulmonary embolism, and need for oxygen supplementation at the time of hospital discharge (Fig. 19-23).³⁸ Patients with more than a 60

pack-year history of smoking are 2.5 times more likely to develop any pulmonary complication and three times more likely to develop pneumonia than patients with a history of 60 or fewer pack-years (odds ratio = 2.54; 95% CI = 1.28 to 5.04; $P = .0008$). In addition, impaired exchange of carbon dioxide was predictive of increased risk, independent of the smoking history. For every 10% decline in percent DLCO the risk of any pulmonary complication (as estimated by the odds ratio) increased by 42% (odds ratio = 1.42; 95% CI = 1.16 to 1.75; $P = .008$).³⁸ To diminish the risk significantly requires cessation of smoking at least 8 weeks preoperatively, a requirement that often is not feasible for a cancer patient. Nevertheless, efforts to abstain should be encouraged, ideally for 2 weeks before surgery. Smoking cessation on the day of surgery leads to increased sputum production and potential secretion retention postoperatively, and some authors have reported increased rates of pulmonary complications in this group.⁴⁷

Patients with chronic daily sputum production will have more problems postoperatively with retention and atelectasis; they are also at higher risk for pneumonia. Sputum culture, antibiotic administration, and bronchodilators may be warranted preoperatively.

The physical examination should focus on the following signs of chronic obstructive pulmonary disease (COPD) or airflow limitation: cyanosis, peripheral edema from right heart failure, mild post-cough shortness of breath, use of accessory muscles for breathing, decreased air entry, wheezes or crackles, and a "wet" cough. The combination of the patient's answers to the questions on exercise tolerance presented earlier and results of the cough test allow the experienced thoracic surgeon to gauge operative risk remarkably well.

Pulmonary function studies are routinely performed when any resection greater than a wedge resection will be performed. Of all the measurements available, the two most valuable are FEV₁ and DLCO.

General guidelines for the use of FEV₁ in assessing the patient's ability to tolerate pulmonary resection are as follows: patients with an FEV₁ of >2.0 L can tolerate pneumonectomy, and those with an FEV₁ of >1.5 L can tolerate lobectomy. It must be emphasized that these are guidelines only. It is also important to note that the raw value is often imprecise, because normal values are reported as "percent predicted" based on corrections made for age, height, and gender. For example, a raw FEV₁ value of 1.3 L in a 62-year-old, 75-in male has a percent predicted value of 30% (because the normal expected value is 4.31 L); in a 62-year-old, 62-in female, the percent predicted value is 59% (normal expected value of 2.21 L). The male patient falls into the high-risk group for lobectomy, whereas the female could potentially tolerate pneumonectomy.

The percent predicted value for both FEV₁ and DLCO correlates with the risk of development of complications postoperatively, particularly pulmonary complications. Complication rates are significantly higher among patients with percent predicted values of <50%, with the risk of complications increasing in a stepwise fashion for each 10% decline. Figure 19-24 shows the relationship between predicted postoperative DLCO and estimated operative mortality.

Fig. 19-24.

Operative mortality after major pulmonary resection for non-small cell lung cancer (334 patients) as a function of the percent predicted postoperative carbon monoxide diffusion capacity (ppoDLCO%). *Solid line* is the logistic regression model; *dashed lines* represent the 95% confidence limits.

(Adapted with permission from Wang J, et al: Diffusing capacity predicts operative mortality but not long-term survival after resection for lung cancer. *J Thorac Cardiovasc Surg* 117:582, 1999. Copyright Elsevier.)

To calculate the predicted postoperative value for FEV₁ or DLCO, the percent predicted value of FEV₁ or DLCO is multiplied by the fraction of remaining lung after the proposed surgery. For example, in a planned right upper lobectomy, a total of three segments will be removed. Therefore, removing 3 of a total of 20 segments will leave the patient with $(20 - 3/20) \times 100 = 85\%$ of original lung capacity. Of the two patients mentioned earlier, the man will have a postoperative percent predicted FEV₁ of $30\% \times 0.85 = 25\%$, whereas the woman will have a postoperative percent predicted FEV₁ of 50%.

The effect of the primary tumor on lung function must also be considered. Figure 19-25 shows a tumor with significant right main stem airway obstruction with associated atelectasis and volume loss of the right lung. At presentation, the patient was dyspneic with ambulation and the FEV₁ was 1.38 L. The referring physician told the patient that surgery was not feasible because he would require pneumonectomy, which he would not be able to tolerate. This case history illustrates a common pitfall for clinicians: failure to determine a patient's functional status before the development of the tumor. Six months earlier, this patient could walk up two flights of stairs without dyspnea. Similarly, if a patient with limited pulmonary function experiences complete collapse of a lobe (e.g., right upper lobe) and has only a mild decline in functional status, the surgeon can anticipate that the patient will tolerate lobectomy because the lobe already is not functioning and in fact may be contributing to a shunt.

Chest computed tomographic scan of an obstructing right main stem lung tumor. *Arrow* indicates location of right main bronchus. The right lung volume is much less than the left lung volume.

Quantitative perfusion scanning is used in select circumstances to help estimate the functional contribution of a lobe or whole lung. Such perfusion scanning is most useful when the impact of a tumor on pulmonary physiology is difficult to discern. With complete collapse of a lobe or whole lung, the impact is apparent, and perfusion scanning is usually unnecessary. However, with centrally located tumors associated with partial obstruction of a lobar or main bronchus or of the pulmonary artery, perfusion scanning may be valuable in predicting the postoperative result of resection. For example, if the quantitative perfusion to the right lung is measured to be 21% (normal is 55%) and the patient's percent predicted FEV₁ is 60%, the predicted postoperative FEV₁ after a right pneumonectomy would be 60% x 0.79 = 47%, which indicates the ability to tolerate pneumonectomy. If the perfusion value is 55%, the predicted postoperative value would be 27%, and pneumonectomy would pose a significantly higher risk.

Exercise testing that yields maximum oxygen consumption ($\dot{V}O_2\text{max}$) has emerged as a valuable decision-making technique to help in evaluation of patients with abnormal FEV₁ and DLCO. Table 19-8 provides a summary of the existing data regarding the relationship between $\dot{V}O_2\text{max}$ and postoperative mortality risk. It is not uncommon to encounter patients with significant reductions in percent predicted FEV₁ and DLCO whose history shows a functional status that is inconsistent with the pulmonary function test results. In these circumstances, and in other situations in which decision making is difficult, the $\dot{V}O_2\text{max}$ should be measured. Values of <10 mL/kg per minute generally prohibit any major pulmonary resection, because the mortality associated with this level is 26%, compared with only 8.3% for $\dot{V}O_2\text{max}$ levels of ≥ 10 mL/kg per minute; $\dot{V}O_2\text{max}$ levels >15 mL/kg per minute generally indicate the patient's ability to tolerate pneumonectomy.

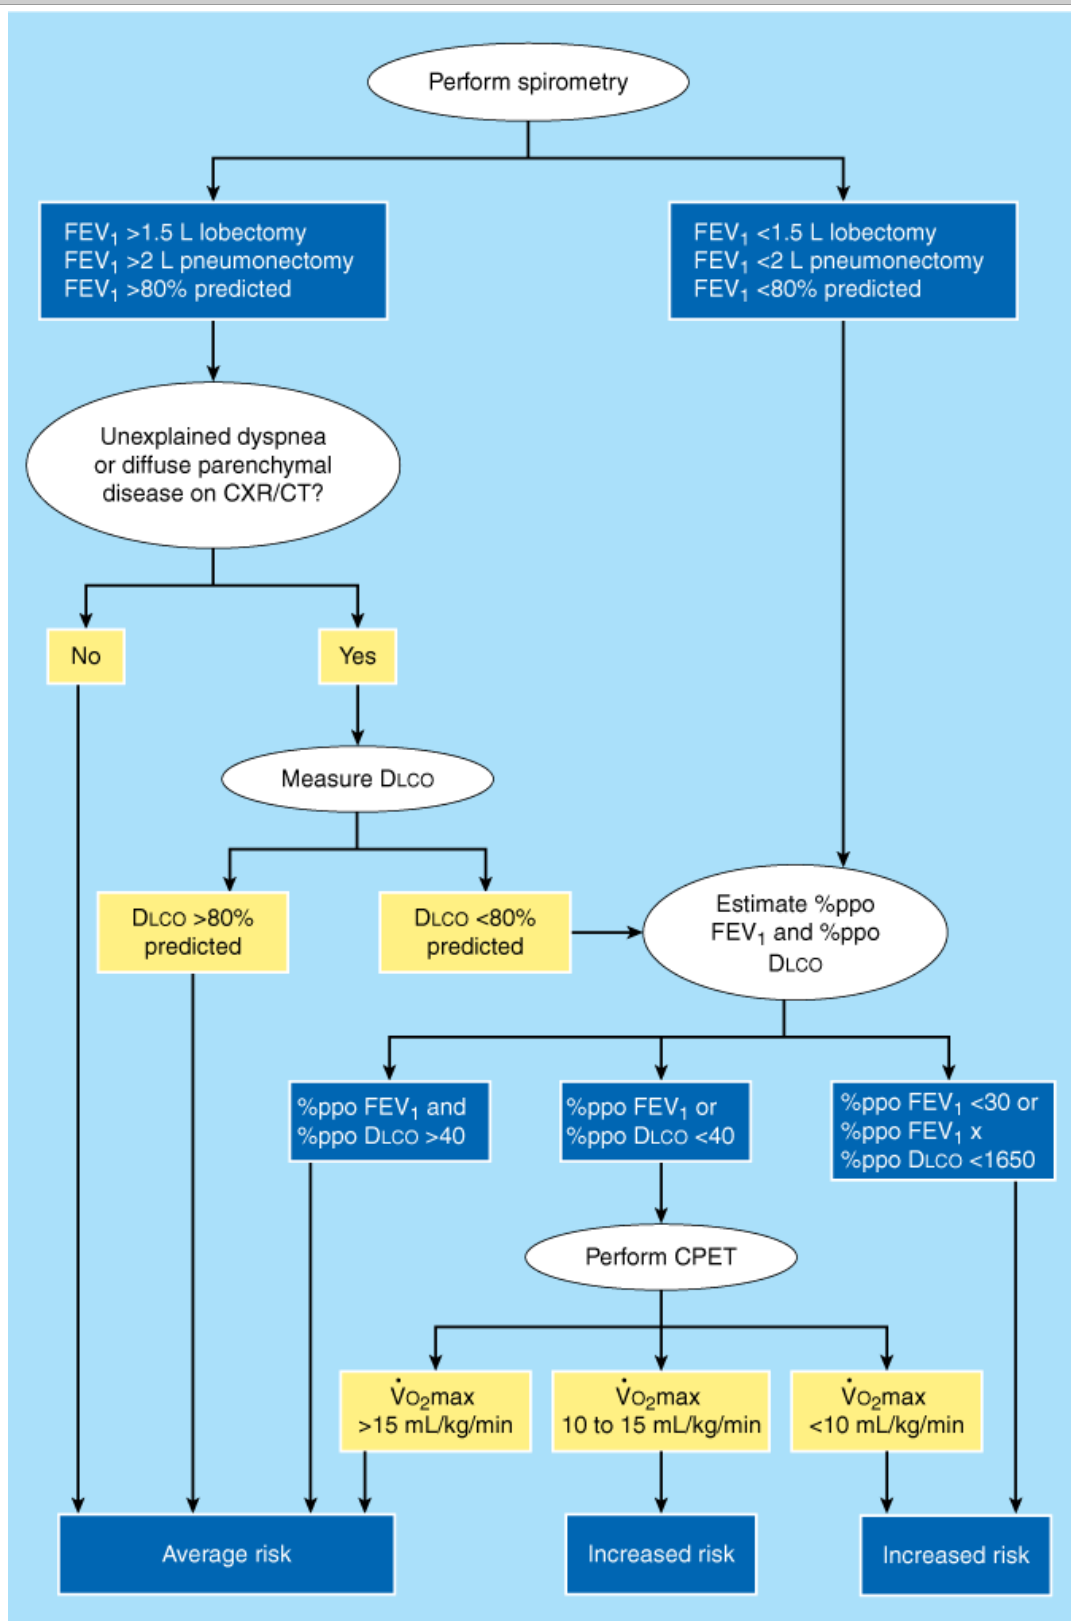

Table 19-8 Relation between Maximum Oxygen Consumption ($\dot{V}O_2\text{Max}$) as Determined by Preoperative Exercise Testing and Perioperative Mortality

The risk assessment for a patient is based on a combination of clinical judgment and data. Commonly, there are gray areas in which data such as those described earlier can enable more accurate determination of the risk. This risk assessment must be integrated with the experienced clinician's sense of the

patient and with the patient's attitude toward the disease and toward life. Figure 19-26 provides a useful algorithm for determining suitability for lung resection.⁴⁸

LUNG CANCER STAGING SYSTEMS

The staging of any tumor is an attempt to measure or estimate the extent of disease present and in turn use that information to help determine the patient's prognosis. The staging of solid epithelial tumors is based on the tumor, node, and metastasis (TNM) staging system. The T status provides information about the primary tumor itself, such as its size and relationship to surrounding structures; the N status provides information about regional lymph nodes; and the M status provides information about the presence or absence of metastatic disease. Table 19-9 lists the TNM descriptors that have been developed for use in NSCLC. These recommendations have been in place since 1997 and are in the process of revision for the next edition of the Union Internationale Contre le Cancer staging system. The proposed changes are discussed at length in the following paragraphs.^{49–54}

Table 19-9 American Joint Committee on Cancer Staging System for Lung Cancer

Stage	TNM
IA	T1 N0 M0
IB	T2 N0 M0
IIA	T1 N1 M0
IIB	T2 N1 M0
	T3 N0 M0
IIIA	T3 N1 M0
	T1–3 N2 M0
IIIB	T4 Any N M0
	Any T N3 M0
IV	Any T Any N M1
TNM definitions	
T	TX Positive malignant cell, but primary tumor not visualized by imaging or bronchoscopy
	T0 No evidence of primary tumor
	Tis Carcinoma in situ
	T1 Tumor ≤3 cm, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus
	T2 Tumor with any of the following features of size or extent:
	<ul style="list-style-type: none"> • >3 cm in greatest dimension • Involves main bronchus, ≥2 cm distal to the carina • Invades the visceral pleura • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
	T3 Tumor of any size that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus <2 cm distal to the carina, but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
	T4 Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor with a malignant pleural or pericardial effusion, or with satellite tumor nodule(s) within the ipsilateral primary-tumor lobe of the lung
N	NX Regional lymph nodes cannot be assessed
	N0 No regional lymph node metastasis
	N1 Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and intrapulmonary nodes involved by direct extension of the primary tumor
	N2 Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)

	N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M	MX	Presence of distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis present [including metastatic tumor nodule(s) in the ipsilateral nonprimary tumor lobe(s) of the lung]
Summary of staging definitions		
Occult stage	Microscopically identified cancer cells in lung secretions on multiple occasions (or multiple daily collections); no discernible primary cancer in the lung	
Stage 0	Carcinoma in situ	
Stage IA	Tumor surrounded by lung or visceral pleura ≤ 3 cm arising more than 2 cm distal to the carina (T1 N0)	
Stage IB	Tumor surrounded by lung > 3 cm, or tumor of any size with visceral pleura involved arising more than 2 cm distal to the carina (T2 N0)	
Stage IIA	Tumor ≤ 3 cm not extended to adjacent organs, with ipsilateral peribronchial and hilar lymph node involvement (T1 N1)	
Stage IIB	Tumor > 3 cm not extended to adjacent organs, with ipsilateral peribronchial and hilar lymph node involvement (T2 N1)	
	Tumor invading chest wall, pleura, or pericardium but not involving carina, nodes negative (T3 N0)	
Stage IIIA	Tumor invading chest wall, pleura, or pericardium and nodes in hilum or ipsilateral mediastinum (T3, N1–2) or tumor of any size invading ipsilateral mediastinal or subcarinal nodes (T1–3, N2)	
Stage IIIB	Direct extension to adjacent organs (esophagus, aorta, heart, cava, diaphragm, or spine); satellite nodule same lobe, or any tumor associated with contralateral mediastinal or supraclavicular lymph node involvement (T4 or N3)	
Stage IV	Separate nodule in different lobes or any tumor with distant metastases (M1)	

The designation of lymph nodes as N1, N2, or N3 requires familiarity with the lymph node map devised by Naruke and colleagues in 1978,⁵⁵ which was subsequently modified by the American Thoracic Society in 1983 and by Mountain and Dresler in 1997^{56,57} (see Fig. 19-8). Because the mapping system is based on clearly delineated anatomic boundaries, accurate and reproducible localization of thoracic lymph nodes is possible, which allows detailed nodal staging for individual patients and facilitates standardization of nodal assessment among surgeons.

A tumor in a given patient is typically classified into a clinical stage and a pathologic stage. The clinical stage (cTNM) is derived from an assessment of all data short of surgical resection of the primary tumor and lymph nodes. Thus clinical staging information includes the history and physical examination, radiographic test results, and diagnostic biopsy information. A therapeutic plan is then generated based on the clinical stage. After surgical resection of the tumor and lymph nodes, a postoperative pathologic stage (pTNM) is determined, providing further prognostic information.

In 1986, an international staging system for lung cancer was developed by Mountain and applied to a database of > 3000 patients from the M. D. Anderson Hospital in Houston, Texas, and the Lung Cancer Study Group.⁵⁸ In 1997, Mountain reviewed the survival data from an additional 1524 patients beyond the original database. Taking into account the combined total of 5319 patients, he revised the staging system.⁵⁹ These changes were subsequently adopted by the American Joint Committee on Cancer. The 1997 version of the international staging system, which is still in use, is shown in Table 19-9.

Significant variation in survival is seen within stage groupings, however (Table 19-10), which has prompted a critical evaluation of the variables that predict poor long-term survival. For example, a tumor that is ≤ 1.0 cm in diameter has a significantly better prognosis than tumors 2.0 to 3.0 cm in diameter. The wide range of postoperative 5-year survival rates (5 to 25%) after surgical resection of patients with N2 nodal involvement demonstrates the effect of the number and location of involved nodal stations and of the presence of extracapsular nodal extension.

Table 19-10 Cumulative Percentage of Survival by Stage after Treatment for Lung Cancer		
	Time after Treatment	
Pathologic Stage	24 mo (%)	60 mo (%)
pT1 N0 M0 (<i>n</i> = 511)	86	67
pT2 N0 M0 (<i>n</i> = 549)	76	57
pT1 N1 M0 (<i>n</i> = 76)	70	55
pT2 N1 M0 (<i>n</i> = 288)	56	39
pT3 N0 M0 (<i>n</i> = 87)	55	38

Source: Modified from Mountain.⁵⁹

To address the wide variability in survival within stages, the International Association for the Study of Lung Cancer Staging Committee was created in 1999. A database encompassing over 100,000 patients worldwide has been created and intensively examined for important determinants of survival by tumor, node, and metastasis staging.^{51–54} The results of this analysis, as well as recommended changes to the TNM staging system, have been recently published after vigorous analysis of multinational data.^{50–53} These changes were validated in 23,583 patients and shown to predict survival better than the current staging system.^{31,54} Proposed changes to the TNM staging are outlined in Tables 19-11 and 19-12.

Table 19-11 Summary of Proposed Lung Cancer Staging Revisions		
Current TNM Staging		Proposed (IASLC) TNM Staging
Tumor Stage		
T1 (up to 3 cm) →		T1a ≤2 cm
		T1b >2 cm to ≤3 cm
T2 (>3 cm) →		T2a >3 cm to ≤5 cm
		T2b >5 cm to ≤7 cm
		T3 >7 cm
T →	Mediastinal invasion →	Remain T4
	Satellite nodules →	Downstage to T3
	Malignant pleural or pericardial effusion →	Malignant pleural effusion M1a Malignant pericardial effusion M1b*
Metastasis Stage		
M1a (ipsilateral intrapulmonary nodules →		Downstage to T4

*Additional recommendation after further validation that was not in the proposal for changes to the TNM system by Goldstraw et al.⁵¹

IASLC = International Association for the Study of Lung Cancer; TNM = tumor, nodes, and metastasis.

Table 19-12 International Association for the Study of Lung Cancer Proposed Changes to the Tumor, Nodes, and Metastasis (TNM) Staging System for 2009					
Sixth Edition T/M Descriptor	Proposed T/M	N0	N1	N2	N3

TREATMENT

Early-Stage Disease

Early-stage disease typically is defined as stages I and II. In this group are T1 and T2 tumors (with or without local N1 nodal involvement) and T3 tumors (without N1 nodal involvement). This group represents a small, but increasing, proportion of the total number of patients diagnosed with lung cancer each year (approximately 20% of 101,844 patients from 1989 to 2003).⁴⁹

The current standard of treatment is surgical resection, accomplished by lobectomy or pneumonectomy, depending on the tumor location. Despite use of the

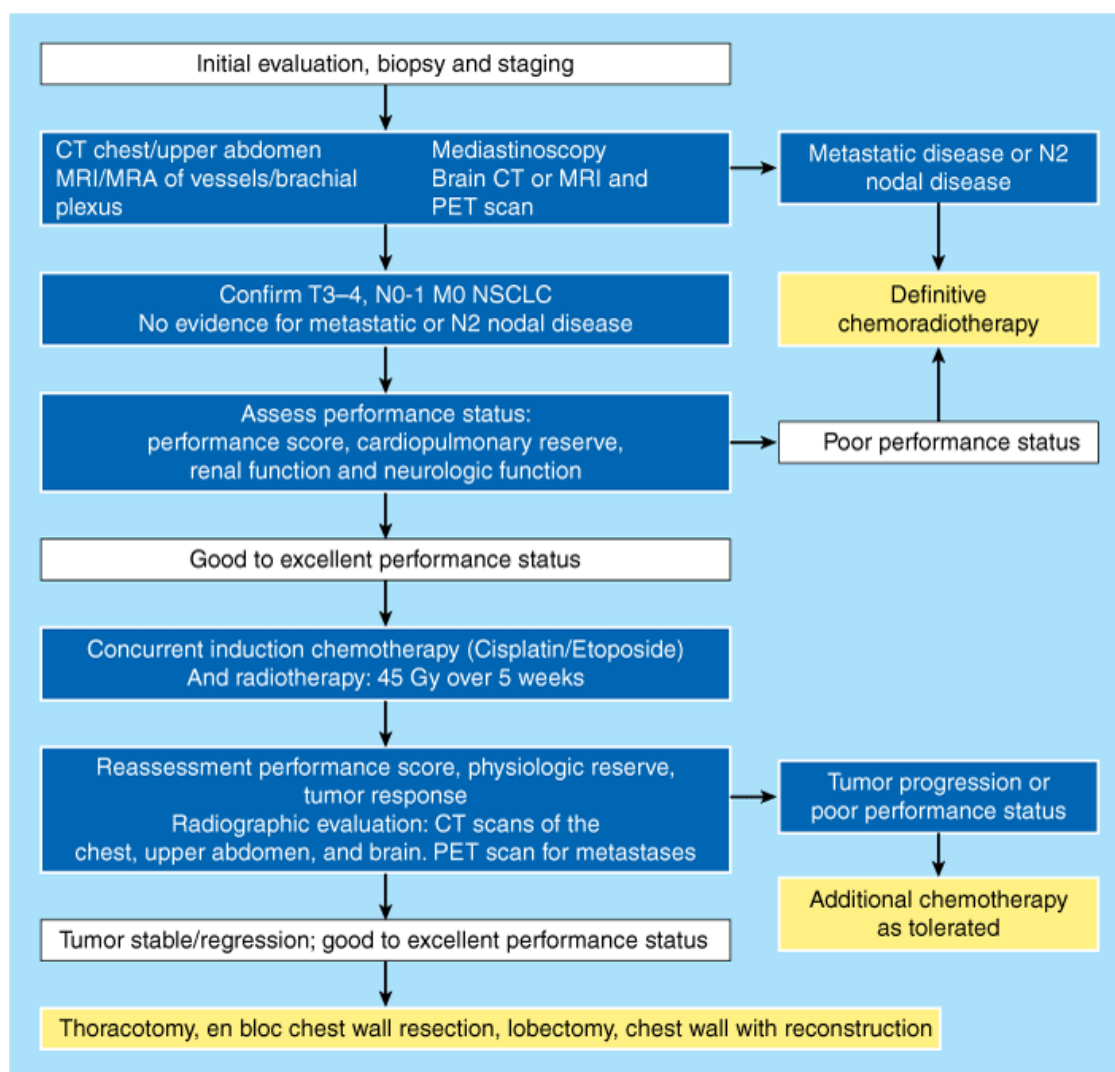

term *early stage*, 5-year survival is suboptimal, and the results of surgery as a single treatment modality remain disappointing. Patients with stage IA non-small cell lung cancer (NSCLC) who were offered resection but refused any treatment, including chemotherapy and radiation, were recently reported to have a median survival of 14 months and a 5-year survival rate of 22%.⁶⁰ For tumors evaluated postoperatively as pathologic stage IA disease, 5-year survival is better after surgical resection than with no treatment, but still only 67%, as reported in 1997 by Mountain.⁵⁹ The figures decline with higher-stage disease. Advanced age at diagnosis, male sex, low socioeconomic status, nonsurgical treatment, and poor histologic grade are associated with increased mortality risk on multivariate analysis.⁴⁹ The overall 5-year survival rate for stage I tumors as a group is approximately 65%; for stage II disease it is approximately 41%.

Appropriate surgical procedures for patients with early-stage disease include lobectomy, sleeve lobectomy, and occasionally pneumonectomy with mediastinal lymph node dissection or sampling. Sleeve resection is performed for tumors located at airway bifurcations when an adequate bronchial margin cannot be obtained by standard lobectomy. Pneumonectomy rarely is performed; primary indications for pneumonectomy in early-stage disease include the presence of large central tumors involving the distal main stem bronchus and inability to completely resect involved N1 lymph nodes. The latter circumstance occurs with bulky adenopathy or with extracapsular nodal spread. Carcinoma arising in the extreme apex of the chest with associated arm and shoulder pain, atrophy of the muscles of the hand, and Horner syndrome was first described by Henry Pancoast in 1932.⁶¹ Any tumor of the superior sulcus, including tumors without evidence of involvement of the neurovascular bundle, is now commonly known as *Pancoast's tumor*. The designation should be reserved for those tumors involving the parietal pleura or deeper structures overlying the first rib. Chest wall involvement at or below the second rib should not be considered Pancoast's tumor.⁶² Treatment involves a multidisciplinary approach. Goals of operative treatment obviously include curative resection; however, due to the location of the tumor and involvement of the neurovascular bundle that supplies the ipsilateral extremity, preserving postoperative function of the extremity also is critical. The recommendation for resection of Pancoast's tumors (apical tumors) depends on the results of mediastinal lymph node analysis. Survival of those with N2 nodal spread in this setting is poor, and in part because of the risk of morbidity and mortality, surgical resection has no role. For this reason, resection should always be preceded by mediastinoscopy.

Historically, Pancoast's tumors have been difficult to treat, with high rates of local recurrence and poor 5-year survival with radiation and/or surgical resection. Tumor invasion into surrounding structures prompted investigations into modalities such as induction radiation and, more recently, concomitant radiation and chemotherapy, to improve rates of complete resection. The Southwest Oncology Group formally studied the use of induction chemoradiotherapy followed by surgery, and long-term results are now available. The treatment regimen was well tolerated, with 95% of patients completing induction treatment. Complete resection was achieved in 76%. Five-year survival was 44% overall and 54% when complete resection was achieved. Disease progression with this regimen was predominantly at distant sites, with the brain being the most common.⁶³ A treatment algorithm for Pancoast's tumors is presented in Fig. 19-27.

Fig. 19-27.

Treatment algorithm for Pancoast's tumors. CT = computed tomography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; NSCLC = non-small cell lung cancer; PET = positron emission tomography.

Surgical excision is performed via thoracotomy with en bloc resection of the chest wall, vascular structures, and anatomic lobectomy. A portion of the lower trunk of the brachial plexus and the stellate ganglion are also typically resected. With chest wall involvement, en bloc chest wall resection, along with lobectomy, is performed, with or without chest wall reconstruction. For small rib resections or those posterior to the scapula, chest wall reconstruction is usually unnecessary. Larger defects (two rib segments or more) usually are reconstructed with polytetrafluoroethylene (Gore-Tex) material to provide chest wall contour and stability.

En bloc resection also is used for other locally advanced tumors (T3) with direct invasion of the adjacent chest wall, diaphragm, or pericardium. If a large portion of the pericardium is removed, reconstruction with thin Gore-Tex membrane will be required to prevent cardiac herniation and venous obstruction.

If a patient is deemed medically unfit for major pulmonary resection due to inadequate pulmonary reserve or other medical conditions, then options include limited surgical resection and radiotherapy. Limited resection, defined as segmentectomy or wedge resection, can be used only for more peripheral T1 or T2 tumors. A randomized trial of lobectomy vs. limited resection for stage I NSCLC conducted by the Lung Cancer Study group confirmed an increased risk of local recurrence, found a slight trend toward decreased overall survival, and concluded that limited resection, even for small, localized tumors, should not be the only therapy.^{64,65} Other studies suggest decreased long-term survival rate for tumor size >3 cm but not for smaller tumors, probably due to incomplete resection of occult intrapulmonary lymphatic tumor metastasis.⁶⁶ Table 19-13 shows the findings of a meta-analysis by Nakamura and colleagues comparing the mortality and morbidity outcomes for segmental resection and lobectomy. With the increasing prevalence of screening CT in high-risk populations, this topic is again the subject of intensive review. Studies are ongoing to evaluate the role of limited resection, including limited resection with and without brachytherapy in high-risk operative candidates. In addition, the Cancer and Leukemia Group B has initiated a randomized trial of lobectomy vs. sublobar resection (CALGB 140503) that will address the question of whether sublobar resection is equivalent to lobectomy for tumors ≤2 cm in size with no evidence of nodal involvement. At this time, however, for patients who will tolerate lobectomy, complete resection remains the standard of care.

Table 19-13 Summary of Studies Comparing Limited Resection and Lobectomy						
Study	Study Design	Stage	No. of Limited Resections	No. of Lobectomies	Reasons for Limited Resection	Survival Difference
Hoffman and Ransdell (1980) ²⁰⁵	RS	IA	33 (W)	40 ^a	Poor cardiopulmonary function and smaller lesions	NS

Another option for patients who are poor operative candidates is definitive radiotherapy. Traditional external beam radiation is used to deliver a total dose of 60 to 65 Gy, producing 5-year survival rates of approximately 30% in patients with stage I disease. Significant advances have been made in the focused delivery of radiation for definitive treatment of early-stage lung cancer, including tomotherapy and robotic radiosurgery (CyberKnife) therapy. These treatments deliver high doses of radiation in several sessions directly to the tumor rather than to the tumor and surrounding normal lung. This minimizes the toxicity of the treatment to surrounding lung parenchyma. Preservation of normal lung is critical for patients with limited pulmonary reserve. Excellent 5-year survival and low recurrence rates are being reported. In addition, the therapy is well tolerated, with minimal side effects.

The role of chemotherapy in early-stage NSCLC is evolving. Postoperative adjuvant chemotherapy previously was found to be of no benefit in multiple prospective randomized trials; however, newer, more effective agents have been of benefit, although the final results of current trials are pending. Similarly, prospective phase II studies have shown a potential benefit for preoperative (or induction) chemotherapy.^{67,68} There are concerns that induction

chemotherapy may result in increased perioperative morbidity or mortality; however, except in patients undergoing right-sided pneumonectomy after induction chemotherapy, the incidence of perioperative morbidity and mortality is not different for the two groups.⁶⁹

Locoregional Advanced Disease

Surgical resection as sole therapy has a limited role in treatment of stage III disease.⁷⁰ T3 N1 tumors can be treated with surgery alone, and a 5-year survival rate of approximately 25% is seen with such therapy. Patients with N2 disease are a heterogeneous group. Patients with clinically evident N2 disease (i.e., bulky adenopathy on CT scan or mediastinoscopy, with lymph nodes often replaced by tumor) have a 5-year survival rate of 5 to 10% with surgery alone. In contrast, patients with microscopic N2 disease discovered incidentally in one lymph node station after surgical resection have a 5-year survival rate that may be as high as 30%. Surgery is occasionally appropriate for select patients with T4, N0 or N1, M0 primary tumors (e.g., tumors invading the superior vena caval, carinal or vertebral body involvement, or satellite nodules in the same lobe); surgery generally does *not* have a role in the care of patients with a tumor of any size and N3 disease or with T4 tumors and N2 disease. Survival rates remain low for these patients.

Definitive radiotherapy is predominantly used for palliation of symptoms in patients with poor performance status, because the cure rate of radiotherapy as a single modality in patients with N2 or N3 disease is <7%. Recently improvement has been seen with three-dimensional conformal radiotherapy and altered fractionation. Such poor results for patients with stage IIIA lung cancer reflect the limitations of locoregional therapy in treating a disease process that results in death because of systemic metastatic spread.

Definitive treatment of stage III disease (when surgery is not felt to be feasible at any time) is usually a combination of chemotherapy and radiotherapy. Two strategies for delivery are available. Sequential chemoradiation involves full-dose systemic chemotherapy (i.e., cisplatin combined with a second agent) followed by standard radiotherapy (approximately 60 Gy). The combination of chemotherapy followed by radiation has been shown to improve the 5-year survival rate to 17%, compared with 6% with radiotherapy alone.⁷¹

An alternative approach, referred to as *concurrent chemoradiation*, is to administer chemotherapy and radiotherapy at the same time. When certain chemotherapeutic agents are given at the same time as radiotherapy, tumor cells become sensitized to the radiation, which enhances the radiation effect. The advantages of this approach are improved local control of the primary tumor and associated nodal disease and a lack of delay in administering radiotherapy. A disadvantage, however, is the necessary reduction in chemotherapy dosage to diminish overlapping toxicities, which can potentially lead to undertreatment of systemic micrometastases. Randomized trials have shown a modest 5-year survival benefit compared with chemotherapy alone.

Preoperative (Induction) Chemotherapy for Non–Small Cell Lung Cancer

The use of chemotherapy before possible surgical resection has a number of potential advantages:

1. The tumor's blood supply is still intact, which allows better chemotherapy delivery and avoids tumor cell hypoxia (in any residual microscopic tumor remaining postoperatively), which would increase radioresistance.
2. The primary tumor may be downstaged with enhanced resectability.
3. Patients are better able to tolerate chemotherapy before surgery and are more likely to complete the prescribed regimen than when chemotherapy is given after surgery.
4. Preoperative chemotherapy functions as an in vivo test of the primary tumor's sensitivity to chemotherapy.
5. Response to chemotherapy can be monitored and used to guide decisions about additional therapy.
6. Systemic micrometastases are treated.
7. Patients who have progressive disease (non-responders) are identified and spared a pulmonary resection.

Potential disadvantages include the following:

1. In theory the perioperative complication rate may increase (predominantly in patients requiring right pneumonectomy after induction chemotherapy).
2. While the patient is receiving chemotherapy, potentially curative resection is delayed; if the patient does not respond, this delay could result in tumor spread.

In stage IIIA N2 disease, the response rates to such chemotherapy are high—in the range of 70%. The treatment is generally safe, because it does not cause a significant increase in perioperative morbidity. Two randomized trials have now compared surgery alone for patients with N2 disease to preoperative chemotherapy followed by surgery.^{68,70} Both trials were stopped before complete accrual because of a significant increase in survival in the chemotherapy arm. The initially observed survival differences have been maintained up to 3 years and beyond (Table 19-14). Given these results, induction chemotherapy with cisplatin-based regimens (two to three cycles) has become standard for patients with N2 disease.

The role of surgery in Stage IIIA NSCLC is still the subject of intense debate. Many surgeons and oncologists differentiate between microscopic and bulky N2 lymphadenopathy and the number of involved N2 nodal stations in determining whether to proceed with resection after induction therapy. Although randomized trials specifically investigating resection after induction therapy in patients with single-station microscopic disease have not yet been performed, proceeding to resection is thought to be appropriate by many surgeons. Furthermore, histologic confirmation of N2 nodal metastases is imperative; false-positive findings on PET scan are unacceptably high, and reliance on this modality will lead to significant undertreatment of patients with earlier-stage cancers. This is particularly true in regions with a high incidence of granulomatous diseases. Patients should not be denied surgical resection after induction

chemotherapy unless they have proven N2 disease, because the survival of patients with early-stage NSCLC is significantly better with resection than with chemotherapy alone.

The use of induction chemotherapy in patients with stage I and II disease is undergoing investigation. Table 19-15 summarizes the findings of a systematic review and meta-analysis reporting stage-specific 5-year survival benefit after induction chemotherapy followed by surgical resection. As shown in Table 19-15, an absolute survival benefit of 4 to 7% can be realized using induction chemotherapy for all stages of lung cancer.

Table 19-15 Five-Year Stage-Specific Survival after Induction Chemotherapy Followed by Surgery			
Stage	5-y Survival (%)	Absolute Benefit (%)	New 5-y Survival (%)

Surgery in Stage IV Disease

The treatment of patients with stage IV disease is chemotherapy. However, on occasion, patients with a single site of metastasis are encountered, particularly patients with adenocarcinomas who have a solitary brain metastasis. In this highly select group, 5-year survival rates of 10 to 15% can be achieved with surgical excision of the brain metastasis and the primary tumor, provided it is early stage.

Small Cell Lung Carcinoma

Small cell lung carcinoma (SCLC) accounts for approximately 20% of primary lung cancers and generally is not treated surgically. These aggressive neoplasms have early, widespread metastases. Histologically, they can be difficult to distinguish from lymphoproliferative lesions and atypical carcinoid tumors. Therefore, a definitive diagnosis must be established with adequate tissue samples. Three groups of SCLC are recognized: pure small cell carcinoma (sometimes referred to as *oat cell carcinoma*), small cell carcinoma with a large cell component, and combined (mixed) tumors.

Unlike with NSCLC, the clinical stage of SCLC is defined broadly by the presence of either local "limited" or distant "disseminated" disease. SCLC presenting with bulky locoregional disease but no evidence for distant metastatic disease is termed *limited* SCLC. Most often, the primary tumor is large and associated with bulky mediastinal adenopathy, which may lead to obstruction of the superior vena cava. SCLC falling into the other clinical stage, termed *disseminated*, usually presents with metastatic disease throughout the patient's body. Regardless of the stage of presentation, treatment is primarily chemotherapy and radiation. Surgery is appropriate for the rare patient with an incidentally discovered peripheral nodule that is found to be SCLC. If a stage I SCLC is identified after resection, postoperative chemotherapy usually is given.

Metastatic Lesions to the Lung

The cause of one or more new pulmonary nodules in a patient with a previous malignancy can be difficult to discern.⁷² Features suggestive of metastatic disease are multiplicity; smooth, round borders on CT scan; and temporal proximity to the original primary lesion. One must always entertain the possibility that a single new lesion is a primary lung cancer. The probability of a new primary cancer vs. a metastasis in patients presenting with solitary lesions depends on the type of initial neoplasm. The likelihood of a new primary lung cancer is highest in patients with a history of uterine carcinoma (74%), bladder carcinoma (89%), lung carcinoma (92%), and head and neck carcinoma (94%).⁷³

Surgical resection of pulmonary metastases has a role in properly selected patients.⁷⁴ Resection of pulmonary metastases is associated with modest survival benefits in a very select group of patients. The general principles of patient selection for metastasis resection are listed in Table 19-16.

Table 19-16 General Principles Governing Appropriate Selection of Patients for Pulmonary Metastasectomy	
1. Primary tumor must already be controlled.	
2. Patient must be able to tolerate general anesthesia, potential single-lung ventilation, and the planned pulmonary resection.	
3. Metastases must be completely resectable based on computed tomographic imaging.	
4. There is no evidence of extrapulmonary tumor burden.	
5. Alternative superior therapy must not be available.	

The technical aim of pulmonary metastasis resections is complete resection of all macroscopic tumors. In addition, any adjacent structure involved should be resected en bloc (i.e., chest wall, diaphragm, and pericardium). Multiple lesions and/or hilar lesions may require lobectomy. Pneumonectomy rarely is justified or used.

Pulmonary metastasis resection can be carried out via thoracotomy or VATS techniques. McCormack and colleagues reported their experience at Memorial Sloan-Kettering in a prospective study of 18 patients who had no more than two pulmonary metastatic lesions and underwent VATS resection.⁷⁵ A thoracotomy was performed during the same operation; if palpation identified any additional lesions, they were resected. The study concluded that the probability that a metastatic lesion will be missed by VATS excision is 56%. The patients in that study were evaluated by standard chest CT scan, because spiral CT scanning was not yet available. It remains controversial whether metastasis resection should be performed via thoracotomy or VATS. Proponents of an open approach refer to the above-referenced study. Proponents of VATS techniques argue that the resolution of spiral CT scanning is so far superior to that of conventional CT that any data collected using old standard CT scans are no longer applicable; they also point to the significantly reduced pain and faster recovery when VATS is used. To date, no prospective study using spiral CT scanning has been performed to resolve this clinical dilemma.

The best data regarding outcomes after resection of pulmonary metastases come from the International Registry of Lung Metastases. The registry was established in 1991 by 18 thoracic surgery departments in Europe, the United States, and Canada, and included data on 5206 patients. Approximately 88% of patients underwent complete resection. An analysis of survival at 5, 10, and 15 years (with grouping of all primary tumor types) was performed (Table 19-17). Multivariate analysis showed a better prognosis for patients with germ cell tumors, osteosarcomas, a disease-free interval of >36 months, and a single metastasis.⁷⁶

Pulmonary Infections

LUNG ABSCESS

A *lung abscess* is a localized area of pulmonary parenchymal necrosis caused by an infectious organism. Tissue destruction results in a solitary or dominant cavity measuring at least 2 cm in diameter. Less often, there may be multiple, smaller cavities (<2 cm). In that case, the infection typically is referred to as *necrotizing pneumonia*. An abscess that is present for >6 weeks is considered chronic.

Based on the etiology (Table 19-18), lung abscesses are further classified as primary or secondary. A primary lung abscess occurs, for example, in immunocompromised patients (as a result of malignancy, chemotherapy, organ transplantation, etc), in patients in whom highly virulent organisms incite a necrotizing pulmonary infection, and in patients who have a predisposition to aspirate oropharyngeal or GI secretions. A secondary lung abscess occurs in patients with an underlying condition such as a partial bronchial obstruction, a lung infarct, or adjacent suppurative infections (subphrenic or hepatic abscesses).⁷⁷

Table 19-18 Causes of Lung Abscess
I. Primary
A. Necrotizing pneumonia
1. <i>Staphylococcus aureus</i> , <i>Klebsiella</i> , <i>Pseudomonas</i> , <i>Mycobacterium</i>
2. <i>Bacteroides</i> , <i>Fusobacterium</i> , <i>Actinomyces</i>
3. <i>Entamoeba</i> , <i>Echinococcus</i>
B. Aspiration pneumonia
1. Anesthesia
2. Stroke
3. Drugs or alcohol
C. Esophageal disease
1. Achalasia, Zenker's diverticulum, gastroesophageal reflux
D. Immunodeficiency
1. Cancer (and chemotherapy)
2. Diabetes

3. Organ transplantation
4. Steroid therapy
5. Malnutrition
II. Secondary
A. Bronchial obstruction
1. Neoplasm
2. Foreign body
B. Systemic sepsis
1. Septic pulmonary emboli
2. Seeding of pulmonary infarct
C. Complication of pulmonary trauma
1. Infection of hematoma or contusion
2. Contaminated foreign body or penetrating injury
D. Direct extension from extraparenchymal infection
1. Pleural empyema
2. Mediastinal, hepatic, subphrenic abscess

Source: Adapted with permission from Rusch VW, et al: Chest wall, pleura, and mediastinum, in Schwartz SI, et al (eds): *Principles of Surgery*, 7th ed. New York: McGraw-Hill, 1999, p 735.

The incidence of bacterial lung abscess in the United States has declined significantly over the past 50 years, with a concomitant decrease in the mortality rate from between 30 and 40% to between 5 and 10%. This decrease has been attributed to the development of bactericidal antibiotics. Factors associated with a worse outcome include advanced patient age, prolonged symptoms, comorbid disease, nosocomial infection, and perhaps larger cavity size. More recently, a greater proportion of lung abscesses have been associated with pulmonary malignancies or immunosuppression, which has resulted in an increase in lung abscesses caused by unusual or opportunistic organisms.

Pathogenesis

Lung abscess is the result of a lower respiratory tract infection only by organisms that cause necrosis. Microorganisms gain access to the respiratory tract via inhalation of aerosolized particles, aspiration of oropharyngeal secretions, or hematogenous spread from distant sites. Direct extension from a contiguous site is less frequent. Most primary lung abscesses are suppurative bacterial infections secondary to aspiration. Risk factors for increased aspiration include impaired consciousness, suppressed cough reflex, dysfunctional esophageal motility, laryngopharyngeal reflux disease, and centrally acting neurologic diseases (e.g., stroke). At the time of aspiration, the composition of the oropharyngeal flora determines the etiologic organisms; those organisms that are most numerous or virulent proliferate and emerge as single or predominant pathogens. With increasing use of proton pump inhibitors to suppress acid secretion in the stomach, the oropharyngeal flora has shifted, and risk of aspiration-associated bacterial infections has increased.⁷⁸ Secondary lung abscesses occur most often distal to an obstructing bronchial carcinoma. Infected cysts or bullae are not considered true abscesses.

The characteristic pathologic features of aspiration pneumonia include alveolar edema and infiltration with inflammatory cells. Because of the effect of gravity, foci of infection tend to develop in the subpleural regions of the superior segments of the lower lobes and in the posterior segments of the upper lobes. The right lung is involved more frequently, presumably because of the less acute angle of the right main bronchus. Thus, the right upper and lower lobes are most commonly affected, followed by the left lower lobe and right middle lobe.

Microbiology

In community-acquired pneumonia, the causative bacteria are predominantly gram positive; in hospital-acquired pneumonia, 60 to 70% of the organisms are gram negative. Gram-negative bacteria associated with nosocomial pneumonia include *Klebsiella pneumoniae*, *Haemophilus influenzae*, *Proteus* species, *Pseudomonas aeruginosa*, *Escherichia coli*, *Enterobacter cloacae*, and *Eikenella corrodens*. Immunosuppressed patients may develop abscesses caused by the usual pathogens as well as less virulent and opportunistic organisms such as *Salmonella* species, *Legionella* species, *Pneumocystis jiroveci*, atypical mycobacteria, and fungi.

Normal oropharyngeal secretions contain many more *Streptococcus* species and more anaerobes (approximately 1×10^8 organisms/mL) than aerobes (approximately 1×10^7 organisms/mL). Pneumonia that follows from aspiration, with or without abscess development, is typically polymicrobial. An average of two to four isolates present in large numbers have been cultured from lung abscesses sampled percutaneously. Overall, at least 50% of these infections are caused by purely anaerobic bacteria, 25% are caused by mixed aerobes and anaerobes, and 25% or fewer are caused by aerobes only.

Clinical Features and Diagnosis

The typical presentation may include productive cough, fever [$>38.9^{\circ}\text{C}$ (102°F)], chills, leukocytosis ($>15,000$ cells/ mm^3), weight loss, fatigue, malaise, pleuritic chest pain, and dyspnea. Lung abscesses also may present in a more indolent fashion, with weeks to months of cough, malaise, weight loss, low-grade fever, night sweats, leukocytosis, and anemia. After aspiration pneumonia, 1 to 2 weeks typically elapse before cavitation occurs; 40 to 75% of such patients produce a putrid, foul-smelling sputum. Severe complications such as massive hemoptysis, endobronchial spread to other portions of the lungs, rupture into the pleural space and development of pyopneumothorax, or septic shock and respiratory failure are rare in the modern antibiotic era. The mortality rate is approximately 5 to 10% except in immunosuppressed patients, in whom rates range from 9 to 28%.

The chest radiograph is the primary tool for diagnosing a lung abscess (Fig. 19-28). Its distinguishing characteristic is a density or mass with a relatively thin-walled cavity. Frequently, an air-fluid level is observed within the abscess, indicating a communication with the tracheobronchial tree. CT scan of the chest is useful to clarify the diagnosis when the chest radiograph is equivocal, assess for endobronchial obstruction and/or an associated mass, and evaluate other pathologic anomalies. A cavitating lung carcinoma frequently is mistaken for a lung abscess. Other possible differential diagnoses include loculated or interlobar empyema, infected lung cysts or bullae, tuberculosis, bronchiectasis, fungal infections, and noninfectious inflammatory conditions (e.g., Wegener's granulomatosis).

Lung abscess resulting from emesis and aspiration after an alcoholic binge. **A.** Chest radiograph showing an abscess cavity in the left upper lobe (arrow). **B.** Coronal tomogram highlighting the thin wall of the abscess (arrow). **C.** Healing of the abscess cavity after 4 weeks of antibiotic therapy and postural drainage.

Identification of the specific etiologic organism should ideally occur before antibiotic administration. Attempts should be made to obtain an adequate specimen for culture analysis to appropriately direct antibiotic therapy and minimize the risk of promoting drug-resistant bacterial speciation. Unfortunately, routine sputum cultures are often of limited usefulness because of contamination with upper respiratory tract flora. Bronchoscopy, which is essential to rule out endobronchial obstruction due to tumor or foreign body, is ideal for obtaining uncontaminated cultures using bronchoalveolar lavage. Culture samples also can be obtained by percutaneous transthoracic FNA under ultrasound or CT guidance.

Management

Systemic antibiotics directed against the causative organism represent the mainstay of therapy. For community-acquired infections secondary to aspiration, likely pathogens are oropharyngeal streptococci and anaerobes. Penicillin G, ampicillin, and amoxicillin are the main therapeutic agents, but a beta-lactamase inhibitor or metronidazole should be added because of the increasing prevalence of gram-negative anaerobes that produce beta-lactamase. Clindamycin is also a primary therapeutic agent. For hospital-acquired infections, frequently encountered causative agents include *Staphylococcus aureus* and aerobic gram-negative bacilli, common organisms of the oropharyngeal flora. Piperacillin or ticarcillin with a beta-lactamase inhibitor (or equivalent alternatives) provides better coverage of likely pathogens. The duration of antimicrobial therapy is variable: 1 to 2 weeks for simple aspiration pneumonia and 3 to 12 weeks for necrotizing pneumonia and lung abscess. It is probably best to treat until the cavity is resolved or until serial radiographs show significant improvement. Parenteral therapy generally is used until the patient is afebrile and able to demonstrate consistent enteral intake. Oral therapy can then be used to complete the course of therapy.

Surgical drainage of lung abscesses is uncommon, because drainage usually occurs spontaneously via the tracheobronchial tree. Indications for intervention are listed in Table 19-19.

Table 19-19 Indications for Surgical Drainage Procedures for Lung Abscesses
1. Failure of medical therapy
2. Abscess under tension
3. Abscess increasing in size during appropriate treatment
4. Contralateral lung contamination
5. Abscess >4–6 cm in diameter
6. Necrotizing infection with multiple abscesses, hemoptysis, abscess rupture, or pyopneumothorax
7. Inability to exclude a cavitating carcinoma

External drainage may be accomplished with tube thoracostomy, percutaneous drainage, or surgical cavernostomy. The choice between thoracostomy placement and radiologic placement of a drainage catheter depends on the treating physician's preference and the availability of interventional radiology. Surgical resection is required in <10% of lung abscess patients. Lobectomy is the preferred intervention for bleeding from a lung abscess or pyopneumothorax. An important intraoperative consideration is to protect the contralateral lung with a double-lumen tube, bronchial blocker, or contralateral main stem intubation. Surgical treatment has a 90% success rate, with an associated mortality of 1 to 13%.

BRONCHIECTASIS

Bronchiectasis is defined as a pathologic and permanent dilation of bronchi with bronchial wall thickening. This condition may be localized to certain bronchial segments or it may be diffuse throughout the bronchial tree, typically affecting the medium-sized airways. Overall, this is a rare clinical entity in the United States with a prevalence of <1 in 10,000.

Pathogenesis

Development of bronchiectasis can be attributed to either congenital or acquired causes. The principal congenital diseases that lead to bronchiectasis include cystic fibrosis, primary ciliary dyskinesia, and immunoglobulin deficiencies (e.g., selective immunoglobulin A deficiency). Congenital causes tend to produce a diffuse pattern of bronchial involvement.

Acquired causes are categorized broadly as infectious and inflammatory. Adenoviruses and influenza viruses are the predominant childhood viral infections associated with the development of bronchiectasis. Chronic infection with tuberculosis remains an important worldwide cause of bronchiectasis.

More significant in the United States are nontuberculous mycobacterial (NTM) infections that cause bronchiectasis, particularly infection by *Mycobacterium avium-intracellulare* complex. Recently, several studies have suggested an association between chronic gastroesophageal reflux disease, acid suppression, and NTM infection with bronchiectasis.^{79,80} This interaction is thought to be related to chronic aspiration of colonized gastric secretions in the setting of acid suppression. Although a causative relationship has not been proven, these findings suggest a role for gastroesophageal reflux disease in the pathogenesis of this disease process.

Noninfectious causes of bronchiectasis include inhalation of toxic gases such as ammonia, which results in severe and destructive airway inflammatory responses. Allergic bronchopulmonary aspergillosis, Sjögren's syndrome, and alpha1-antitrypsin deficiency are some additional examples of presumed immunologic disorders that may be accompanied by bronchiectasis.

The common pathway shared by all of these causes of bronchiectasis is impairment of airway defenses or deficits in immunologic mechanisms that permit bacterial colonization and establishment of chronic infection. Common causative organisms include *Haemophilus* species (55%), *Pseudomonas* species (26%),

and *Streptococcus pneumoniae* (12%). Both the bacterial organisms and the inflammatory cells recruited to thwart the bacteria elaborate proteolytic and oxidative molecules, which progressively destroy the muscular and elastic components of the airway walls; those components are then replaced by fibrous tissue. Thus chronic airway inflammation is the essential pathologic feature of bronchiectasis. The dilated airways usually are filled with thick purulent material; more distal airways are often occluded by secretions or obliterated by fibrous tissue. The vascularity of affected bronchial walls increases, bronchial arteries become hypertrophied, and abnormal anastomoses form between the bronchial and pulmonary arterial circulation.

There are three principal types of bronchiectasis, based on pathologic morphology: cylindrical—uniformly dilated bronchi; varicose—an irregular or beaded pattern of dilated bronchi; and saccular (cystic)—peripheral balloon-type bronchial dilation (Fig. 19-29). The saccular type is the most common after bronchial obstruction or infection.

Fig. 19-29.

Multiple cystic-type bronchiectatic cavities can be seen on a cut section of the right lower lobe of the lung.

Clinical Manifestations and Diagnosis

A daily persistent cough and purulent sputum production are the typical symptoms of bronchiectasis. The quantity of daily sputum production (10 mL to >150 mL) tends to correlate with disease extent and severity. Often, patients with bronchiectasis may appear asymptomatic or have a dry, nonproductive cough ("dry bronchiectasis"). These patients are likely to have involvement of the upper lobes. The clinical course is characterized by progressive symptoms and respiratory impairment. Increasing resting and exertional dyspnea are the result of progressive airway obstruction. Acute exacerbations may be triggered by viral or bacterial pathogens. Hemoptysis may become more frequent as the disease progresses, and bleeding is attributable to chronically inflamed, friable airway mucosa. In more advanced stages, massive bleeding may result from erosions of the hypertrophied bronchial arteries.

The current gold standard of diagnosis is chest CT scanning, which affords a highly detailed cross-sectional view of bronchial architecture. Both mild and severe forms of bronchiectasis are readily demonstrated with this imaging modality. A chest radiograph, although less sensitive, may reveal characteristic signs of bronchiectasis such as lung hyperinflation, bronchiectatic cysts, and dilated, thick-walled bronchi forming train track–like patterns radiating from the lung hila. Sputum culture may identify characteristic pathogens, including *H. influenzae*, *S. pneumoniae*, and *P. aeruginosa*. Acid-fast bacillus smears and cultures of sputum should be performed to evaluate for the presence of NTM, which are common in this setting. The severity of airway obstruction should be determined by spirometry, which also can evaluate the course of disease.

Management

Standard therapy includes optimizing clearance of secretions from the tracheobronchial tree, using bronchodilators to reverse any airflow limitation, and correcting reversible underlying causes whenever possible.⁸² Chest physiotherapy based on vibration, percussion, and postural drainage is widely accepted as the basis for therapy, although randomized trials demonstrating efficacy are lacking. Acute exacerbations should be treated with courses of broad-spectrum antibiotics tailored to culture and sensitivity profiles. Usually, a 2- to 3-week course of IV antibiotics, followed by an oral regimen, will result in a longer-lasting remission. Hyperosmolar agents such as 7% normal saline and dry mannitol also have been suggested as reasonable adjuncts to maintain quality of life and decrease exacerbations by reducing sputum volume, improving mucociliary clearance, and slowing the decline in lung function, although adequately powered randomized trials of these therapies have not been performed.

Over the past decade, investigations into the use of inhaled antibiotics such as tobramycin and colistin have suggested that they improve resolution of

bacterial infection and slow the decline in pulmonary function associated with bronchiectasis, but large, randomized trials showing overall clinical benefit have not yet been published.^{83,84} Macrolide antibiotics have also generated significant interest, for both their antibacterial and nonantibacterial properties. Macrolide antibiotics have been shown to decrease sputum production, inhibit cytokine release, and inhibit neutrophil adhesion and formation of reactive oxygen species. They also inhibit migration of *Pseudomonas*, disrupt biofilm, and prevent release of virulence factors.⁸⁵ Although macrolide therapy does appear to be efficacious, it is important to remember that macrolides have significant activity against NTM, and widespread prophylactic use in patients with bronchiectasis may lead to the emergence of multidrug-resistant NTM species.

Surgical resection of a localized bronchiectatic segment or lobe may benefit patients with refractory symptoms who are receiving maximal medical therapy. Multifocal disease must be excluded before any surgery is attempted; any uncorrectable predisposing factor (e.g., ciliary dyskinesia) also must be excluded. An important surgical tenet is to preserve as much normal parenchyma as possible. Patients with end-stage lung disease from bronchiectasis may be potential candidates for bilateral lung transplantation. Surgical resection also is indicated in patients with large hemoptysis secondary to hypertrophied bronchial arteries. Because resection may not always be clinically practical, bronchial artery embolization is an alternative.

MYCOBACTERIAL INFECTIONS

Epidemiology

Tuberculosis is a widespread problem that affects nearly one third of the world's population. Currently, approximately 9 million new cases of tuberculosis are reported annually worldwide and almost 2 million tuberculosis-related deaths occur—more than for any other single infectious disease. In 2007, it was the leading killer of persons infected with HIV.⁸⁶ In the United States, infection with mycobacteria is also a significant health problem, with an estimated 3 to 4% of infected individuals developing active disease within the first year, and 5 to 15% of all patients thereafter. During the 1980s a resurgence of tuberculosis occurred, related primarily to the emergence of AIDS. More than 20,000 new cases of tuberculosis are now reported annually in the United States, although there has been a sharp decline in the incidence of new cases among U.S.-born citizens since 1993 (2.1 per 100,000, which represents a decrease of 71% since 1993). This is partly attributable to renewed public and federal interest in eliminating tuberculosis from the United States.⁸⁷

The elderly, minorities, and recent immigrants are the populations that most commonly show clinical manifestations of infection, yet no age group, sex, or race is exempt from infection. In most large urban centers, reported cases of tuberculosis are more numerous among the homeless, prisoners, and drug-addicted populations. Tuberculosis in immunocompromised patients also contributes to the increased incidence, and such patients often develop unusual systemic as well as pulmonary manifestations.⁸⁸ In comparison with past decades, surgical intervention now is required more frequently in patients with multidrug-resistant tuberculosis (MDRTB) who do not respond to medical treatment and in selected patients with NTM infections.

Microbiology

Mycobacterial species are obligate aerobes. They are primarily intracellular parasites with slow rates of growth. Their defining characteristic is the property of acid-fastness, which is the ability to withstand decolorization by an acid-alcohol mixture after being stained.

Mycobacterium tuberculosis is the highly virulent bacillus of this species that produces invasive infection among humans, principally pulmonary tuberculosis. Because of improper application of antimycobacterial drugs and multifactorial interactions, MDRTB organisms have emerged that are defined by their resistance to at least two of the first-line antimycobacterial drugs (isoniazid and rifampin). Approximately 10% of new tuberculosis cases and 40% of recurrent cases are attributed to MDRTB organisms. In addition, there is another rare variant termed *extensively drug-resistant tuberculosis*, which is caused by organisms resistant to isoniazid and rifampin, all fluoroquinolones, and at least one of the injectable second-line drugs (capreomycin, amikacin, kanamycin).⁸⁹

The more important NTM organisms include *Mycobacterium kansasii*, *M. avium*, *M. avium-intracellulare* complex (MAC), and *M. fortuitum*. The highest incidence of *M. kansasii* infection is in midwestern U.S. cities among middle-aged males in good socioeconomic environments. MAC organisms are important agents of infection in elderly and immunocompromised patient groups. *M. fortuitum* infections are common complications of underlying severe debilitating disease. None of these organisms is as contagious as *M. tuberculosis*.

Pathogenesis and Pathology

The main route of transmission is via airborne inhalation of viable mycobacteria. Three stages of primary infection have been described. In the first stage, alveolar macrophages become infected through ingestion of the bacilli. These infected macrophages then release chemoattractants to recruit additional macrophages. In the second stage, from days 7 to 21, the patient typically remains asymptomatic while the bacteria multiply within the infected macrophages. The third stage is characterized by the onset of cell-mediated immunity (CD4⁺ helper T cells) and delayed-type hypersensitivity. Activated macrophages acquire an increased capacity for bacterial killing. Macrophage death increases, which results in the formation of a granuloma, the characteristic lesion found on pathologic examination.

Tuberculous granulomas are composed of blood-derived macrophages, degenerating macrophages or epithelioid cells, and multinucleated giant cells (fused macrophages with nuclei around the periphery, also known as *Langerhans cells*). T lymphocytes are found at the periphery of granulomas. The low oxygen

content of this environment inhibits macrophage function and bacillary growth, with subsequent central caseation as macrophage death occurs. A Ghon complex is a single small lung lesion that often is the only remaining trace of a primary infection. The primary infection usually is located in the peripheral portion of the middle zone of the lungs. Reactivation of tuberculosis infection may occur after hydrolytic enzymes liquify the caseum. Typically, the apical and posterior segments of the upper lobes and the superior segments of the lower lobes are involved. Edema, hemorrhage, and mononuclear cell infiltration also are present. The tuberculous cavity may become secondarily infected with other bacteria, fungi, or yeasts, all of which may contribute to enhanced tissue destruction.

The pathologic changes caused by NTM organisms are similar to those produced by *M. tuberculosis*. MAC infections commonly occur not only in immunocompromised patients but also in patients with previously damaged lungs. Caseous necrosis is uncommon, and the infection is characterized by clusters of tissue macrophages filled with mycobacteria. There is a poor granulomatous response, and immune cell infiltration is confined to the interstitium and alveolar walls. Cavitory disease is infrequent, although nodules may be noted.

Clinical Presentation and Diagnosis

The clinical course of infection and the presentation of symptoms are influenced by many factors, including the site of primary infection, the stage of disease, and the degree of cell-mediated immunity. Approximately 80 to 90% of tuberculosis patients present with clinical disease in the lungs. In 85 to 90% of these patients, involution and healing occur, which leads to a dormant phase that may last a lifetime. The only evidence of tuberculosis infection may be a positive skin reaction to tuberculin challenge or a Ghon complex observed on chest radiograph. Within the first 2 years of primary infection, reactivation may occur in up to 10 to 15% of infected patients. In 80%, reactivation occurs in the lungs; other reactivation sites include the lymph nodes, pleura, and musculoskeletal system.

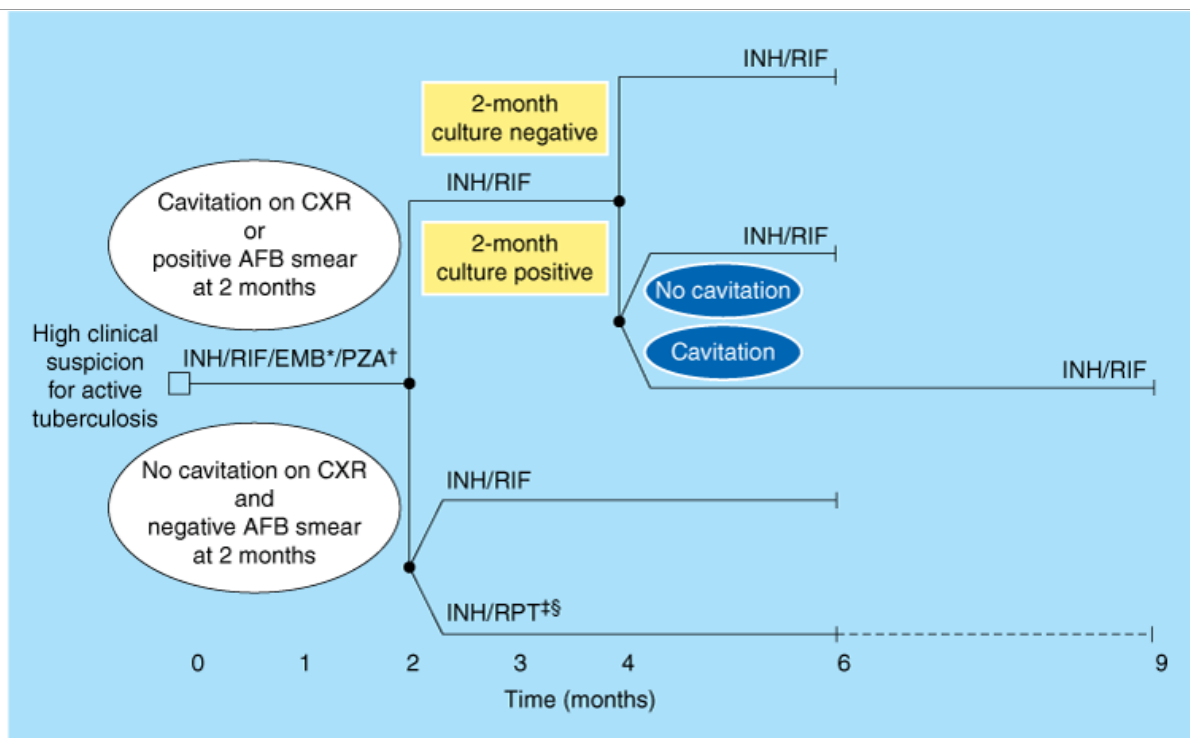

After primary infection, pulmonary tuberculosis frequently is asymptomatic. Systemic symptoms of low-grade fever, malaise, and weight loss are subtle and may go unnoticed. A productive cough may develop, usually after tubercle cavitation. Many radiographic patterns can be identified at this stage, including local exudative lesions, local fibrotic lesions, cavitation, bronchial wall involvement, acute tuberculous pneumonia, bronchiectasis, bronchostenosis, and tuberculous granulomas. Hemoptysis often develops from complications of disease such as bronchiectasis or erosion into vascular malformations associated with cavitation. Extrapulmonary involvement is due to hematogenous or lymphatic spread from pulmonary lesions. Virtually any organ can become infected, which gives rise to the protean manifestations of tuberculosis. Of note to the thoracic surgeon, the pleura, chest wall, and mediastinal organs may all be involved. More than one third of immunocompromised patients have disseminated disease, with hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

A definitive diagnosis of tuberculosis requires identification of the mycobacterium in a patient's bodily fluids or involved tissues. Skin testing using purified protein derivative is important for epidemiologic purposes and can help exclude infection in uncomplicated cases. For pulmonary tuberculosis, sputum examination is inexpensive and has a high diagnostic yield. Bronchoscopy with alveolar lavage also may be a useful diagnostic adjunct and has high diagnostic accuracy. Chest CT scan can delineate the extent of parenchymal disease.

Management

Medical therapy is the primary mode of treatment of pulmonary tuberculosis and often is initiated before a mycobacterial pathogen is definitively identified. Combinations of two or more drugs are routinely used to minimize resistance, which inevitably develops with only single-agent therapy. A current treatment algorithm is outlined in Fig. 19-30. First-line drugs include isonicotinic acid hydrazine (isoniazid), ethambutol, rifampin, and pyrazinamide. Second-line drugs include cycloserine, ethionamide, kanamycin, ciprofloxacin, and amikacin, among others. In the case of MDRTB organisms, four or more antimycobacterial drugs often are used, generally for 18 to 24 months. Rifampin and isoniazid augmented with one or more second-line drugs are most commonly used to treat NTM infections. Generally, therapy lasts approximately 18 months. The overall response is satisfactory in 70 to 80% of patients with *M. kansasii* infection. Surgical intervention rarely is required in those 20 to 30% who do not respond to medical therapy. In contrast, pulmonary MAC infections respond poorly, even to combinations of four or more drugs, and most patients eventually require surgical intervention. Overall, sputum conversion is achieved in only 50 to 80% of those with NTM infections, and relapses occur in up to 20% of patients.

Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proven or strongly suspected should have treatment initiated with isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph (CXR) or the acid-fast bacillus (AFB) smear results are positive at completion of 2 months of treatment, the continuation phase of treatment should consist of INH and RIF daily or twice daily for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial CXR and the culture results at the time of completion of 2 months of therapy are positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD4⁺ cell count is <100/ μ L, the continuation phase should consist of daily or three times weekly INH and RIF. In HIV-uninfected patients with no cavitation on CXR and negative results on AFB smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly INH and rifapentine (RPT) or daily or twice weekly INH and RIF to complete a total of 6 months of treatment (*bottom*). For patients receiving INH and RPT whose 2-month culture results are positive, treatment should be extended by an additional 3 months (total of 9 months). *EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses). ‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. §Therapy should be extended to 9 months if results of 2-month culture are positive.

Official Journal of the American Thoracic Society. Copyright © American Thoracic Society.)

In the United States, surgical intervention is most often required to treat patients infected with MDRTB organisms whose lungs have been destroyed and who have persistent thick-walled cavitation.⁹⁰ The indications for surgery related to mycobacterial pulmonary infections are presented in Table 19-20.

Table 19-20 Indications for Surgery to Treat Mycobacterial Pulmonary Infections

1. Complications resulting from previous thoracic surgery to treat tuberculosis
2. Failure of optimized medical therapy (e.g., progressive disease, lung gangrene, or intracavitary aspergillosis superinfection)
3. Need for tissue acquisition for definitive diagnosis
4. Complications of pulmonary scarring (e.g., massive hemoptysis, cavernomas, bronchiectasis, or bronchostenosis)
5. Extrapulmonary thoracic involvement
6. Pleural tuberculosis
7. Nontuberculous mycobacterial infection

The governing principle of mycobacterial surgery is to remove all gross disease while preserving any uninvolved lung tissue. Scattered nodular disease may be left intact, given its low mycobacterial burden. Antimycobacterial medications should be given preoperatively (for approximately 3 months) and continued postoperatively for 12 to 24 months. Overall, >90% of patients who were deemed good surgical candidates are cured when appropriate medical and surgical therapy is used.

ACTINOMYCETIC INFECTIONS

Actinomycosis

Members of the families Actinomycetaceae and Nocardiaceae were once considered fungi but are now classified as bacteria. Actinomycosis is a chronic disease usually caused by *Actinomyces israelii*. It is characterized by chronic suppuration, sinus formation, and discharge of purulent material containing yellow-brown sulfur granules.⁹⁰ Approximately 15% of infections involve the thorax; organisms enter the lungs via the oral cavity (where they normally reside). Because the disease is uncommon, making the correct diagnosis can be challenging,⁹² and the clinician must first suspect the disease and then perform appropriate culture analysis under anaerobic conditions. Lung involvement can present with progressive pulmonary fibrosis in the periphery. Pleural and chest wall involvement (periostitis of the ribs) is an associated finding. Treatment consists of prolonged high-dose penicillin, which is very effective. Because of the intense fibrotic reaction surrounding affected parenchyma, surgery is seldom possible.

Nocardiosis

Nocardia asteroides is an aerobic, acid-fast, gram-positive organism that usually causes nocardiosis, a disease similar to actinomycosis with additional CNS involvement. In addition, hematogenous dissemination from a pulmonary focus may lead to generalized systemic infection. The disease process ranges from benign, self-limited suppuration of skin and subcutaneous tissues to pulmonary (extensive parenchymal necrosis and abscesses) and systemic (e.g., CNS) manifestations. In immunosuppressed patients, pulmonary cavitation or hematogenous dissemination may be accelerated. Prolonged treatment (2 to 3 months) with sulfadiazine, minocycline, or trimethoprim-sulfamethoxazole is typically required. Surgery to drain abscesses and empyema is indicated.

PULMONARY MYCOSES

An important differential diagnosis to consider in thoracic pathology in general is a mycotic lung infection, which can mimic a bronchial carcinoma or tuberculosis. Most fungi are secondary or opportunistic pathogens that cause pulmonary and systemic infections in humans only when natural host resistance is impaired. Clinically significant examples include species of *Aspergillus*, *Cryptococcus*, *Candida*, and *Mucor*. However, some fungi are primary or true pathogens, able to cause infections in otherwise healthy patients. Some examples endemic in the United States are species of *Histoplasma*, *Coccidioides*, and *Blastomyces*.⁹³

The incidence of fungal infections has increased significantly, with many new opportunistic fungi emerging. This increase is attributed to the growing population of immunocompromised patients (i.e., organ transplant recipients, cancer patients undergoing chemotherapy, HIV-infected patients, and young and elderly patients), who are more likely to become infected with fungi.⁹⁴ Other at-risk patient populations include those who are malnourished, severely debilitated, or diabetic, or who have hematologic disorders. Patients receiving high-dose, intensive antibiotic therapies are also susceptible. Definitive diagnosis of a fungal infection is achieved by directly identifying the organism in body exudates or tissues, preferably by growing in culture. Serologic testing to identify mycotic-specific antibodies also may be a useful diagnostic tool. Although these infections were previously difficult to treat, several new classes of antifungal agents are now available that are effective against many life-threatening fungi and are less toxic than older agents. In addition, thoracic surgery may be a useful therapeutic adjunct for patients with pulmonary mycoses.

Aspergillosis

The genus *Aspergillus* comprises over 350 species, three of which are most commonly responsible for clinical disease: *A. fumigatus*, *A. flavus*, and *A. niger*. *Aspergillus* is a saprophytic, filamentous fungus with septate hyphae. Spores (2.5 to 3 µm in diameter) are released and easily inhaled by susceptible patients; because the spores are microns in size, they are able to reach the distal bronchi and alveoli.

Aspergillosis can manifest as one of three clinical syndromes: *Aspergillus* hypersensitivity lung disease, aspergilloma, or invasive pulmonary aspergillosis. Overlap occurs between these syndromes, depending on the patient's immune status.⁹⁵ Hypersensitivity results in productive cough, fever, wheezing, pulmonary infiltrates, eosinophilia, and elevated levels of immunoglobulin E antibodies to *Aspergillus*.

Aspergilloma (fungus ball) is a matted sphere of hyphae, fibrin, and inflammatory cells that tends to colonize pre-existing intrapulmonary cavities. Grossly, it appears as a round or oval, friable, gray (or red, brown, or even yellow), necrotic-looking mass (Fig. 19-31). This form is the most common presentation of noninvasive pulmonary aspergillosis. Although some aspergillomas are found incidentally during radiographic evaluation for other reasons, they most commonly present with hemoptysis. Other common complaints include chronic and productive cough, clubbing, malaise, or weight loss. Chest radiography can suggest the diagnosis by the finding of a crescentic radiolucency above a rounded radiopaque lesion (Monad sign).

Pulmonary aspergilloma. **A.** The chest radiograph shows a solid mass within a cavity surrounded by a rim of air between the mass and cavity wall (Monad sign, *arrows*). **B.** A cut section shows the fungus ball occupying an old, fibrotic cavity. **C.** Histologic stain reveals characteristic *Aspergillus* hyphae invading the wall of the cavity.

Treatment of pulmonary aspergilloma is individualized. Asymptomatic patients can be observed without any additional therapy. Similarly, mild hemoptysis that is not life-threatening can be managed with medical therapy, including antifungals and cough suppressants. Amphotericin B is the drug of choice, although voriconazole recently has been used for treatment of aspergillosis, with fewer side effects and equivalent efficacy.

Massive hemoptysis had traditionally been an indication for urgent or emergent operative intervention. However, with the advancement of endovascular techniques, bronchial artery embolization in select centers with experience in these techniques has been effective. Patients can now be successfully stabilized with endovascular embolization and may, in many cases, require no further intervention. This approach is particularly important to consider in patients with severely impaired pulmonary function who may not have sufficient reserve to tolerate even a very small pulmonary resection. Other indications for surgical intervention include recurrent hemoptysis, particularly after bronchial artery embolization⁹⁶; chronic cough with systemic symptoms; progressive infiltrate around the mycetoma; and a pulmonary mass of unknown cause.

When operative intervention is indicated, the surgeon must remain cognizant of the goals of the procedure. Because this disease typically occurs in patients with significantly impaired pulmonary function, attempts should be made to excise all diseased tissue with as limited a resection as possible. Once resection is completed, the postresection space in the hemithorax should be obliterated with a pleural tent, pneumoperitoneum, pulmonary decortications, intrathoracic rotation of a muscle, or omental flap or thoracoplasty. Long-term follow-up is necessary, given that the recurrence rate after surgery is approximately 7%.

Invasive pulmonary aspergillosis typically affects immunocompromised patients who have dysfunctional cellular immunity, namely, defective polymorphonuclear leukocytes. Invasion of pulmonary parenchyma and blood vessels by a necrotizing bronchopneumonia may be complicated by thrombosis, hemorrhage, and then dissemination. Patients present with fever that is nonresponsive to antibiotic therapy in the setting of neutropenia. They may also have pleuritic chest pain, cough, dyspnea, or hemoptysis. Chest CT scanning, in addition to routine radiography, may reveal finer details of the infective process and characteristic signs (e.g., halo sign and cavitary lesions). Treatment of invasive pulmonary aspergillosis has been revolutionized in the past decade, with a randomized trial demonstrating a significant survival benefit with voriconazole over amphotericin B.⁹⁷ The mortality rate is high, ranging from 93 to 100% in bone marrow transplant recipients to approximately 38% in kidney transplant recipients, although this is improved to approximately 60% at 12 weeks with voriconazole therapy. Several other advances in diagnosis and treatment, including CT scanning in high-risk populations and development of additional triazoles and echinocandins, have improved early identification and response to therapy in this patient population. Serologic tests have been developed, but their accuracy is limited at this time. Additional treatment considerations include the use of hematopoietic growth factors to minimize the neutropenic period, which contributes to uncontrolled disease. Surgical removal of the infectious nidus is advocated by some groups because medical treatment is associated with such poor outcomes.

Cryptococcosis

Cryptococcosis is a subacute or chronic infection caused by *Cryptococcus neoformans*, a round, budding yeast (5 to 20 μm in diameter) that is sometimes surrounded by a characteristic wide gelatinous capsule. Cryptococci typically are present in soil and dust contaminated by pigeon droppings. When inhaled, such droppings can cause a nonfatal disease primarily affecting the pulmonary and central nervous systems. At present, cryptococcosis is the fourth most common opportunistic infection in patients with HIV infection, affecting 6 to 10% of that population. Four basic pathologic patterns are seen in the lungs of infected patients: granulomas, granulomatous pneumonia, diffuse alveolar or interstitial involvement, and proliferation of fungi in alveoli and lung vasculature. Symptoms are nonspecific, as are the radiographic findings. *Cryptococcus* may be isolated from sputum, bronchial washings, samples obtained by percutaneous needle aspiration of the lung, or cerebrospinal fluid. Multiple antifungal agents are effective against *C. neoformans*, including amphotericin B and the azoles.

Candidiasis

Candida organisms are oval, budding cells (with or without mycelial elements) that colonize the oropharynx of many healthy individuals. The fungi of this genus are common hospital and laboratory contaminants. Usually, *C. albicans* causes disease in the oral or bronchial mucosa, among other anatomic sites. Other potentially pathogenic *Candida* species include *C. tropicalis*, *C. glabrata*, and *C. krusei*. Historically, *C. albicans* was the pathogen that most commonly caused invasive candidal infection. However, more recent reports suggest the other *Candida* species, particularly *C. glabrata* and *C. krusei*, are becoming more prevalent. These species are relatively resistant to fluconazole, and the shift is likely related to the widespread use of this antifungal agent.⁹⁸

Candida infections have increased in incidence and are no longer confined to immunocompromised patients. Rising incidence of infection has been seen in patients with any of the following risk factors: critical illness of long duration; long-term use of antibiotics, particularly multiple drugs; indwelling urinary or vascular catheter; and GI perforation or burn wounds.⁹⁹ With respect to the thorax, such patients commonly have candidal pneumonia, pulmonary abscess, esophagitis, and mediastinitis. Pulmonary candidal infections typically result in an acute or chronic granulomatous reaction. Because *Candida* can invade blood vessel walls and a variety of tissues, systemic or disseminated infections can occur, but are less common.

Treatment of candidal infection, similar to that of other fungal infections, has changed dramatically in the past decade. Amphotericin B, often in combination with 5-fluorocytosine, is a proven therapeutic treatment for *Candida* tissue infections. Newer classes of antifungals have been developed. The fungicidal medications include polyenes (amphotericin B deoxycholate and various lipid-associated amphotericin B preparations) and the echinocandins (caspofungin, micafungin, and anidulafungin). Fungistatic drugs include the triazoles (fluconazole, itraconazole, voriconazole, and posaconazole).⁹⁸ The availability of multiple effective therapies allows for specific tailoring of treatment, including the use of combination regimens, based on the patient's ability to tolerate associated toxicities, the microbiologic information for the specific candidal species, and the route of administration. Although their demonstrated efficacy is similar, the triazoles and echinocandins appear to have fewer side effects and are better tolerated than the other classes of antifungal drugs. For patients with *Candida* mediastinitis (which has a mortality rate of over 50%), surgical intervention to débride all infected tissues is required, in addition to prolonged administration of antifungal drugs.

Mucormycosis

The *Mucor* species, rare members of the class Zygomycetes, are responsible for rapidly fatal disease in immunocompromised patients. Other disease-causing species of the class Zygomycetes include *Absidia*, *Rhizopus*, and *Mortierella*.¹⁰⁰ These fungi are characterized by nonseptate, branching hyphae and are difficult to culture. Infection occurs via inhalation of spores. Neutropenia, acidosis, diabetes, and hematologic malignancy all predispose patients to clinical susceptibility. In the lungs, disease consists of blood vessel invasion, thrombosis, and infarction of infected organs. Tissue destruction is significant, along with cavitation and abscess formation. Initial treatment is to correct underlying risk factors and administer antifungal therapies, although the optimal duration and optimal total dose are unknown. Surgical resection of any localized disease should be performed after initial medical treatment attempts fail.

Primary Fungal Pathogens

Histoplasma capsulatum is a dimorphic fungus existing in mycelial form in soil contaminated by fowl or bat excreta, and in yeast form in human hosts. Histoplasmosis primarily affects the respiratory system after spores are inhaled. It is the most common of all fungal pulmonary infections. In the United States, this disease is endemic in the Midwest and Mississippi River Valley, where approximately 500,000 new cases arise each year. Active, symptomatic disease is uncommon. Acute forms of the disease present as primary or disseminated pulmonary histoplasmosis; chronic forms present as pulmonary granulomas (histoplasmomas), chronic cavitary histoplasmosis, mediastinal granulomas, fibrosing mediastinitis, or broncholithiasis. In immunocompromised patients, the infection becomes systemic and more virulent; because cell-mediated immunity is impaired, uninhibited fungal proliferation occurs within pulmonary macrophages and then spreads. Histoplasmosis is definitively diagnosed by fungal smear, culture, direct biopsy of infected tissues, or serologic testing.

The clinical presentation depends on the inoculum size and on host factors. Patients with acute pulmonary histoplasmosis commonly present with fever, chills, headache, chest pain, musculoskeletal pain, and nonproductive cough. Chest radiographs may be normal or may show mediastinal lymphadenopathy and

patchy parenchymal infiltrates. Most patients improve in a few weeks and do not require antifungal therapy. Amphotericin B is the treatment of choice if moderate symptoms persist for 2 to 4 weeks; if the illness is extensive, including dyspnea and hypoxia; and if patients are immunosuppressed.¹⁰¹

As the pulmonary infiltrates from acute histoplasmosis heal, consolidation into a solitary nodule or histoplasmoma may occur. This condition is asymptomatic and usually is seen incidentally on radiographs as a coin-shaped lesion. Central calcification may occur; if so, no further treatment is required. Noncalcified lesions require further diagnostic work-up including chest CT scan, needle biopsy, or surgical excision to rule out a malignancy. Figure 19-32 shows the differences in pathologic findings between infections in normal and in immunocompromised hosts.¹⁰²

Fig. 19-32.

Pathologic findings of infection in normal and immunocompromised hosts. Histopathologic preparations are shown contrasting acute diffuse pulmonary involvement in a lung segment of a normal host with a probable primary infection (**A** through **D**) with pulmonary granulomas from an immunocompromised patient who had an opportunistic reinfection with *Histoplasma capsulatum* (**E**, **F**). **A**. Diffuse interstitial pneumonitis in an adult (normal host) with recent heavy environmental exposure and subsequent development of progressive pulmonary disease. There is an inflammatory cell infiltrate primarily involving the interalveolar interstitial spaces but present within many alveolar spaces as well. The exudate consists mostly of mononuclear phagocytes, lymphocytes, and occasional plasma cells. Many of the alveolar walls are markedly thickened [hematoxylin and eosin stain (H&E), x50]. **B**. Another area from the same lung as in **A** showing focal vasculitis with an infiltrate of lymphocytes and macrophages (H&E, x25). **C**. Relatively large alveolar macrophages packed with single and budding yeasts 2 to 4 μm in diameter (same lung as in **A** and **B**). The basophilic cytoplasm of these yeasts is retracted from their thin outer cell walls, leaving halo-like clear areas that can be confused with capsules (H&E, x500). **D**. Intracellular and extracellular yeasts, 2 to 4 μm in diameter, some of which are single, budding, or in short chains (Gomori methenamine silver stain, x500). **E**. Nonnecrotizing (sometimes called *epithelioid cell* or *noncaseating*) granuloma from a patient who had recently received chemotherapy for a germ cell tumor (different patient than in **A** through **D**). This lesion consists of a focal collection of macrophages (sometimes referred to as *histiocytes* or *epithelioid cells*) plus lymphocytes and occasional plasma cells. A few multinucleated macrophages are present. A thin layer of fibroblasts circumscribes the lesion. Yeasts of *H. capsulatum*, probably present within macrophages of this lesion at an earlier stage, were not identified in this granuloma or in any of several other nonnecrotizing granulomas within the specimen. Lesions of this type often undergo necrosis to become necrotizing granulomas (H&E, x50). **F**. Necrotizing (sometimes referred to as *caseating*) granuloma from the same lung as in **E**. This lesion has a necrotic center surrounded by macrophages, encapsulating fibroblasts, fibrous connective tissue in the periphery, and scattered lymphocytes. A prominent giant cell is present in the lower left of the granuloma (at approximately 8 o'clock). Micro-organisms are usually present only in

relatively small numbers in these types of lesions. They are most frequently detected within the most central necrotic material in these granulomas (H&E, x25).

(Reproduced with permission from Hage et al.¹⁰²)

When lymph nodes and pulmonary granulomas calcify over time, pressure atrophy on the bronchial wall may result in erosion and migration of the granulomatous mass into the bronchus, causing broncholithiasis. Typical symptoms include cough, hemoptysis, and dyspnea. Life-threatening complications include massive hemoptysis or bronchoesophageal fistula. In addition to radiography, bronchoscopy should be performed to aid in diagnosis. Definitive treatment is surgical; the bronchial mass should be removed and any associated complications repaired. Endobronchial débridement is not advised, because this can result in massive, fatal bleeding.

Chronic cavitary histoplasmosis occurs in approximately 10% of patients who become symptomatic after infection. Most such patients have pre-existing lung pathology such as COPD or emphysema. The disease begins with colonization of diseased lung spaces, development of ongoing pneumonitis and necrosis, cavity enlargement, new cavity formation, and eventual spread to other areas of lung. Nonspecific symptoms, such as cough, sputum production, fever, weight loss, weakness, and hemoptysis are common. Chest radiography may reveal intrapulmonary cavitation and scarring. Occasionally, partial resolution of the inflammatory changes may be observed. Triazole therapy (such as itraconazole or ketoconazole) provides effective therapy. Occasionally, combination therapy or the use of polyenes (such as lipid-associated amphotericin B) or echinocandins is necessary for management of more severe infections. In patients with adequate pulmonary reserve and localized, thick-walled cavities that have been unresponsive to antifungal therapy, surgical excision should be considered.

Disseminated histoplasmosis occurs most frequently in patients who are severely immunocompromised, such as posttransplantation patients, HIV-infected patients, and patients using immunosuppressive medications. The presentation is a spectrum of illness, ranging from nonspecific signs of fever, weight loss, and malaise to shock, respiratory distress, and multiorgan failure. Diagnosis can be made with a combination of *Histoplasma* urine antigen testing, serologic assay, and fungal culture and should be suspected in patients with the aforementioned symptoms in any endemic area, particularly if the patient is immunosuppressed. Any of the antifungal therapies can be used in the treatment of disseminated histoplasmosis.¹⁰³ Use of amphotericin B has decreased the mortality rate to <25% in this type of serious infection.

Coccidioides immitis is an endemic fungus found in the soil and dust of the southwestern United States. The major risk factors for symptomatic infection are related to occupation, host factors, and exposure to the fungus in endemic areas. Those in occupations that involve significant exposure to soil, such as agricultural workers and military personnel, especially in endemic areas, are at substantial risk. Those with immunosuppression due to medications or illness (such as AIDS) are also at risk.¹⁰⁴ The infection results from inhalation of spores (arthroconidia), which individually swell into spherules that later subdivide into endospores. Positive results from cultures of sputum, other body fluid, or tissue are necessary for a definitive diagnosis. Of patients who develop symptomatic disease, 95% have pulmonary involvement, which can be divided into three main categories, depending on the associated signs and symptoms: primary, complicated, and residual pulmonary coccidioidomycosis. Primary pulmonary coccidioidomycosis occurs in approximately 40% of people who inhale spores. The other 60% will remain asymptomatic and develop lifelong immunity. The symptoms of coccidioidomycosis, known as *valley fever*, consist of fever, chills, headache, erythema multiforme, erythema nodosum, polyarthralgias, nonproductive cough, and chest pain. Chest radiographic findings of hilar and paratracheal adenopathy and the aforementioned constellation of atypical symptoms are suggestive of pulmonary coccidioidomycosis. When symptoms and radiographic findings persist for longer than 6 to 8 weeks, the disease is considered to be persistent coccidioidal pneumonia, which occurs in approximately 1% of patients. Progression to caseous nodules, cavities, and calcified, fibrotic, or ossified lesions indicates complicated or residual stages of the disease.

There are several relative indications for surgery in pulmonary coccidioidomycosis. A rapidly expanding (>4 cm) cavity that is close to the visceral pleura presents a high risk for rupture into the pleural space and subsequent empyema. Life-threatening hemoptysis or hemoptysis that is persistent despite medical therapy, symptomatic fungus ball, and bronchopleural fistula are also indications for operative intervention. Long-standing cavities with sputum persistently positive for the fungus and pulmonary nodules that degenerate over time should also be resected. Finally, any nodule that causes concern for malignancy must be biopsied and/or resected to determine the underlying cause.

Diagnosis of coccidioidomycosis is confirmed by histopathologic, mycologic, and serologic evaluation. In a small minority of infected patients (0.5%) extrapulmonary disease may develop, with involvement of the meninges, bones, joints, skin, or soft tissues. Immunocompromised patients are especially susceptible to disseminated coccidioidomycosis, which carries a mortality rate of >40%. Treatment options for this disease vary depending on the severity of the disease as well as the stage. Amphotericin B deoxycholate or the triazoles continue to be the primary antifungal medications. Treatment of primary pulmonary coccidioidomycosis remains controversial, because in most patients the infection will resolve without further intervention. Itraconazole and fluconazole are effective treatments for patients with mild to moderate disease with evidence of pulmonary cavitation or progressive chronic pulmonary lesions. Amphotericin B is warranted for patients with severe pulmonary or disseminated disease and for immunocompromised patients.

Blastomyces dermatitidis is a round, single-budding yeast with a characteristic thick, refractile cell wall. It resides in the soil as a nonmotile spore called a *conidia*. Exposure occurs when contaminated soil is disturbed and the conidia are aerosolized. The spore is inhaled and transforms into a yeast phase at body temperature.¹⁰⁵ The majority of exposed persons develop a self-limited infection. A small minority of patients develop chronic pulmonary infection or disseminated disease, including cutaneous, osteoarticular, or genitourinary involvement.

B. dermatitidis has a worldwide distribution. In the United States it is endemic in the central states.¹⁰⁶ In the chronic infection, the organism induces a granulomatous and pyogenic reaction with microabscesses and giant cells; caseation, cavitation, and fibrosis may also occur. Symptoms are nonspecific and consistent with chronic pneumonia in 60 to 90% of patients. They include cough, mucoid sputum production, chest pain, fever, malaise, weight loss, and, uncommonly, hemoptysis. In acute disease, radiographs are either completely negative or have nonspecific findings; in chronic disease, fibronodular lesions (with or without cavitation) similar to those of tuberculosis are noted. Pulmonary parenchymal abnormalities in the upper lobe(s) may be noted. Mass lesions similar to carcinoma are common, and lung biopsy is frequently performed. Over 50% of patients with chronic blastomycosis also have extrapulmonary manifestations, but <10% of patients present with severe clinical manifestations.¹⁰⁵

Once a patient manifests symptoms of chronic blastomycosis, antifungal treatment is required to achieve resolution. If the disease is untreated, mortality approaches 60%.¹⁰⁵ While controversial, many support a short course of triazole therapy (oral itraconazole 200 mg daily) for 6 months as the treatment of choice for most patients with mild to moderate forms of the disease. Itraconazole has poor CNS penetration. The most common site of recurrence after apparently successful therapy is in the CNS. In the absence of therapy, close follow-up is warranted for evidence of progression to chronic or extrapulmonary disease. Amphotericin B is indicated for patients with severe or life-threatening disease, CNS involvement, disseminated disease, or extensive lung involvement, and for immunocompromised patients. After adequate drug therapy, surgical resection of known cavitary lesions should be considered, because viable organisms are known to persist in such lesions.

Antifungals

Limitations still exist in the treatment of fungal pneumonias. The major classes of antifungal therapies now include the polyenes (amphotericin and lipid-associated amphotericin), the triazoles (fluconazole, voriconazole, itraconazole), and the echinocandins (caspofungin, micafungin, and anidulafungin). These agents differ in terms of their side-effect profiles, efficacy against various fungi, and fungicidal vs. fungistatic characteristics. The important disease-specific characteristics of these agents have been detailed earlier. Amphotericin B, a by-product of the actinomycete *Streptomyces nodosus*, has served as the mainstay for deep, systemic fungal infections. A complex lipophilic organic compound or polyene, amphotericin B binds to ergosterol in the cell membranes of fungi, causing disruption and ion leakage. However, nephrotoxicity limits its usefulness and applicability. Three lipid-based formulations of amphotericin B have now shown decreased nephrotoxicity and higher drug-dose delivery. Higher costs and limited data concerning greater efficacy have tempered widespread adoption of these three drugs as first-line antifungal therapy. Susceptible fungi convert 5-fluorocytosine (flucytosine) to 5-fluorouracil, which inhibits DNA and RNA synthesis. Flucytosine is commonly used in combination with amphotericin B in patients with cryptococcal or candidal infections to decrease the amount of amphotericin B necessary. The azole compounds include miconazole, ketoconazole, fluconazole, itraconazole, and voriconazole.¹⁰⁷ This class of drugs inhibits the enzyme cytochrome P-450, thereby interfering with fungal cell membrane synthesis; in the presence of these drugs, lanosterol is not converted to ergosterol, a necessary fungal component.

Echinocandins are a new class of antifungals that inhibit cell wall synthesis by interfering with glucan synthesis. Caspofungin was the first echinocandin to be approved by the U.S. Food and Drug Administration for the treatment of invasive pulmonary aspergillosis that is refractory to first-line agents. The most common associated side effects are headache, transient elevation of transaminase levels, and infusion-related venous effects.¹⁰⁸ This class of antifungals has become an integral part of the management of candidiasis.

Massive Hemoptysis

Massive hemoptysis generally is defined as expectoration of >600 mL of blood within a 24-hour period. It is a medical emergency associated with a mortality rate of 30 to 50%. Most clinicians would agree that losing over a liter of blood via the airway within 1 day is significant, yet use of an absolute volume criterion presents difficulties. First, it is difficult for the patient or caregivers to quantify the volume of blood being lost. Second, and most relevant, the rate of bleeding necessary to produce respiratory compromise is highly dependent on the individual's prior respiratory status. For example, the loss of 100 mL of blood over 24 hours in a 40-year-old male with normal pulmonary function would be of little immediate consequence, because his normal cough would ensure his ability to clear the blood and secretions. In contrast, the same amount of bleeding in a 69-year-old male with severe COPD, chronic bronchitis, and an FEV₁ of 1.1 L may be life-threatening.

ANATOMY

The lungs have two sources of blood supply: the pulmonary and bronchial arterial systems. The pulmonary system is a high-compliance, low-pressure system, and the walls of the pulmonary arteries are very thin and delicate. The bronchial arteries, part of the systemic circulation, have systemic pressures and thick walls; most branches originate from the proximal thoracic aorta. Most cases of massive hemoptysis involve bleeding from the bronchial artery circulation or from the pulmonary circulation pathologically exposed to the high pressures of the bronchial circulation. In many cases of hemoptysis, particularly those due to inflammatory disorders, the bronchial arterial tree becomes hyperplastic and tortuous. The systemic pressures within these arteries, combined with a disease process within the airway and erosion, lead to bleeding.

CAUSES

Significant hemoptysis has many causes, which can broadly be categorized into pulmonary, extrapulmonary, and iatrogenic causes. Table 19-21 summarizes the most common causes of hemoptysis.¹⁰⁹ Most are secondary to inflammatory processes. An acute necrotizing pneumonic infection can lead to destruction and erosion of vascular structures and bleeding. Chronic inflammatory disorders (e.g., bronchiectasis, cystic fibrosis, tuberculosis) lead to localized bronchial arterial proliferation, and with erosion, bleeding of these hypervascular areas occurs.

Table 19-21 Pulmonary and Extrapulmonary Causes of Massive Hemoptysis		
Pulmonary	Extrapulmonary	Iatrogenic
Pulmonary parenchymal disease	Congestive heart failure	Intrapulmonary catheter
Bronchitis	Coagulopathy	
Bronchiectasis	Mitral stenosis	
Tuberculosis	Medications	
Lung abscess		
Pneumonia		
Cavitary fungal infection (e.g., aspergilloma)		
Lung parasitic infection (ascariasis, schistosomiasis, paragonimiasis)		
Pulmonary neoplasm		
Pulmonary infarction or embolism		
Trauma		
Arteriovenous malformation		
Pulmonary vasculitis		
Pulmonary endometriosis		
Wegener's granulomatosis		
Cystic fibrosis		
Pulmonary hemosiderosis		

Tuberculosis also can cause hemoptysis by erosion of a broncholith (a calcified tuberculous lymph node) into a vessel or, when a tuberculous cavity is present, by erosion of a blood vessel within the cavity. Within such cavities, aneurysms of the pulmonary artery (referred to as *Rasmussen aneurysms*) can develop that are accompanied by subsequent erosion and massive bleeding.

Hemoptysis due to lung cancer is usually mild, resulting in blood-streaked sputum. Massive hemoptysis in patients with lung cancer typically is caused by malignant invasion of pulmonary artery vessels by large central tumors. Although rare, it is often a terminal event.

MANAGEMENT

The treatment of patients with life-threatening hemoptysis is best carried out by a multidisciplinary team of intensive care physicians, interventional radiologists, and thoracic surgeons. Table 19-22 provides an algorithm for management of patients with massive hemoptysis.

Table 19-22 Treatment Priorities in the Management of Massive Hemoptysis
1. Achieve respiratory stabilization and prevent asphyxiation.
2. Localize the bleeding site.
3. Control the hemorrhage.
4. Determine the cause.
5. Definitively prevent recurrence.

The pragmatic clinical definition of *massive hemoptysis* is a degree of bleeding that threatens respiratory stability. Therefore clinical judgment of the risk of respiratory compromise is the first step in evaluating a patient.^{110,111} Two scenarios are possible: (a) bleeding is significant and persistent, but its rate allows a rapid but sequential diagnostic and therapeutic approach, and (b) bleeding is so rapid that emergency airway control and therapy are necessary.

Scenario 1: Significant, Persistent, But Nonmassive Bleeding

Although bleeding is brisk in scenario 1, the patient may be able to maintain clearance of the blood and secretions with his or her own respiratory reflexes. Immediate measures are admission to an intensive care unit, strict bedrest, Trendelenburg positioning with the affected side down (if known), administration of humidified oxygen, monitoring of oxygen saturation and arterial blood gas levels, and insertion of large-bore IV catheters. Strict bedrest with sedation may lead to slowing or cessation of bleeding, and the judicious use of IV narcotics or other relaxants to mildly sedate the patient and diminish some of the

reflexive airway activity is often necessary. Also recommended are administration of aerosolized adrenaline, IV antibiotic therapy if needed, and correction of abnormal blood coagulation. Finally, unless contraindicated, IV vasopressin (20 units over 15 minutes, followed by an infusion of 0.2 unit/min) can be given.

A chest radiograph is the first test and often proves to be the most revealing. Localized lesions may be seen, but the effects of blood soiling of other areas of the lungs may predominate, obscuring the area of pathology. Chest CT scanning provides more detail and is nearly always performed if the patient is stable. Pathologic areas may be obscured by blood soiling.

Flexible bronchoscopy is the next step in evaluating the patient's condition. Some clinicians argue that rigid bronchoscopy should always be performed. However, if the patient is clinically stable and the ongoing bleeding is not imminently threatening, flexible bronchoscopy is appropriate. It allows diagnosis of airway abnormalities and will usually permit localization of the bleeding site to a lobe or even a segment. The person performing the bronchoscopy must be prepared with excellent suction and must be able to perform saline lavage with a dilute solution of epinephrine.

Most cases of massive hemoptysis arise from the bronchial arterial tree; therefore, the next therapeutic option frequently is selective bronchial arteriography and embolization. Prearteriogram bronchoscopy is extremely useful to direct the angiographer. However, if bronchoscopy fails to localize the bleeding site, then bilateral bronchial arteriography can be performed. Typically, the abnormal vascularity is visualized, rather than extravasation of the contrast dye. Embolization will acutely arrest the bleeding in 80 to 90% of patients. However, 30 to 60% of patients will have recurrences. Therefore, embolization should be viewed as an immediate but probably temporizing measure to acutely control bleeding. Subsequently, definitive treatment of the underlying pathologic process is appropriate. If bleeding persists after embolization, a pulmonary artery source should be suspected and pulmonary angiography performed.

If respiratory compromise is impending, orotracheal intubation should be performed. After intubation, flexible bronchoscopy should be performed to clear blood and secretions and to attempt localization of the bleeding site. Depending on the possible causes of the bleeding, bronchial artery embolization or (if appropriate) surgery can be considered.

Scenario 2: Significant, Persistent, and Massive Bleeding

Life-threatening bleeding requires emergency airway control and preparation for potential surgery. Such patients are best cared for in an operating room equipped with rigid bronchoscopy equipment. Immediate orotracheal intubation may be necessary to gain control of ventilation and suctioning. However, rapid transport to the operating room and rigid bronchoscopy should be facilitated. Rigid bronchoscopy allows adequate suctioning of bleeding with visualization of the bleeding site; the nonbleeding side can be cannulated with the rigid scope and the patient ventilated. After stabilization, ice-saline lavage of the bleeding site can then be performed (up to 1 L in 50-mL aliquots); bleeding stops in up to 90% of patients.¹¹²

Alternatively, blockade of the main stem bronchus of the affected side can be accomplished with a double-lumen endotracheal tube, with a bronchial blocker, or by intubation of the nonaffected side using an uncut standard endotracheal tube. Placement of a double-lumen endotracheal tube is challenging in these circumstances, given the bleeding and secretions. Proper placement and suctioning may be difficult, and attempts could compromise the patient's ventilation. The best option is to place a bronchial blocker in the affected bronchus with inflation. The blocker is left in place for 24 hours and the area is then re-examined bronchoscopically. After this 24-hour period, bronchial artery embolization can be performed.

Surgical Intervention

In most patients, bleeding can be stopped, recovery can occur, and plans can be made to definitively treat the underlying cause. In scenario 1 (significant, persistent, but nonmassive bleeding), the patient may undergo further evaluation as an inpatient or outpatient. Chest CT scanning and pulmonary function studies should be performed preoperatively. In scenario 2 (significant, persistent, and massive bleeding), surgery, if appropriate, usually will be performed during the same hospitalization in which the rigid bronchoscopy or main stem bronchus blockade is carried out. In <10% of patients, emergency surgery will be necessary, delayed only by efforts to localize the bleeding site by rigid bronchoscopy.

Surgical treatment is individualized according to the source of bleeding and the patient's medical condition, prognosis, and pulmonary reserve. General indications for urgent surgery are presented in Table 19-23. In patients with significant cavitary disease or fungus balls, the walls of the cavities are eroded and necrotic; rebleeding will likely ensue. In addition, bleeding from cavitary lesions may be due to pulmonary artery erosion, which requires surgery for control.

Table 19-23 General Indications for Urgent Operative Intervention for Massive Hemoptysis
1. Presence of a fungus ball
2. Presence of a lung abscess
3. Presence of significant cavitary disease
4. Failure to control the bleeding

End-Stage Lung Disease

LUNG VOLUME REDUCTION SURGERY

Lung volume reduction surgery (LVRS) was originally described by Brantigan in the late 1950s, and the procedure was resurrected and refined by Cooper and associates in the early 1990's.^{113–115} As described by Cooper, the ideal patient for LVRS has heterogeneous emphysema with apical predominance; that is, the worst emphysematous changes are in the apex of both lungs (as seen on chest CT scan). The physiologic lack of function of these areas is demonstrated by quantitative perfusion scan, which shows minimal or no perfusion. When these nonfunctional areas are surgically excised, the volume of the lung is reduced, which theoretically restores respiratory mechanics. Diaphragm position and function are improved, and there may be an improvement in the dynamic small airway collapse in the remaining lung. After favorable outcomes were reported for LVRS in studies at the Barnes-Jewish Hospital and in other various smaller trials, application of LVRS rapidly escalated.

In the mid-1990s, analysis of Medicare claims for LVRS revealed an operative mortality of 16.9% and a 1-year mortality of 23%. In 1997 the National Emphysema Treatment Trial conducted a randomized study involving 1218 patients that used a noncrossover design to compare medical and surgical management after a 10-week pretreatment pulmonary rehabilitation program. Subgroup analysis demonstrated that in patients with the anatomic changes delineated by Cooper and colleagues, LVRS significantly improved exercise capacity, lung function, quality of life, and dyspnea compared with medical therapy. After 2 years, functional improvements began to decline toward baseline. In medically treated patients, similar parameters steadily declined below baseline. LVRS was associated with increased short-term morbidity and mortality and did not confer a survival benefit over medical therapy.¹¹⁶

LUNG TRANSPLANTATION

Cooper and associates at the University of Toronto performed the first successful single-lung transplant in 1983.¹¹⁷ Pasque and colleagues introduced the modern technique of bilateral sequential lung (BSL) transplant in 1990.¹¹⁸

Today, the most common indications for referral for a lung transplantation are COPD and idiopathic pulmonary fibrosis (IPF). Most patients with IPF and older patients with COPD are offered a single-lung transplant. Younger COPD patients and patients with alpha1-antitrypsin deficiency and severe hyperinflation of the native lungs are offered BSL transplantation. Most patients with primary pulmonary hypertension and almost all patients with cystic fibrosis are treated with BSL transplantation. Heart-lung transplantation is reserved for patients with irreversible ventricular failure or uncorrectable congenital cardiac disease.

Patients with COPD are considered for placement on the transplant waiting list when their FEV₁ has fallen to below 25% of its predicted value. Patients with significant pulmonary hypertension should be listed earlier. IPF patients should be referred when their forced vital capacity has fallen to <60% or their carbon monoxide diffusion capacity (DLCO) is <50% of the predicted value.

In the past, patients with primary pulmonary hypertension and New York Heart Association class III or IV symptoms were listed for a lung transplant. However, treatment of such patients with IV prostacyclin and other pulmonary vasodilators has now markedly altered that strategy. Virtually all patients with primary pulmonary hypertension are now treated with IV epoprostenol. Some of these patients have experienced a marked improvement in their symptoms associated with a decrease in their pulmonary arterial pressures and an increase in exercise capacity. Listing of these patients is deferred until they develop New York Heart Association class III or IV symptoms or until their mean pulmonary artery pressure rises above 75 mmHg. Medium-term and bronchiolitis obliterans syndrome-free survival rates of patients who underwent a lung transplantation at the University of Minnesota during a recent 5-year period are shown in Figs. 19-33 and 19-34.¹¹⁹ The mortality of patients while awaiting transplantation is approximately 10%. In an effort to expand the number of lung donors, many transplant groups have liberalized their criteria for donor selection. Still, the partial pressure of arterial oxygen should be >300 mmHg on a fraction of inspired oxygen of 100%. In special circumstances, lungs may be used from donors with a smoking history; from donors >50 years of age; and from donors with positive Gram's stains or infiltrates on chest radiograph.^{120–123} The use of two living donors, each donating a single lower lobe, is another strategy for increasing the donor pool. Recipient outcomes are similar to outcomes of those with cadaver donors in carefully selected patients.

Survival rate after lung transplantation in the absence of bronchiolitis obliterans syndrome (BOS) at the University of Minnesota.

Most of the early mortality after lung transplantation is related to primary graft failure resulting from a severe ischemia-reperfusion injury to the lung(s) (Fig. 19-35). Reperfusion injury is characterized radiographically by interstitial and alveolar edema, and clinically by hypoxia and ventilation-perfusion mismatch. Donor neutrophils and recipient lymphocytes probably play an important role in the pathogenesis of reperfusion injury. The most important impediment to longer-term survival after lung transplantation is the development of bronchiolitis obliterans syndrome, a manifestation of chronic rejection. Episodes of acute rejection are the major risk factors for developing bronchiolitis obliterans syndrome. Other injuries to the lung (including early reperfusion injury and injury from chronic gastroesophageal reflux disease) may also adversely affect long-term outcomes of patients.^{119,124}

Survival rate after lung transplantation at the University of Minnesota for patients with and without primary graft failure (PGF).

Spontaneous Pneumothorax

Spontaneous pneumothorax is secondary to intrinsic abnormalities of the lung, and the most common cause is rupture of an apical subpleural bleb. The cause of these blebs is unknown, but they occur more frequently in smokers and males, and they tend to be seen predominately in young postadolescent males with a tall, thin body habitus. Treatment is generally insertion of a chest tube with water seal. If a leak is present and it persists for >3 days, thorascopic management (i.e., bleb resection with pleurodesis by talc or pleural abrasion) is performed. Recurrences or complete lung collapse with the first episode are generally indications for thorascopic intervention.¹²⁵ Additional indications for intervention on the first episode include exposure to occupational hazards such as air travel, deep sea diving, or travel to remote locations. CT findings of multiple small bullae or a large bleb are associated with an increased risk of recurrent pneumothorax.¹²⁶ Many surgeons are now using screening CT to recommend VATS bleb resection with pleurodesis for first-episode spontaneous pneumothorax.

Other causes of spontaneous pneumothorax are emphysema (rupture of a bleb or bulla), cystic fibrosis, AIDS, metastatic cancer (especially sarcoma), asthma, lung abscess, and occasionally lung cancer. Catamenial pneumothorax, a rare but interesting type of spontaneous pneumothorax in women in their second and third decades, occurs within 72 hours of the onset of menses and is possibly related to endometriosis. Management of pneumothorax in these circumstances often is tied to treatment of the specific disease process and may involve tumor resection, thorascopic pleurectomy, or talc pleurodesis.

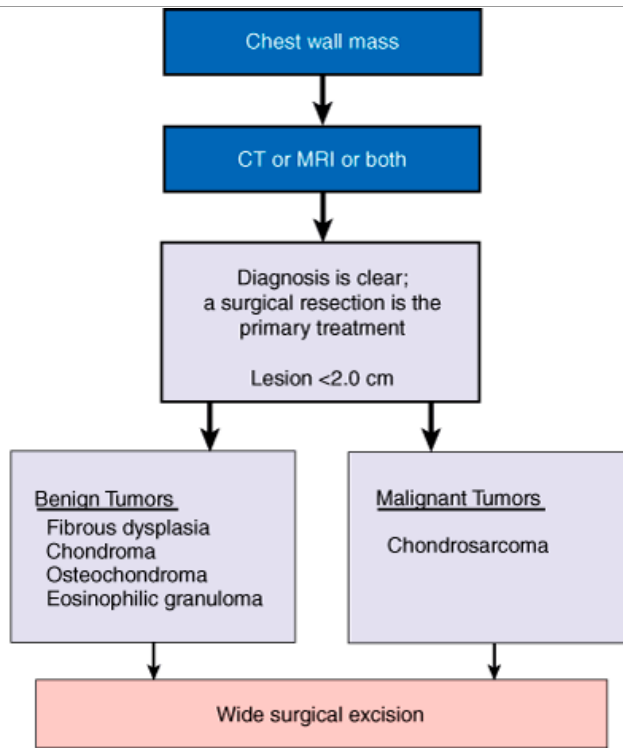

CHEST WALL

Chest Wall Mass

CLINICAL APPROACH

Surgeons confronted with a patient with a chest wall mass must be aware that their approach to diagnosis and treatment has significant impact on the patient's chances for long-term survival. All chest wall tumors should be considered malignant until proven otherwise. It is critically important that the surgeon(s) be mindful of this tenet and well versed in the diagnostic and treatment principles for chest wall malignancies. These tenets must be applied starting with the initial biopsy, because the placement of the incision can significantly affect success in achieving complete resection and reconstructing the chest wall. Complete resection is imperative if there is any hope for cure and/or long-term survival. A general approach is outlined in Figs. 19-36 and 19-37.

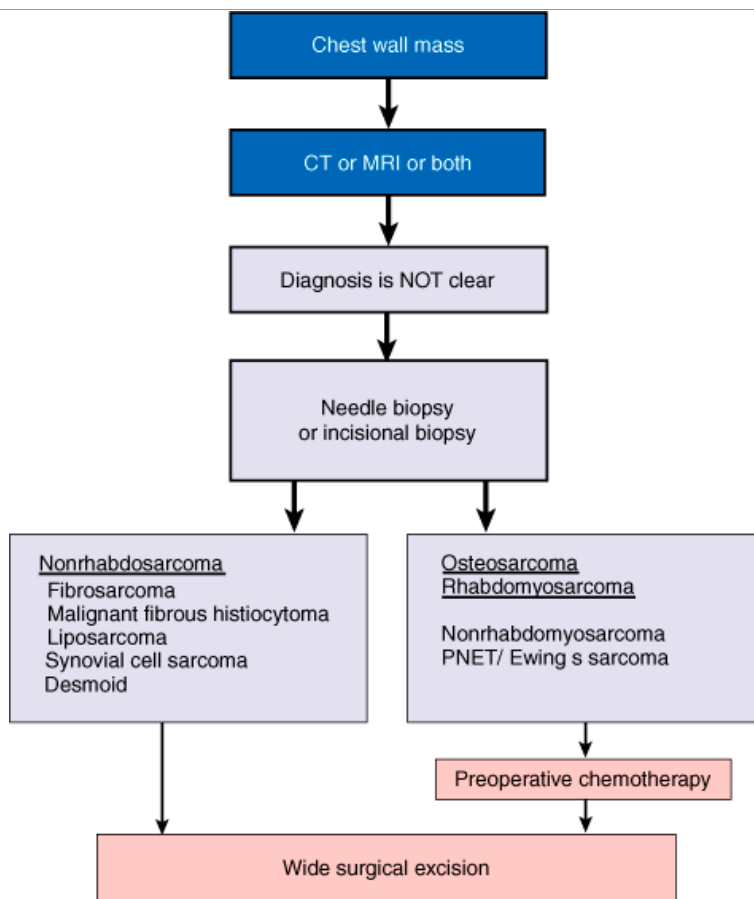

Fig. 19-36.

Systematic approach for evaluating a chest wall mass for which the diagnosis is not unequivocal. A tissue diagnosis is critical for effective management of chest wall masses. CT = computed tomography; MRI = magnetic resonance imaging; PNET = primitive neuroectodermal tumor.

Patients with either a benign or malignant chest wall tumor typically present with complaints of a slowly enlarging palpable mass (50 to 70%), chest wall pain (25 to 50%), or both. The interval from the time the patient first notices the mass until the time the patient is seen by medical providers often can be months. Interestingly, masses often are not noticed by patients until they experience a trauma to the area.

Pain from a chest wall mass is typically localized to the area of the tumor. Pain is more often present (and more intense) with malignant tumors, but it also can be present with up to one third of benign tumors. With Ewing's sarcoma, fever and malaise may also be present. Age can provide guidance regarding the possibility of malignancy. Patients with benign chest wall tumors are on average 26 years old; the average age for patients with malignant tumors is 40 years. Overall, the probability that a chest wall tumor is malignant is 50 to 80%.

EVALUATION AND MANAGEMENT

Laboratory evaluations are usually of little help in assessing chest wall masses. In plasmacytoma, there may be monoclonality of one of the immunoglobulins with normal levels of other immunoglobulins. Another exception is osteosarcoma, in which alkaline phosphatase levels may be elevated. Still another exception is Ewing's sarcoma, in which the erythrocyte sedimentation rate may be elevated.

Radiography

Radiographic evaluation begins with a chest radiograph, which may reveal evidence of rib destruction and calcification within the lesion, and, if old films are available, provide a clue to growth rate. CT scanning should be done in all patients to evaluate the nature of the primary lesion, to determine its relationship to contiguous structures (e.g., mediastinum, lung, soft tissues, and other skeletal elements), and to search for possible pulmonary metastases. Importantly, contiguous involvement of underlying lung or other soft tissues or the presence of pulmonary metastases does not preclude successful surgery. CT also is valuable in assessing for the presence of extraosseous bone formation and bone destruction, both typically seen with osteosarcoma.

MRI has a number of advantages in the radiographic evaluation of chest wall masses, particularly those that may be malignant. Multiple planes of imaging (coronal, sagittal, and oblique) are possible. MRI also may better define the relationship between tumor and muscle. For tumors contiguous to or near neurovascular structures or the spine, MRI and magnetic resonance angiography with multiple planes of imaging provide invaluable information about the tumor. Thus they greatly facilitate preoperative planning and may further delineate tissue abnormalities, potentially enhancing the ability to distinguish benign

from malignant sarcomas.

Biopsy

The first step in the management of all chest wall tumors is to obtain a tissue diagnosis. Inappropriate or misguided attempts at tissue diagnosis through casual open biopsy techniques have the potential (if the lesion is a sarcoma) to seed surrounding tissues and contiguous body cavities (e.g., the pleural space) with tumor cells, potentially compromising local tumor control and patient survival. Accurate typing of chest wall sarcomas has a profound impact on their management.

Tissue diagnosis can be made by one of three methods: a needle biopsy (typically CT guided, FNA, or core biopsy), an incisional biopsy, or an excisional biopsy. Until recently, the thoracic surgery literature has been dogmatic in advocating only an excisional biopsy.¹²⁷ Reasons for insisting on this technique were that (a) the entire mass is removed, which allows 100% accurate sampling and diagnosis; (b) unlike with incisional biopsy, the potential problem of seeding the surrounding soft tissues with tumor cells does not exist; and (c) adjuvant chemotherapy can be administered.

Management of extremity sarcomas has changed dramatically in the last decade, however. Neoadjuvant therapy is now the standard of care for certain sarcomas. Because sarcomas of the thorax are the same as sarcomas of the extremities, management principles for both should be parallel, whenever technically and medically possible.

An excisional biopsy should still be performed when the initial diagnosis (based on radiographic evaluation) indicates that the lesion is benign or when the lesion has the classic appearance of a chondrosarcoma (in which case definitive surgical resection can be undertaken). Any lesion of <2.0 cm can be excised as long as the resulting wound is small enough to close primarily.

When the diagnosis cannot be made by radiographic evaluation, a needle biopsy (FNA or core) should be performed. Pathologists experienced with sarcomas can accurately diagnose approximately 90% of patients using FNA techniques. A needle biopsy (FNA or core) has the advantage of avoiding wound and body cavity contamination (a potential complication with an incisional biopsy).

If results of a needle biopsy are nondiagnostic, an incisional biopsy may be performed, with the following caveats. When an incisional biopsy is performed, the skin incision must be placed directly over the mass and oriented to allow subsequent excision of the scar. Development of skin flaps must be avoided, and in general no drains are used. A drain may be placed if a hematoma is likely to develop, because this can potentially limit soft tissue contamination by tumor cells. Subsequently, if definitive surgical resection is undertaken, the entire area of the biopsy (including skin and the drain track) must be excised en bloc with the tumor.

Chest Wall Neoplasms

BENIGN TUMORS

Chondroma

Chondromas are one of the more common benign tumors of the chest wall. They are primarily seen in children and young adults. Chondromas usually occur at the costochondral junction anteriorly. Given their typical location and the young age of most patients, chondromas may be confused with costochondritis. Clinically, a mass (usually without pain) is present in the case of chondromas. Radiographically, the lesion is lobulated and radiodense; it may have diffuse or focal calcifications and may displace the bony cortex without penetration. Chondromas may grow to huge sizes if left untreated. Treatment is surgical resection with a 2-cm margin. One must be certain, however, that the lesion is not a well-differentiated chondrosarcoma. In this case, a wider 4-cm margin is required to prevent local recurrence. Therefore, large chondromas should be treated surgically as low-grade chondrosarcomas.¹²⁸

Fibrous Dysplasia

The ribs are a frequent site of origin of fibrous dysplasia. As with chondromas, fibrous dysplasia most frequently occurs in young adults. Pain is an infrequent complaint, and the lesion is typically located in the posterolateral aspect of the rib cage. Fibrous dysplasia may be associated with trauma. Radiographically, an expansile mass is present, with cortical thinning and no calcification. Local excision with a 2-cm margin is curative.

Osteochondroma

Osteochondromas are the most common benign bone tumor. Many are detected as incidental radiographic findings. Most are solitary. If a patient has multiple osteochondromas, the surgeon must have a high index of suspicion for malignancy, because the incidence of chondrosarcoma is significantly higher in this population.

Osteochondromas occur in the first 2 decades of life, and they arise at or near the growth plate of bones. The lesions are benign during youth or adolescence. Osteochondromas that enlarge after completion of skeletal growth have the potential to develop into chondrosarcomas.

Osteochondromas in the thorax arise from the rib cortex. They are one of several components of the autosomal dominant syndrome known as *hereditary*

multiple exostoses. When part of this syndrome, osteochondromas have a high rate of degeneration into chondrosarcomas. Any patient with hereditary multiple exostoses syndrome who develops new pain at the site of an osteochondroma or who notes gradual growth in the mass over time should be carefully evaluated for osteosarcoma. Local excision of a benign osteochondroma is sufficient treatment. If malignancy is determined, wide excision is performed, with a 4-cm margin.

Eosinophilic Granuloma

Eosinophilic granulomas are benign osteolytic lesions. They were originally thought to be destructive lesions with large numbers of eosinophilic cells. Yet eosinophilic granulomas of the ribs also can occur as solitary lesions or as part of a more generalized disease process of the lymphoreticular system termed *Langerhans cell histiocytosis (LCH)*. In LCH, the involved tissue is infiltrated with large numbers of histiocytes (similar to Langerhans cells seen in skin and other epithelia), which are often organized as granulomas. The cause is unknown. Of all LCH bone lesions, 79% are solitary eosinophilic granulomas, 7% involve multiple eosinophilic granulomas, and 14% belong to other forms of more systemic LCH.

Isolated single eosinophilic granulomas can occur in the ribs, skull, pelvis, mandible, humerus, and other sites. They are diagnosed primarily in children between the ages of 5 and 15 years. Because of the associated pain and tenderness, they may be confused with Ewing's sarcoma or with an inflammatory process such as osteomyelitis. Healing may occur spontaneously, but the typical treatment is limited surgical resection with a 2-cm margin.

Desmoid Tumors

Desmoid tumors are unusual soft tissue neoplasms that arise from fascial or musculoaponeurotic structures. Histologically, they consist of proliferations of benign-appearing fibroblastic cells, abundant collagen, and few mitoses. Accordingly, some authorities consider desmoid tumors to be a form of fibrosarcoma.

Desmoid tumors have recently been shown to possess alterations in the adenomatous polyposis coli/ β -catenin pathway, and cyclin D1 dysregulation is thought to play a significant role in their pathogenesis.¹²⁹ Associations with other diseases and conditions are well documented, especially those with similar alterations in the adenomatous polyposis coli pathway, such as familial adenomatous polyposis (Gardner's syndrome). Other conditions with increased risk of desmoid tumor formation include states of increased estrogen levels (pregnancy) and trauma. Surgical incisions (abdominal and thoracic) have been the site of desmoid development, either in or near the scar.

Clinically, patients are usually in the third to fourth decade of life and have pain, a chest wall mass, or both. The tumor usually is fixed to the chest wall but not to the overlying skin. No radiographic findings are typical, but MRI may delineate muscle or soft tissue infiltration. Histologic diagnosis may not be possible by a needle biopsy because of low cellularity. An open incisional biopsy often is necessary for lesions over 3 to 4 cm, with attention to the caveats listed earlier (see "Biopsy").

Desmoid tumors do not metastasize, but they have a strong propensity to recur locally, with local recurrence rates as high as 5 to 50%, sometimes despite complete initial resection with histologically negative margins.¹³⁰ Such locally aggressive behavior is secondary to microscopic tumor infiltration of muscle and surrounding soft tissues.

Surgery consists of wide local excision with a margin of 2 to 4 cm and with intraoperative assessment of resection margins by frozen-section analysis. Typically, a rib is removed above and below the tumor with a 4- to 5-cm margin of rib. A margin of <1 cm results in much higher local recurrence rates.¹³¹ If a major neurovascular structure would have to be sacrificed, which would lead to high morbidity, then a margin of <1 cm would have to suffice. Survival after wide local excision with negative margins is 90% at 10 years.

PRIMARY MALIGNANT CHEST WALL TUMORS

A malignant tumor of the chest wall is either a metastatic lesion from another primary tumor or a sarcoma. Although many different cell types are seen in sarcomas, the primary features affecting prognosis are histologic grade and responsiveness to chemotherapy.

Sarcomas can be divided into two broad groups according to potential responsiveness to chemotherapy (Table 19-24). Preoperative (neoadjuvant) chemotherapy offers the ability to (a) assess tumor chemosensitivity by the degree of tumor size reduction and microscopic necrosis, (b) determine to which chemotherapeutic agents the tumor is sensitive, and (c) lessen the extent of surgical resection by reducing tumor size. Patients whose tumors are responsive to preoperative chemotherapy (as judged by the reduction in the size of the primary tumor and/or by the degree of necrosis seen histologically after resection) have a much better prognosis than those whose tumors show a poor response.

Table 19-24 Classification of Sarcomas by Therapeutic Response	
Tumor Type	Chemotherapy Sensitivity
Osteosarcoma	+
Rhabdomyosarcoma	+
Primitive neuroectodermal tumor	+
Ewing's sarcoma	+

Malignant fibrous histiocytoma	±
Fibrosarcoma	±
Liposarcoma	±
Synovial sarcoma	±

Information about the tumor's propensity to respond to chemotherapy, the patient's physiologic state and capacity to receive treatment, and the presence or absence of metastatic disease can then be used to determine optimal therapy. The following guidelines, based on tumor type and assuming fitness for therapy, can be used to direct therapy. Based on the tumor's known potential response to chemotherapy or the presence of metastatic disease, the initial treatment is either (a) preoperative chemotherapy [for patients with osteosarcoma, rhabdomyosarcoma, primitive neuroectodermal tumor (PNET), or Ewing's sarcoma] followed by surgery and postoperative chemotherapy, (b) primary surgical resection and reconstruction (for patients with nonmetastatic malignant fibrous histiocytoma, fibrosarcoma, liposarcoma, or synovial sarcoma), or (c) neoadjuvant chemotherapy followed by surgical resection if indicated in patients with metastatic soft tissue sarcomas. Exceptions to these guidelines may apply at specific centers at which the impact of neoadjuvant chemotherapy on soft tissue sarcomas is under investigation. Typically such exceptions apply to pediatric patients and to adult patients who have deep, high-grade, nonmetastatic tumors >10 cm in diameter.

MALIGNANT CHEST WALL BONE TUMORS

Chondrosarcoma

Chondrosarcomas are the most common primary chest wall malignancies. As with chondromas, they usually arise anteriorly from the costochondral arches. These slowly enlarging, often painful masses of the anterior chest wall can reach massive proportions.¹²⁸ CT scan shows a radiolucent lesion, often with stippled calcifications pathognomonic for chondrosarcomas (Fig. 19-38). The involved bony structures also are destroyed. Metastatic disease to the lungs or bones should be ruled out by CT and bone scan.

Fig. 19-38.

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Chest computed tomographic scan showing a right posterior lung tumor. In the appropriate clinical setting, stippled calcifications (white streaks in right lung mass) are highly indicative of chondrosarcomas.

Most chondrosarcomas are slow-growing, low-grade tumors. For this reason, any lesion in the anterior chest wall likely to be a low-grade chondrosarcoma should be treated with wide (4-cm) resection. Chondrosarcomas are not sensitive to chemotherapy or radiation therapy. Prognosis is determined by tumor grade and extent of resection. With a low-grade tumor and wide resection, patient survival at 5 to 10 years can be as high as 60 to 80%.

Osteosarcoma

Osteosarcomas are the most common bone malignancy, but they are an uncommon malignancy of the chest wall, representing only 10% of all malignant chest wall tumors.¹³² They present as rapidly enlarging, painful masses. Although they primarily occur in young adults, osteosarcomas can occur in patients >40 years of age, sometimes in association with previous radiation therapy, Paget's disease, or chemotherapy.

Radiographically, the typical appearance consists of spicules of new periosteal bone formation producing a sunburst appearance. As with chondrosarcomas, careful CT assessment of the pulmonary parenchyma for metastasis is necessary. Osteosarcomas have a propensity to spread to the lungs. Up to one third of patients present with metastatic disease.

Osteosarcomas are potentially sensitive to chemotherapy. Currently, administration of chemotherapy before surgical resection is common. After chemotherapy, complete resection is performed with wide (4-cm) margins, followed by reconstruction. In patients presenting with lung metastases that are potentially amenable to surgical resection, induction chemotherapy may be given, followed by surgical resection of the primary tumor and of the pulmonary

metastases. After surgical treatment of known disease, additional maintenance chemotherapy usually is recommended.

Other Tumors

Primitive Neuroectodermal Tumors

PNETs derive from primordial neural crest cells that migrate from the mantle layer of the developing spinal cord. This group of tumors includes neuroblastomas, ganglioneuroblastomas, and ganglioneuromas. Ewing's sarcomas and Askin's tumors are closely related to PNETs. Askin's tumor was originally described by Askin in 1979 as a "malignant, small cell tumor of the thoracopulmonary region," and is now known to be a member of the Ewing's sarcoma/PNET family.^{132,133} Histologically, Ewing's sarcomas and PNETs are small round cell tumors; both possess a translocation between the long arms of chromosomes 11 and 22 within their genetic makeup. They also share a consistent pattern of proto-oncogene expression and have been found to express the product of the *MIC2* gene.

Ewing's Sarcoma

Ewing's sarcoma occurs in adolescents and young adults, who present with progressive chest wall pain but without a mass. Systemic symptoms of malaise and fever are often present. Laboratory studies reveal an elevated erythrocyte sedimentation rate and mild elevation of white blood cell count.

Radiographically, the characteristic onion peel appearance is produced by multiple layers of periosteum in the bone formation. Evidence of bony destruction is also common. The diagnosis can be made by a percutaneous needle biopsy or an incisional biopsy.

These tumors have a strong propensity to spread to the lungs and skeleton. Due to their clinically aggressive behavior, patient survival rates are only ≤50% at 3 years. Increasing tumor size is associated with decreasing survival. Treatment has improved significantly and now consists of multiagent chemotherapy, radiation therapy, and surgery. Patients are typically treated preoperatively with chemotherapy and re-evaluated with radiographic imaging. When residual disease is identified, surgical resection and reconstruction are performed, followed by maintenance chemotherapy.

Plasmacytoma

Solitary plasmacytomas of the chest wall are very rare, and only 25 to 30 cases are seen annually in the United States.¹³² The typical presentation is pain without a palpable mass. Radiographs show an osteolytic lesion. As with other chest wall tumors, a needle biopsy is performed under CT guidance for diagnosis. Histologically, the lesion is identical to that of multiple myeloma, with sheets of plasma cells. It occurs at an average age of 55 years. Evaluation for systemic myeloma is performed with bone marrow aspiration, testing of calcium levels, and measurement of urinary Bence Jones protein levels. If the results of these studies are negative, then a solitary plasmacytoma is diagnosed. Surgery is usually limited to a biopsy only, which may be excisional. Treatment consists of irradiation with doses of 4000 to 5000 cGy. Up to 75% of patients go on to develop systemic multiple myeloma. Patient survival at 10 years is approximately 20%.

MALIGNANT CHEST SOFT TISSUE SARCOMAS

Soft tissue sarcomas of the chest wall are uncommon (Fig. 19-39). They include fibrosarcomas, liposarcomas, malignant fibrous histiocytomas, rhabdomyosarcomas, angiosarcomas, and other extremely rare lesions. Leiomyosarcoma and GI stromal tumors are the most common, representing approximately 65% of the total. Localized disease is present in 55 to 60% of cases; the remaining approximately 40% of cases show an even split between regional and distant spread.¹³⁴ Despite the prevalence of localized disease, soft tissue sarcomas of the chest wall are associated with significantly worse survival than are similar tumors located on the extremities or in the head and neck region. The factors affecting risk of death from soft tissue sarcomas are presented in Table 19-25.

Patients receiving surgical intervention have significantly better overall survival. Median survival with surgical resection is 25 months compared to 8 months without resection. Additional prognostic variables that are important for long-term survival include tumor size, grade, and stage, and achievement of a negative resection margin.¹³⁴ With the exception of rhabdomyosarcomas, the primary treatment of these lesions is wide surgical resection with 4-cm margins and reconstruction.¹³⁵ Rhabdomyosarcomas are sensitive to chemotherapy and often are treated with preoperative chemotherapy. As with all sarcomas, soft tissue sarcomas of the chest wall have a propensity to spread to the lungs.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytomas were originally thought to derive from histiocytes because of the microscopic appearance of cultured tumor cells. Subsequently it was shown that their likely origin is the fibroblast. Malignant fibrous histiocytomas are generally the most common soft tissue sarcoma of late adult life, although they very rarely occur on the chest wall. The typical age at presentation is between 50 and 70 years. These tumors are rare in those <20 years of age. They present with pain, with or without a palpable mass. Radiographically, a mass is usually evident, with destruction of surrounding tissue and bone. Treatment is wide resection with a margin of ≥4 cm and reconstruction. Over two thirds of patients develop distant metastasis or local recurrence.

Liposarcoma

Liposarcomas make up 15% of chest wall sarcomas. Most liposarcomas are low-grade tumors that have a propensity to recur locally, given their infiltrative nature. Clinically, they present most often as painless masses. Treatment is wide resection and reconstruction. Intraoperative margins should be evaluated (as with all sarcomas) and resection continued, if feasible, until margins are negative. Local recurrence can be treated with re-excision, and radiotherapy is occasionally used.

Fibrosarcoma

Fibrosarcomas often present as large painful masses. Radiographically, a mass is seen with surrounding tissue destruction. Treatment is wide local excision with intraoperative frozen-section analysis of margins, followed by reconstruction. Local and systemic recurrence is frequent. Patient survival at 5 years is approximately 50 to 60%.

Rhabdomyosarcoma

Rhabdomyosarcomas are rare tumors of the chest wall. Microscopically, they are a spindle cell tumor. The diagnosis often depends on immunohistochemical staining for muscle markers. Rhabdomyosarcomas are sensitive to chemotherapy. Treatment consists of preoperative chemotherapy with subsequent surgical resection.

CHEST WALL RECONSTRUCTION

The status of the margins after resection of chest wall tumors is the primary determinant of long-term freedom from recurrence and overall survival. As a result, adequate margins of normal tissue must be included in the en bloc resection. En bloc resection should include involved ribs, sternum, superior sulcus, or spine if necessary, and invasion of these structures should not be considered a contraindication to surgery in an otherwise fit patient. The principles of surgery for any malignant chest wall tumor are to strategically plan the anatomy of resection and to carefully assess what structures will need to be sacrificed to obtain a 4-cm margin. Reconstruction at the same operation can be accomplished using prosthetic materials and myocutaneous flaps.¹³⁶ An acceptable cosmetic result is possible with creative use of myocutaneous flaps, even when the defect is large.

Because of the high rate of malignancy of chest wall neoplasms, any mass that likely represents a primary tumor must be aggressively managed. When malignancy is suspected, preliminary plans must be made for chest wall reconstruction that will allow resection of a generous margin of normal tissue around the neoplasm. The resection should include at least one normal adjacent rib above and below the tumor, with all intervening intercostal muscles and pleura. In addition, an en bloc resection of overlying chest wall muscles such as the pectoralis minor or major, serratus anterior, or latissimus dorsi muscle often is necessary. When the periphery of the lung is involved with the neoplasm, it is appropriate to resect the adjacent part of the pulmonary lobe in continuity (Fig. 19-40). Involvement of the sternum by a malignant tumor requires total resection of the sternum with the adjacent cartilage. Techniques for postoperative respiratory support are now good enough that resection should not be compromised because of any concern about the patient's ability to be adequately ventilated in the early postoperative period.

Fig. 19-40.

Principles of reconstruction after resection of a chest wall tumor (osteogenic sarcoma) are illustrated. **A.** En bloc resection of the involved chest wall, including normal ribs above and below the tumor as well as pulmonary parenchyma, must be performed. The resected specimen is shown. **B.** A prosthesis has been sewn in place. In the lower third of the prosthesis, the line of diaphragm reattachment is seen. The skin defect was closed with a myocutaneous flap from the ipsilateral rectus muscle.

The extent of resection depends on the tumor's location and on any involvement of contiguous structures. Laterally based lesions often require simple wide excision, with resection of any contiguously involved lung, pleura, muscle, or skin. Anteriorly based lesions contiguous with the sternum require partial sternectomy. Primary malignant tumors of the sternum may require complete sternectomy. Posterior lesions involving the rib heads over their articulations with the vertebral bodies may, depending on the extent of rib involvement, require partial en bloc vertebrectomy.

Reconstruction of a large defect in the chest wall requires the use of some type of material to prevent lung herniation and to provide stability for the chest wall (see Fig. 19-40). Mild degrees of paradoxical motion are often well tolerated if the area of instability is relatively small. Several authors, notably Pairolero and

Arnold from the Mayo Clinic, have reported extensive experience with chest wall reconstruction after removal of significant portions of the bony thorax.¹³⁷ Historically, a wide variety of materials have been used to re-establish chest wall stability, including rib autografts, steel struts, acrylic plates, and numerous synthetic meshes. The current preference is either a 2-mm polytetrafluoroethylene (Gore-Tex) patch or a double-layer polypropylene (Marlex) mesh sandwiched with methyl methacrylate. Several properties make Gore-Tex an excellent material for use in chest wall reconstruction. It is impervious to fluid, which prevents pleural fluid from entering the chest wall. This quality minimizes the formation of seromas, which can compromise viability of the myocutaneous flap and provide a nidus for infection. In addition, it provides excellent rigidity and stability when secured taut to the surrounding bony structure and, as a result, provides a firm platform for myocutaneous flap reconstruction.

Except for smaller lesions, tissue coverage requires the use of myocutaneous flaps (latissimus dorsi, serratus anterior, rectus abdominis, or pectoralis major muscle).^{138–140} Optimal management of larger tumors includes careful preoperative planning and execution of the surgery by the thoracic surgeon and an experienced plastic surgeon to ensure optimal physiologic and cosmetic results.

MEDIASTINUM

General Concepts

ANATOMY AND PATHOLOGIC ENTITIES

The mediastinum, the central part of the thoracic cavity, can be divided into compartments for classification of anatomic components and disease processes. Although there is substantial overlap, this compartmentalization facilitates understanding of general concepts of surgical interest. Several classification schemes exist, but for the purposes of this chapter, the three-compartment model is used (Fig. 19-41). This model includes the anterior compartment (often referred to as *anterosuperior*), the visceral compartment (middle), and the paravertebral sulci bilaterally (posterior compartment). The anterior compartment lies between the sternum and the anterior surface of the heart and great vessels. The visceral or middle compartment is located between the great vessels and the trachea. Posterior to these two compartments lies the paravertebral sulci bilaterally and the periesophageal area.

The normal content of the anterior compartment includes the thymus gland or its remnant, the internal mammary artery and vein, lymph nodes, and fat. During childhood, the size of the thymus gland is impressive, and it occupies the entire anterior mediastinum (Fig. 19-42). After adolescence, the thymus gland decreases in both thickness and length and takes on a more fatty content, with only residual islands of thymic cellular components (Fig. 19-43). The middle mediastinal compartment contains the pericardium and its contents, the ascending and transverse aorta, the superior and inferior venae cavae, the brachiocephalic artery and vein, the phrenic nerves, the upper vagus nerve trunks, the trachea, the main bronchi and their associated lymph nodes, and the central portions of the pulmonary arteries and veins. The posterior compartment contains the descending aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and lymph nodes. Numerous pathologic variants may be present in the various compartments, with much overlap. Table 19-26 includes the most common pathologic entities, listed by compartment.^{141,142}

HISTORY AND PHYSICAL EXAMINATION

The type of mediastinal pathology encountered varies significantly by age of the patient. In adults, the most common tumors include neurogenic tumors of the posterior compartment, benign cysts occurring in any compartment, and thymomas of the anterior mediastinum (Table 19-27). In children, neurogenic tumors of the posterior mediastinum are also common. Lymphoma is the second most common mediastinal tumor, usually located in the anterior or middle compartment, and thymoma is rare (Table 19-28). In both age groups, approximately 25% of mediastinal tumors are malignant. Pediatric tumors are discussed in Chap. 39.

Table 19-27 Mediastinal Tumors in Adults		
Tumor Type	Percentage of Total	Location
Neurogenic tumors	21	Posterior
Cysts	20	All
Thymomas	19	Anterior
Lymphomas	13	Anterior/middle
Germ cell tumors	11	Anterior
Mesenchymal tumors	7	All
Endocrine tumors	6	Anterior/middle

In most recent series, up to two thirds of mediastinal tumors in adults are discovered as asymptomatic abnormalities on radiologic studies ordered to investigate other problems. When symptomatic, these tumors are significantly more likely to be malignant. Characteristics such as size, location, rate of growth, and associated inflammation are important factors that correlate with symptoms. Large, bulky tumors, expanding cysts, and teratomas can cause compression of mediastinal structures, in particular the trachea, and lead to cough, dyspnea on exertion, or stridor. Chest pain or dyspnea may be reported secondary to associated pleural effusions, cardiac tamponade, or phrenic nerve involvement. Occasionally, a mediastinal mass near the aortopulmonary window may be identified in a work-up for hoarseness because of left recurrent laryngeal nerve involvement (Fig. 19-44). The patient whose CT scan is shown in Fig. 19-44 presented with hoarseness and was found to have a primary lung cancer with metastases to the level 5 and 6 lymph nodes in the region of the aortopulmonary window. Her hoarseness was due to nodal compression of the left recurrent laryngeal nerve. In the era of screening CT examinations, a higher percentage of malignant tumors of the mediastinum are being discovered as asymptomatic, incidental masses.

Computed tomographic scan of a patient who presented with hoarseness due to compression of the left recurrent laryngeal nerve caused by mediastinal lymph node metastases to the aortopulmonary window area (*arrow*) from a primary lung cancer.

The history and physical examination in conjunction with the imaging findings may suggest a specific diagnosis (Table 19-29). In one recent series, systemic symptoms were present in 50% of patients with a mediastinal mass and a lymphoproliferative disorder, compared with only 29% of patients with other masses (such as thymic or neurogenic lesions). Laboratory signs of inflammation were also noted: The erythrocyte sedimentation rate and C-reactive protein levels were elevated and leukocytosis was present in 86% of patients with a lymphoproliferative disorder, compared with only 58% of patients with other types of mediastinal masses.

Table 19-29 Signs and Symptoms Suggestive of Various Diagnoses in the Setting of a Mediastinal Mass

Diagnosis	History and Physical Findings	Compartment Location of Mass
Lymphoma	Night sweats, weight loss, fatigue, extrathoracic adenopathy, elevated erythrocyte sedimentation rate or C-reactive protein level, leukocytosis	Any compartment
Thymoma with myasthenia gravis	Fluctuating weakness, early fatigue, ptosis, diplopia	Anterior
Mediastinal granuloma	Dyspnea, wheezing, hemoptysis	Visceral (middle)
Germ cell tumor	Male gender, young age, testicular mass, elevated levels of human chorionic gonadotropin and/or alpha-fetoprotein	Anterior

Diagnostic Evaluation

IMAGING AND SERUM MARKERS

A number of asymptomatic mediastinal masses are suggested by chest radiographs but are generally poorly defined by this study. CT has become the most common imaging modality for evaluation of mediastinal masses.¹⁴³ Contrast-enhanced CT scans for clear delineation of anatomy are preferred. MRI may be indicated in the work-up of a mediastinal mass, particularly in patients contemplating surgical resection. Specifically, MRI is more accurate than CT in determining if there is invasion of vascular structures or spinal involvement.

Several other imaging modalities are available to evaluate mediastinal masses of suspected endocrine origin (Table 19-30). Single-photon emission computed tomography (SPECT) technology may be used to improve image contrast and give information on three-dimensional localization of some tumors of endocrine origin. SPECT has largely replaced conventional two-dimensional nuclear imaging. If a thyroid origin is suspected, a thyroid scan using iodine 131 or iodine 123 can identify most intrathoracic goiters and define the extent of functioning thyroid tissue. If a thyroid scan is indicated, it should precede other scans requiring iodine-containing contrast agents, because these would interfere with subsequent iodine tracer uptake by thyroid tissue and scanning. If a pheochromocytoma or neuroblastoma is suspected, octreotide scans or *m*-iodobenzylguanidine (iobenguane I 123, or MIBG) scans are helpful in diagnosis and localization. A sestamibi scan may be useful for diagnosing and localizing a mediastinal parathyroid gland.

Table 19-30 Nuclear Imaging Relevant to the Mediastinum

--	--	--

Radiopharmaceutical, Radionuclide, or Radiochemical	Label	Disease of Interest
Iodine	¹³¹ I, ¹²³ I	Retrosternal goiter, thyroid cancer
Monoclonal antibodies	¹¹¹ In, ^{99m} Tc	NSCLC, colon and breast cancer, prostate cancer metastases
Octreotide	¹¹¹ In	Amine precursor uptake decarboxylation tumors: carcinoid, gastrinoma, insulinoma, small cell lung cancer, pheochromocytoma, glucagonoma, medullary thyroid carcinoma, paraganglioma
Gallium	⁶⁷ Ga	Lymphoma, NSCLC, melanoma
Sestamibi	^{99m} Tc	Medullary thyroid carcinoma, nonfunctional papillary or follicular thyroid carcinoma, Hürthle cell thyroid carcinoma, parathyroid adenoma or carcinoma
Thallium	²⁰¹ Tl	See sestamibi
MIBG	¹³¹ I, ¹²³ I	Pheochromocytoma, neuroblastoma; see also octreotide
Fluorodeoxyglucose	¹⁸ F	General oncologic imaging, breast and colon cancer, melanoma

MIGB = *m*-iodobenzylguanidine; NSCLC = non–small cell lung cancer.

PET scanning has improved the noninvasive staging of lung cancer and esophageal cancer. The utility of PET in staging the mediastinum for NSCLC is reviewed in "Mediastinal Lymph Nodes" earlier in this chapter. The value of PET in staging other tumors of the mediastinum is not as clear. It is useful for distinguishing malignant from benign tumors. It may help detect distant metastases in some patients. For example, in patients with esophageal cancer, up to 10% of those with negative results on a metastatic survey by conventional imaging, including CT scan, will have a positive finding on PET scan for distant metastases.¹⁴⁴ The role of routine PET imaging in staging surgically resectable lesions of the mediastinum has not been established.

The use of serum markers to evaluate a mediastinal mass can be invaluable in some patients. For example, seminomatous and nonseminomatous germ cell tumors can frequently be diagnosed and often distinguished from one another by the levels of alpha-fetoprotein (AFP) and human chorionic gonadotropin (hCG). In over 90% of nonseminomatous germ cell tumors, either the AFP or the hCG level will be elevated. Results are close to 100% specific if the level of either AFP or hCG is >500 ng/mL. Some centers initiate chemotherapy based on this result alone, without a biopsy. In contrast, the AFP level is always normal in patients with mediastinal seminomas; only 10% will have an elevated hCG level, which usually is <100 ng/mL. Other serum markers, such as intact parathyroid hormone level for ectopic parathyroid adenomas, may be useful for diagnosis and also for intraoperative confirmation of complete resection. After successful resection of a parathyroid adenoma, the level of this hormone should rapidly normalize.

DIAGNOSTIC NONSURGICAL BIOPSY OF THE MEDIASTINUM

The indications and decision-making steps for performing a diagnostic biopsy of a mediastinal mass remain somewhat controversial. In some patients, given the results of noninvasive imaging and the history, surgical removal may be the obvious choice; preoperative biopsy may be unnecessary and even hazardous. In other patients whose primary treatment is likely to be nonsurgical, a biopsy is essential. Even when biopsy appears to be a reasonable goal, needle aspiration of the mediastinal mass may be considered hazardous or of low diagnostic yield.

Percutaneous biopsy may be technically difficult because of the overlying bony thoracic cavity and the proximity to lung tissue, the heart, and great vessels. FNA biopsy minimizes some of these potential hazards and may be effective in diagnosing mediastinal thyroid tissue, cancers, carcinomas, seminomas, inflammatory processes, and cysts.¹⁴⁵ Other noncarcinomatous malignancies such as lymphoproliferative disorders, thymomas, and benign tumors may require larger pieces of tissue. Such biopsy specimens may be obtained by a core-needle technique (which may not be safe depending on the location of the mass) or by surgery. In light of the issues cited, it is not surprising that the approach to biopsy of mediastinal masses may be different from center to center. Significant controversy exists in the literature regarding this topic. However, the treatment of up to 60% of patients with anterior mediastinal masses is ultimately nonsurgical, so it is essential to understand all options for obtaining adequate tissue for a definitive diagnosis using the least invasive approach. In one recent study, the authors used the medical history, physical examination, laboratory findings (erythrocyte sedimentation rate, C-reactive protein level, and presence of leukocytosis), and CT scan to assign patients to a possible lymphoproliferative diagnosis or a possible nonlymphoproliferative diagnosis. The authors concluded that if features suggest one of the lymphoproliferative group of mediastinal masses, the patient should undergo a surgical biopsy, because

larger pieces of tissues were required to make the diagnosis in their series. However, if a nonlymphoproliferative diagnosis was suggested, they recommended FNA before a potential surgical resection, because the yield of accurate diagnoses by FNA was higher in that group.¹⁴⁶

In 1989, the American Thoracic Society published a position statement declaring that "cutting needles should not be used to biopsy diffuse infiltrative lung diseases or lesions in or adjacent to the mediastinum or hilar areas."¹⁴⁷ Since that time, however, institutions with significant interventional expertise have challenged that statement. In one series of 142 patients with mediastinal masses, CT-guided transthoracic core-needle biopsies were performed using 14- to 22-gauge needles. The sensitivity of the procedure was 98.9% and the specificity was 100%. Inadequate material was obtained from only 0.7% of patients, with no pneumothoraces or bleeding complications reported.¹⁴⁷ The diagnostic yield is lower in series including a higher number of patients with lymphoproliferative disorders. Other series also reported a higher complication rate of 8 to 23% for pneumothorax and up to 10% for hemoptysis. In describing another series of anterior mediastinal masses, Herman and colleagues reported that needle biopsy was >90% specific in diagnosing most carcinomatous tumors, but its accuracy for diagnosing lymphomas was <50%.¹⁴⁸

Similar controversy exists regarding the yield of needle biopsies for definitively diagnosing germ cell tumors and thymomas. Knapp described 56 patients with malignant germ cell tumors of the mediastinum. Various combinations of germ cell elements were present in 34% of tumors, so open biopsies with multiple tissue sections were seen as advisable. For another series of 79 patients with mediastinal masses suspected to be malignant, Larsen reported that endoscopic ultrasound-guided FNA had a sensitivity of 92% and a specificity of 100%.^{145,149}

In the authors' experience, CT-guided needle biopsy has proven most useful for investigating tumors that are clearly unresectable or for assessing suspected carcinomatous tumors. For mediastinal masses suggestive of a lymphoma, obtaining larger pieces of tissue by mediastinoscopy to sample paratracheal adenopathy is preferred. Thoracoscopic biopsies are preferred for other locations. If an anterior mediastinal mass appears localized and is consistent with a thymoma, surgical resection is performed. For most localized tumors of the posterior mediastinum suspected to be neurogenic in origin, surgical resection without biopsy also is the preference of these authors. FNA guided by endoscopic ultrasound and endobronchial ultrasound and even core biopsy (guided by endoscopic ultrasound) are increasingly used for cytologic and tissue diagnosis of mediastinal masses and lymphadenopathy. Demonstration of the safety of the use of Tru-Cut core-needle biopsy (TCB) is a significant advance in the minimally invasive evaluation of mediastinal lymphadenopathy and periesophageal tumors, because the yield and accuracy are significantly improved with this procedure. When FNA and TCB were combined, the accuracy was 98%, compared with 79% for each modality independently. In addition, the results of the TCB changed the diagnosis in nine cases that had been missed by FNA due to inadequacy of the specimens. Finally, TCB was better at diagnosis of benign diseases than was FNA. Accessible nodal stations include subcarinal (level 7), aortopulmonary (level 5), periesophageal (level 8), inferior pulmonary ligament (level 9), and peritracheal (level 4) stations.¹⁵⁰ Technical expertise in these modalities should be pursued by thoracic and general surgeons.

SURGICAL BIOPSY AND RESECTION OF MEDIASTINAL MASSES

For tumors of the mediastinum that are not amenable to an endoscopic or CT-guided needle biopsy or that do not yield sufficient tissue for diagnosis, a surgical biopsy is indicated. The definitive approach to a surgical biopsy of the anterior mediastinum is through a median sternotomy. At the time of sternotomy, if the lesion is easily resectable, it should be completely removed. Given the invasiveness of the procedure and the inability in some patients to obtain a definitive diagnosis by frozen-section analysis, less invasive procedures are preferable if the lesion is large or if the CT scan or history suggests that surgery is not the best definitive treatment. Masses in the paratracheal region are easily biopsied by mediastinoscopy. For tumors of the anterior or posterior mediastinum, a left or right VATS approach often allows safe and adequate surgical biopsy. In some patients, an anterior mediastinotomy (i.e., Chamberlain procedure) may be ideal for an anterior tumor or a tumor with significant parasternal extension. Before a surgical biopsy is pursued, a discussion should be held with the pathologist regarding routine histologic assessment, special stains and markers, and requirements for lymphoma work-up.

The gold standard for the resection of most mediastinal masses is through a median sternotomy or lateral thoracotomy. In some cases, a lateral thoracotomy with sternal extension (hemclamshell) provides excellent exposure for extensive mediastinal tumors that have a lateral component. This standard has been successfully challenged for some anterior mediastinal lesions. For example, good results have been reported using a cervical incision with a sternal retractor for thymus removal. The upward lift allows the surgeon reasonable access to the anterior mediastinum and has proven adequate in some centers for definitive resection of the thymus gland for myasthenia gravis.¹⁵¹ Similarly, several large series have now shown that a right or left VATS approach can be successful for removal of the thymus gland and for resection of small (1 to 2 cm) encapsulated thymomas.^{152,153} Most would agree that if a larger anterior mediastinal tumor is seen or malignancy is suspected, a median sternotomy with a more radical resection should be performed.

Neoplasms

THYMUS

Thymic Hyperplasia

Diffuse thymic hyperplasia was first described in children after successful chemotherapy for lymphoma. It has now been described in adults and is referred to as *rebound thymic hyperplasia*.¹⁵⁴ It is most frequently reported after chemotherapy for lymphoma or germ cell tumors. Initially, atrophy of the thymic gland

is seen; later, on follow-up scans, the patient is noted to have thymic gland enlargement, which can be dramatic. The usual time course for thymic hyperplasia to develop is approximately 9 months after cessation of chemotherapy, but it has been reported anywhere from 2 weeks to 12 months after chemotherapy. Benign hyperplasia must be clearly distinguished from recurrent lymphoma or germ cell tumors. Doing so may be difficult, because thymic hyperplasia is dramatic in some patients, requiring careful follow-up and, at a minimum, serial CT scans. PET scanning may be helpful; a low standardized uptake value of tracer on PET scan suggests a benign tumor, but little has been published on this topic. Biopsies may be required if the clinical index of suspicion is high.

Thymic Tumors

Thymoma

Thymoma is the most frequently encountered neoplasm of the anterior mediastinum in adults (seen most frequently between 40 and 60 years of age). They are rare in children. Most patients with thymomas are asymptomatic, but depending on the institutional referral patterns, between 10 and 50% have symptoms suggestive of myasthenia gravis or have circulating antibodies to acetylcholine receptor. However, <10% of patients with myasthenia gravis are found to have a thymoma on CT. Thymectomy leads to improvement or resolution of symptoms of myasthenia gravis in only approximately 25% of patients with thymomas. In contrast, in patients with myasthenia gravis and no thymoma, thymectomy results are superior: up to 50% of patients have a complete remission and 90% improve. In 5% of patients with thymomas, other paraneoplastic syndromes, including red cell aplasia, hypogammaglobulinemia, systemic lupus erythematosus, Cushing's syndrome, or syndrome of inappropriate secretion of antidiuretic hormone may be present. Large thymic tumors may present with symptoms related to a mass effect, which may include cough, chest pain, dyspnea, or superior vena caval syndrome.

The diagnosis may be suspected based on CT scan and history, but imaging alone is not diagnostic. In most centers, the diagnosis is made after surgical resection because of the relative difficulty of performing a needle biopsy and the likelihood that removal will ultimately be recommended. However, CT-guided FNA biopsy has been reported to have a diagnostic sensitivity of 87% and a specificity of 95% in specialized centers. Cytokeratin is the marker that best distinguishes thymomas from lymphomas. In most patients, the distinction between lymphoma and thymoma can be made on CT scan, because most lymphomas are associated with marked lymphadenopathy and thymomas most frequently appear as a solitary encapsulated mass. PET may have a role in differentiating thymic cancer from thymoma, because thymic cancer tends to be very FDG avid.¹⁵⁵

The most commonly accepted staging system for thymomas is that of Masaoka.¹⁵⁶ It is based on the presence or absence of gross or microscopic invasion of the capsule and surrounding structures, as well as on the presence or absence of metastases (Table 19-31).

Table 19-31 Masaoka Staging System for Thymoma	
Stage I	Encapsulated tumor with no gross or microscopic evidence of capsular invasion
Stage II	Gross capsular invasion or invasion into the mediastinal fat or pleura or microscopic capsular invasion
Stage III	Gross invasion into the pericardium, great vessels, or lung
Stage IVA	Pleural or pericardial dissemination
Stage IVB	Lymphogenous or hematogenous metastasis

Histologically, thymomas generally are characterized by a mixture of epithelial cells and mature lymphocytes. Grossly, many thymomas remain well-encapsulated. Even those with capsular invasion often lack histologic features of malignancy; they appear cytologically benign and identical to early-stage tumors. This lack of classic cellular features of malignancy is the reason that most pathologists use the term *thymoma* or *invasive thymoma* rather than *malignant thymoma*. Thymic tumors with malignant cytologic features are classified separately and referred to as *thymic carcinomas*.

The definitive treatment for thymomas is complete surgical removal of all resectable tumors. Local recurrence rates and survival vary according to stage (Fig. 19-45). Resection generally is accomplished by median sternotomy with extension to hemiclamshell in more advanced cases. In centers with significant experience with VATS procedures, thymoma is not a contraindication to a VATS approach, provided the principles of resection are adhered to, such as a complete resection without disruption of the capsule. Even advanced tumors with local invasion of resectable structures such as the pericardium, superior vena cava, or innominate vessels should be considered for resection with reconstruction. The role of adjuvant or neoadjuvant therapies for advanced-stage tumors remains unclear. Traditionally, stage II thymomas have been treated by complete surgical resection followed by mediastinal irradiation, but due to the relatively small number of cases, randomized trials have not been done. A recent retrospective review of a single-institution series of stage II thymoma patients showed no difference in survival or local recurrence after complete surgical resection alone, compared with surgical resection with radiotherapy.¹⁵⁷ Advanced thymomas have been shown to respond to platinum-based chemotherapy and to corticosteroids.¹⁵⁸ One summary of chemotherapy trials showed an overall response rate of approximately 70%.¹⁵⁹ Combining radiotherapy and chemotherapy for local progression also has been successful in some small series; the combination appears to prolong survival, although most advanced-stage, unresectable thymomas will recur.¹⁶⁰ Therefore, it is imperative that all patients with thymomas undergo a thorough evaluation for potential resection.

Stage-specific survival for thymomas.

Thymic Carcinoma

Thymic carcinomas are unlike encapsulated or invasive thymomas in that they are unequivocally malignant at the microscopic level. Suster and Rosai classified thymic carcinomas into low-grade and high-grade tumors.¹⁶¹ Low-grade tumors are well differentiated with squamous cell, mucoepidermoid, or basaloid features. High-grade thymic carcinomas include those with lymphoepithelial, small cell neuroendocrine, sarcomatoid, clear cell, and undifferentiated or anaplastic features. Compared with thymomas, they are a more heterogeneous group of malignancies with a propensity for early local invasion and widespread metastases. Complete resection is occasionally curative, but most thymic carcinomas will recur and are refractory to chemotherapy.¹⁵⁸ The prognosis of patients with such tumors remains poor.

Thymolipoma

Thymolipomas are rare benign tumors that may grow to a very large size before being diagnosed. On CT scan, their appearance can be dramatic, with a characteristic fat density dotted by isolated areas of soft tissue density representing islands of thymic tissue (Fig. 19-46). Thymolipomas are generally well-encapsulated, soft, and pliable masses that do not invade surrounding structures. Resection is recommended for large masses.

Fig. 19-46.

Massive thymolipoma, which was asymptomatic, in an 18-year-old woman.

NEUROGENIC TUMORS

Most neurogenic tumors of the mediastinum arise from the cells of the nerve sheath, from ganglion cells, or from the paraganglionic system (Table 19-32). The incidence, cell types, and risk of malignancy strongly correlate with patient age. Tumors of nerve sheath origin predominate in adults. Most present as asymptomatic incidental findings and most are benign. In children and young adults, tumors of the autonomic ganglia predominate, with up to two thirds being malignant.¹⁶²

Table 19-32 Classification of Neurogenic Tumors of the Mediastinum		
Tumor Origin	Benign	Malignant
Nerve sheath	Neurilemoma, neurofibroma, melanotic schwannoma, granular cell tumor	Neurofibrosarcoma
Ganglion cell	Ganglioneuroma	Ganglioneuroblastoma, neuroblastoma
Paraganglionic cell	Chemodectoma, pheochromocytoma	Malignant chemodectoma, malignant pheochromocytoma

Source: Reproduced with permission from Bousamra.¹⁶² Copyright Elsevier.

Nerve Sheath Tumors

Nerve sheath tumors account for 20% of all mediastinal tumors. More than 95% of nerve sheath tumors are benign neurilemmas or neurofibromas. Malignant neurosarcomas are much less common.

Neurilemoma

Neurilemmas, also called *schwannomas*, arise from Schwann cells in intercostal nerves. They are firm, well encapsulated, and generally benign. Two characteristic histologic components of benign neurilemmas exist and are referred to as Antoni type A and Antoni type B regions. Antoni type A regions contain compact spindle cells with twisted nuclei and nuclear palisading. Antoni type B regions contain loose and myxoid connective tissue with a haphazard cellular arrangement. These characteristics allow them to be distinguished from malignant, fibrosarcomatous tumors, which lack encapsulation and have no Antoni features. If routine CT scan suggests extension of a neurilemoma into the intervertebral foramen, MRI is suggested to evaluate the extent of this dumbbell configuration (Fig. 19-47). Such a configuration may lead to cord compression and paralysis, and requires a more complex surgical approach. It is recommended that most nerve sheath tumors be resected. Traditionally, this has been performed by open thoracotomy, but a VATS approach has been established as safe and effective for simple surgeries and, in experienced centers, even the more complex operations.¹⁶³ It is reasonable to follow small, asymptomatic paravertebral tumors in older patients or in patients for whom surgery presents a high risk. In children, ganglioneuroblastomas or neuroblastomas are more common; therefore, all neurogenic tumors should be completely resected.

Magnetic resonance image of a neurogenic tumor with extension into the spinal canal via the foramen, which gives a typical dumbbell appearance.

Neurofibroma

Neurofibromas have components of both nerve sheaths and nerve cells and account for up to 25% of nerve sheath tumors. Up to 40% of patients with mediastinal fibromas have generalized neurofibromatosis (von Recklinghausen's disease). Approximately 70% of neurofibromas are benign. Malignant degeneration to a neurofibrosarcoma may occur in 25 to 30% of patients.¹⁶⁴ The risk of malignant degeneration is increased in those of advanced age, those with von Recklinghausen's disease, and those with previous exposure to radiation. Neurofibrosarcomas carry a poor prognosis because of rapid growth and aggressive local invasion along nerve bundles. Complete surgical resection is the mainstay of treatment. Adjuvant radiotherapy or chemotherapy does not confer a significant benefit but may be added if complete resection is not possible.¹⁶⁵ The 5-year survival rate is 53% but drops to 16% in patients who have neurofibromatosis or large tumors (>5 cm).

Ganglion Cell Tumors

Ganglion cell tumors arise from the sympathetic chain or from the adrenal medulla. Histologic cell types include ganglioneuromas, ganglioneuroblastomas, and neuroblastomas.

Ganglioneuroma

Ganglioneuromas are well-differentiated, benign tumors that are characterized histologically by well-differentiated ganglion cells with a background of Schwann cells. They tend to occur in young adults and to be asymptomatic, although diarrhea related to secretion of vasoactive intestinal peptide has been described. These tumors have a propensity for intraspinal canal extension, although they remain well encapsulated. Complete resection is curative, and the risk of local recurrence is low.

Ganglioneuroblastoma

Ganglioneuroblastomas contain a mixture of benign ganglion cells and malignant neuroblasts. The distribution of these cells within the tumor is predictive of the clinical course. The nodular pattern is associated with a high incidence of metastatic disease; tumors with the diffuse pattern rarely metastasize. On gross examination, these tumors often remain encapsulated; histologically, there are focal calcifications around regions of neuroblasts. Ganglioneuroblastomas arise most frequently in infants and children <3 years of age. The majority of tumors are resectable, and the 5-year survival rate is 80%.

Neuroblastoma

Neuroblastomas are highly malignant. They are the most common extracranial solid malignancy in pediatric patients and the most common intrathoracic malignancy of childhood. The adrenal gland is a common primary site, but 14% of all neuroblastomas arise in the thorax, where the tumors are commonly associated with extension into the spinal canal and osseous invasion. These thoracic tumors are not as recalcitrant to chemotherapy and surgical resection as

are other chest malignancies; they are more likely to be resectable, with less invasion of surrounding organs. More than half occur in children <2 years of age; 90% arise within the first decade of life. These tumors are therefore discussed in more detail in Chap. 39 on pediatric surgery.

Paraganglionic Tumors

Paraganglionic tumors arising in the thoracic cavity include chemodectomas and pheochromocytomas. Only 10% of all pheochromocytomas are located in an extra-adrenal site. Intrathoracic pheochromocytomas are one of the rarest tumors. Approximately 10% of thoracic pheochromocytomas are malignant, a rate similar to that of adrenal tumors. The most common thoracic location is within the costovertebral sulcus, but paraganglionic tumors also arise within the visceral compartment of the mediastinum. These catecholamine-producing lesions can lead to life-threatening hemodynamic problems, so complete removal is important. Diagnosis generally is confirmed by the measurement of elevated levels of urinary catecholamines and their metabolites. Localization is by CT scan, aided by MIBG scintigraphy. Preoperative care includes alpha- and beta-adrenergic blockade to prevent intraoperative malignant hypertension and arrhythmias. These tumors tend to be highly vascular and should be approached with care. Chemodectomas are rare tumors that may be located around the aortic arch, vagus nerves, or aorticosympathetics. They rarely secrete catecholamines and are malignant in up to 30% of patients.

LYMPHOMA

Overall, lymphomas are the most common malignancy of the mediastinum. In approximately 50% of patients who have both Hodgkin's and non-Hodgkin's lymphoma, the mediastinum is the primary site. The anterior compartment is most commonly involved, with occasional involvement of the middle compartment and hilar nodes. The posterior compartment is rarely involved. Chemotherapy and/or radiotherapy results in a cure rate of up to 90% for early-stage Hodgkin's disease and up to 60% for more advanced stages.

MEDIASTINAL GERM CELL TUMORS

Germ cell tumors are uncommon neoplasms, with only approximately 7000 diagnosed each year. However, they are the most common malignancy in young men between the ages of 15 and 35 years. Most germ cell tumors are gonadal in origin. Those with the mediastinum as the primary site are rare, constituting <5% of all germ cell tumors, and <1% of all mediastinal tumors (usually occurring in the anterior compartment). If a malignant mediastinal germ cell tumor is found, it is important to exclude a gonadal primary tumor. Primary mediastinal germ cell tumors (including teratomas, seminomas, and nonseminomatous malignant germ cell tumors) are a heterogeneous group of benign and malignant neoplasms thought to originate from primitive pluripotent germ cells "misplaced" in the mediastinum during embryonic development. Previously, most mediastinal germ cell tumors were thought to be metastatic. However, two lines of evidence suggest that many mediastinal germ cell tumors are primary, developing from pluripotent primordial germ cells in the mediastinum: (a) several autopsy series showed that patients with germ cell tumors in extragonadal sites, presumed previously to have originated from the gonads, had no evidence of an occult primary tumor or of any residual scar of the gonads, even after an exhaustive search; and (b) patients treated by surgery or radiation for their mediastinal germ cell tumors had long-term survival with no late testicular recurrences.¹⁶⁶

About one third of all primary mediastinal germ cell tumors are seminomatous. Two thirds are nonseminomatous tumors or teratomas. Treatment and prognosis vary considerably within these two groups. Mature teratomas are benign and can generally be diagnosed by the characteristic CT findings of a multilocular cystic tumor, encapsulated with combinations of fluid, soft tissue, calcium, and/or fat attenuation in the anterior compartment. FNA biopsy alone may be diagnostic for seminomas, and usually levels of serum markers, including hCG and AFP, are normal. In 10% of seminomas, hCG levels are slightly elevated. FNA findings, along with high hCG and AFP levels, can accurately diagnose nonseminomatous tumors. If the diagnosis remains uncertain after assessment of FNA findings and serum marker levels, then core-needle biopsy or surgical biopsy may be required. An anterior mediastinotomy (Chamberlain procedure) or thoracoscopy is the most frequent diagnostic surgical approach.

Teratoma

Teratomas are the most common type of mediastinal germ cell tumors, accounting for 60 to 70% of such tumors. They contain two or three embryonic layers that may include teeth, skin, hair (ectodermal), cartilage and bone (mesodermal), or bronchial, intestinal, or pancreatic tissue (endodermal). Therapy for mature, benign teratomas is surgical resection, which confers an excellent prognosis.

Rarely, teratomas may contain a focus of carcinoma. These malignant teratomas (or teratocarcinomas) are locally aggressive. Often diagnosed at an unresectable stage, they respond poorly to chemotherapy and in a limited manner to radiotherapy; the prognosis is uniformly poor.

Seminoma

Most patients with seminomas have advanced disease at the time of diagnosis and present with symptoms of local compression, including superior vena caval syndrome, dyspnea, or chest discomfort. With advanced disease, the preferred treatments are combination cisplatin-based chemotherapy regimens with bleomycin and either etoposide or vinblastine. Complete responses have been reported in over 75% of patients treated with these regimens. Surgical resection may be curative for small asymptomatic seminomas that are found incidentally on screening CT scans. Surgical resection of residual masses after chemotherapy may be indicated.

Nonseminomatous Germ Cell Tumors

Nonseminomatous germ cell tumors include embryonal cell carcinomas, choriocarcinomas, endodermal sinus tumors, and mixed types. They are often bulky, irregular tumors of the anterior mediastinum with areas of low attenuation on CT scan because of necrosis, hemorrhage, or cyst formation. Frequently, adjacent structures have become involved, with metastases to regional lymph nodes, pleura, and lungs. Lactate dehydrogenase (LDH), AFP, and hCG levels are frequently elevated. Chemotherapy is the preferred treatment and includes combination therapy with cisplatin, bleomycin, and etoposide. With this regimen, survival is 67% at 2 years and 60% at 5 years. Surgical resection of residual masses is indicated, because it may guide further therapy. Up to 20% of residual masses contain additional tumors; in another 40%, mature teratomas; and the remaining 40%, fibrotic tissue.

Mediastinal Cysts

PRIMARY MEDIASTINAL CYST

Benign cysts account for up to 25% of mediastinal masses. Most are located in the middle compartment, and they are the most frequent type of mass occurring in this compartment. A CT scan showing characteristic features of near-water density in a typical location is virtually 100% diagnostic.¹⁶⁷

PERICARDIAL CYST

Pericardial cysts, the most common type of mediastinal cysts, are usually asymptomatic and detected incidentally. Typically they contain a clear fluid and appear in the right costophrenic angle. The cyst wall lining is a single layer of mesothelial cells. For most simple, asymptomatic pericardial cysts, observation alone is recommended. Surgical resection or aspiration may be indicated for complex cysts or large symptomatic cysts.

BRONCHOGENIC CYST

Bronchogenic cysts are developmental anomalies that occur during embryogenesis and manifest as an abnormal budding of the foregut or tracheobronchial tree. Most frequently they arise in the mediastinum, but approximately 15% occur within the pulmonary parenchyma. The most frequent mediastinal location is just posterior to the carina or main stem bronchus. Thin walled and lined with respiratory epithelium, they contain a protein-rich mucoid material and varying amounts of seromucous glands, smooth muscle, and cartilage. They may communicate with the tracheobronchial tree.

The management of bronchogenic cysts remains controversial. In children, most such cysts are symptomatic. Resection generally is recommended, because serious complications may ensue if the cyst becomes larger or infected. Complications include airway obstruction, infection, rupture, and, rarely, malignant transformation.^{168,169}

In adults, over half of all bronchogenic cysts are found incidentally during work-up for an unrelated problem or during screening. The natural history of an incidentally diagnosed, asymptomatic bronchogenic cyst is unknown, but it is clear that many such cysts do not lead to clinical problems. In one study of young military personnel, 78% of all bronchogenic cysts found on routine chest radiographs were asymptomatic.¹⁷⁰ However, in other reports with more comprehensive follow-up, up to 67% of adults with incidentally found bronchogenic cysts eventually became symptomatic.¹⁷¹ Symptoms include chest pain, cough, dyspnea, and fever. Serious complications are less common and include hemodynamic compromise, airway obstruction, pulmonary artery obstruction, hemoptysis, and malignant degeneration. Symptomatic bronchogenic cysts should be removed. Traditionally, removal has been via posterolateral thoracotomy.¹⁷¹ Resection of infected cysts may be quite difficult because of the presence of dense adhesions; elective removal often is recommended before infection has a chance to occur. Thoracoscopic exploration and resection are possible for small cysts with minimal adhesions. The goal of minimally invasive or open surgery should be complete removal of the cyst wall.

ENTERIC CYST

Most clinicians agree that in contrast to bronchogenic cysts, esophageal cysts should be removed, regardless of the presence or absence of symptoms. Esophageal cysts have a propensity for serious complications secondary to enlargement, which leads to hemorrhage, infection, or perforation. Thus, surgical resection is the treatment of choice for both adults and children.

THYMIC CYST

Thymic cysts generally are asymptomatic and are discovered incidentally during radiographic work-up for an unrelated problem. Simple cysts are of no consequence; however, the occasional cystic neoplasm must be ruled out. Cystic components occasionally are seen in patients with thymoma and Hodgkin's disease.

Ectopic Endocrine Glands

Up to 5% of all mediastinal masses are estimated to be of thyroid origin. However, most of these masses are simple extensions of thyroid masses. They usually are nontoxic, and over 95% of such masses can be completely resected through a cervical approach. True ectopic thyroid tissue in the mediastinum is rare. Ten to 20% of abnormal parathyroid glands are found in the mediastinum; most can be removed during exploration from a cervical incision. In cases of true mediastinal parathyroid glands, thoracoscopic or open resection may be indicated. Location generally can be pinpointed by a combination of CT and

Mediastinitis

ACUTE MEDIASTINITIS

Acute mediastinitis is a fulminant infectious process that spreads along the fascial planes of the mediastinum. Infections originate most commonly from esophageal perforations, sternal infections, and oropharyngeal or neck infections, but a number of less common etiologic factors can lead to this deadly process (Table 19-33). As infections from any of these sources enter the mediastinum, spread may be rapid along the continuous fascial planes connecting the cervical and mediastinal compartments. Clinical signs and symptoms include fever, chest pain, dysphagia, respiratory distress, and cervical and upper thoracic subcutaneous crepitus. In severe cases, the clinical course can rapidly deteriorate to florid sepsis, hemodynamic instability, and death. Thus, a high index of suspicion is required in the context of any infection with access to the mediastinal compartments.

Table 19-33 Etiologic Factors in Acute Mediastinitis
Esophageal perforation
Iatrogenic
Balloon dilatation (for achalasia)
Bougienage (for peptic stricture)
Esophagoscopy
Sclerotherapy (for variceal bleeding)
Spontaneous
Postemetic (Boerhaave's syndrome)
Straining during:
Elimination
Weight lifting
Seizure
Pregnancy
Childbirth
Ingestion of foreign bodies
Trauma
Blunt
Penetrating
Postsurgical
Infection
Anastomotic leak
Erosion by cancer
Deep sternotomy wound infection
Oropharynx and neck infections
Ludwig's angina
Quinsy
Retropharyngeal abscess
Cellulitis and suppurative lymphadenitis of the neck
Infections of the lung and pleura
Subphrenic abscess
Rib or vertebral osteomyelitis
Hematogenous or metastatic abscess

A chest CT scan can be particularly helpful in determining the extent of spread and the best approach to surgical drainage. Acute mediastinitis is a true surgical emergency, and treatment must be instituted immediately and must be aimed at correcting the primary problem, such as the esophageal perforation or oropharyngeal abscess. Another major concern is débridement and drainage of the spreading infectious process within the mediastinum, neck, pleura, and other tissue planes. Antibiotic administration, fluid resuscitation, and other supportive measures are important, but surgical correction of the problem at its

source and open débridement of infected areas are critical measures. Surgical débridement may need to be repeated and other planes and cavities explored depending on the patient's clinical status. Blood cell counts and serial CT scans also may be required. Persistent sepsis or collections on CT scan may require further radical surgical débridement.

CHRONIC MEDIASTINITIS

Sclerosing or fibrosing mediastinitis is a result of chronic inflammation of the mediastinum, most frequently as a result of granulomatous infections such as histoplasmosis or tuberculosis. The process begins in lymph nodes and continues as a chronic, low-grade inflammation leading to fibrosis and scarring. In many patients, the clinical manifestations are silent. However, if the fibrosis is progressive and severe, it may lead to encasement of the mediastinal structures, causing entrapment and compression of the low-pressure veins (including the superior vena cava and innominate and azygos veins). This fibrotic process can compromise other structures such as the esophagus and pulmonary arteries. There is no definitive treatment. Surgery is indicated only for diagnosis or in specific patients to relieve airway or esophageal obstruction or to achieve vascular reconstruction. Reports of palliative success with less invasive procedures (such as dilation and stenting of airways, the esophagus, or the superior vena cava) are promising. In one series of 22 patients, ketoconazole was effective in controlling progression.¹⁷² In another series of 71 patients, 30% died during long-term follow-up. Chronic mediastinitis is similar to the fibrotic changes that occur in other sites, including retroperitoneal fibrosis, sclerosing cholangitis, and Riedel's thyroiditis.

PLEURA AND PLEURAL SPACE

Anatomy

The parietal pleura is a mesothelial lining of each hemithorax that invaginates at the hilum of each lung and continues on to cover each lung as the visceral pleura. Between these two surfaces is the potential pleural space, which is normally occupied only by a thin layer of lubricating pleural fluid. Two physiologic processes hold the visceral pleura of the lung in close apposition to the parietal pleura of the chest wall: those mechanisms that constantly remove pleural fluid and those that prevent an accumulation of free gas in the pleural space. A network of somatic, sympathetic, and parasympathetic fibers innervates the parietal pleura. Irritation of the parietal surface by inflammation, tumor invasion, trauma, and other processes can lead to a sensation of chest wall pain. The visceral pleura have no somatic innervation.^{173,174}

Pleural Effusion

Pleural effusion refers to any significant collection of fluid within the pleural space. Normally, there is an ongoing balance between the flow of lubricating fluid into the pleural space and its continuous absorption. Between 5 and 10 L of fluid normally enters the pleural space daily by filtration through microvessels supplying the parietal pleura (located mainly in the less dependent regions of the cavity). The net balance of pressures in these capillaries leads to fluid flow from the parietal pleural surface into the pleural space, and the net balance of forces in the pulmonary circulation leads to absorption through the visceral pleura. Normally, 15 to 20 mL of pleural fluid is present at any given time. Any disturbance in these forces can lead to imbalance and accumulation of pleural fluid. Common pathologic conditions in North America that lead to pleural effusion include congestive heart failure, bacterial pneumonia, malignancy, and pulmonary emboli (Table 19-34).¹⁷⁵

Table 19-34 Leading Causes of Pleural Effusion in the United States, Based on Data from Patients Undergoing Thoracentesis			
Cause	Annual Incidence	Transudate	Exudate
Congestive heart failure	500,000	Yes	No
Pneumonia	300,000	No	Yes
Cancer	200,000	No	Yes
Pulmonary embolus	150,000	Sometimes	Sometimes
Viral disease	100,000	No	Yes
Coronary artery bypass surgery	60,000	No	Yes
Cirrhosis with ascites	50,000	Yes	No

DIAGNOSTIC WORK-UP

The initial diagnostic work-up for pleural effusion is guided in large part by the patient's history and findings of the physical examination. Bilateral pleural effusions are due to congestive heart failure in over 80% of patients. If the clinical history suggests this diagnosis, a trial of diuresis (rather than thoracentesis) may be indicated. Up to 75% of effusions due to congestive heart failure resolve within 48 hours with diuresis alone.

A patient presenting with cough, fever, leukocytosis, and unilateral infiltrate and effusion is likely to have a parapneumonic process. If the effusion is small

and the patient responds to antibiotic therapy, a diagnostic thoracentesis may be unnecessary. However, a patient who has an obvious pneumonia and a large pleural effusion that is purulent and foul smelling has an empyema. Aggressive drainage with chest tubes is required, possibly with surgical intervention. Outside of the setting of congestive heart failure or small effusions associated with an improving pneumonia, most patients with pleural effusions of unknown cause should undergo thoracentesis.

A general classification of pleural fluid collections into transudates and exudates is helpful in understanding the various causes (Table 19-35). Transudates are protein-poor ultrafiltrates of plasma that form because of alterations in systemic hydrostatic pressures or colloid osmotic pressures (e.g., with congestive heart failure or cirrhosis). On gross visual inspection, a transudative effusion is generally clear or straw colored. Exudates are protein-rich pleural fluid collections that generally occur because of inflammation or invasion of the pleura by tumors. Grossly, they are often turbid, bloody, or purulent. Grossly bloody effusions in the absence of trauma are frequently malignant but also may occur in the setting of a pulmonary embolism or pneumonia. Several criteria have traditionally been used to differentiate transudates from exudates. An effusion is considered exudative if the ratio of pleural fluid protein to serum protein is >0.5 and the LDH ratio is >0.6 or the absolute pleural LDH level is more than two thirds of the normal upper limit for serum. If these criteria suggest a transudate, the patient should be carefully evaluated for congestive heart failure, cirrhosis, and other conditions associated with transudative effusion.

Table 19-35 Differential Diagnosis of Pleural Effusions
I. Transudative pleural effusions
A. Congestive heart failure
B. Cirrhosis

17. Iatrogenic pleural effusions
J. Hemothorax
K. Chylothorax

If an exudative effusion is suggested, further diagnostic studies may be helpful. If total and differential cell counts reveal a predominance of neutrophils (>50% of cells), the effusion is likely to be associated with an acute inflammatory process (such as a parapneumonic effusion or empyema, pulmonary embolus, or pancreatitis). A predominance of mononuclear cells suggests a more chronic inflammatory process (such as cancer or tuberculosis). Gram's staining and culture should be performed, if possible with inoculation of fluid specimens into culture bottles at the bedside. Pleural fluid glucose levels are frequently decreased (<60 mg/dL) with complex parapneumonic effusions or malignant effusions. Cytologic testing should be done on exudative effusions to rule out an associated malignancy. Cytologic analysis is accurate in diagnosing >70% of malignant effusions associated with adenocarcinomas but is less sensitive for those associated with mesotheliomas (<10%), squamous cell carcinomas (20%), or lymphomas (25 to 50%). If the diagnosis remains uncertain after drainage and fluid analysis, thoracoscopy and direct biopsy are indicated. Tuberculous effusions can now be diagnosed accurately by measurement of increased levels of adenosine deaminase (>40 units/L) in the pleural fluid.^{176,177} Pulmonary embolism should be suspected in a patient with a pleural effusion occurring in association with pleuritic chest pain, hemoptysis, or dyspnea out of proportion to the size of the effusion. These effusions may be transudative, but if an associated infarct occurs near the pleural surface, an exudate may be seen. If a pulmonary embolism is suspected in a postoperative patient, most clinicians would obtain a spiral CT scan. Alternatively, duplex ultrasonography of the lower extremities may yield a diagnosis of deep vein thrombosis, which calls for anticoagulant therapy and precludes the need for a specific diagnosis of pulmonary embolism. In some patients, a blood test for levels of D-dimer may be helpful; if results of a sensitive D-dimer blood test are negative, pulmonary embolism may be ruled out.

MALIGNANT PLEURAL EFFUSION

Malignant pleural effusions may occur in association with a number of different malignancies, most commonly lung cancer, breast cancer, and lymphomas, depending on the patient's age and gender (Tables 19-36 and 19-37).¹⁷⁸ Malignant effusions are exudative and often tinged with blood. An effusion in the setting of a malignancy means a more advanced stage of disease and generally indicates an unresectable tumor. Mean survival in such cases is 3 to 11 months. Occasionally, benign pleural effusions may be associated with a bronchogenic NSCLC, and surgical resection may still be indicated if the results of cytologic testing of the effusion is negative for malignancy. An important issue is the size of the effusion and the degree of dyspnea that results. Symptomatic, moderate to large effusions should be drained by chest tube, pigtail catheter, or VATS, followed by instillation of a sclerosing agent. Before the pleural cavity is sclerosed, whether by chest tube or VATS, the lung should be nearly fully expanded. Poor expansion of the lung (because of entrapment by tumor or adhesions) generally predicts a poor result with pleurodesis and is the primary indication for placement of indwelling pleural catheters. These catheters have dramatically changed the management of end-stage cancer treatment because they substantially shorten the amount of time patients spend in the hospital during their final weeks of life.¹⁷⁹ The choices for sclerosing agent include talc, bleomycin, and doxycycline. Success rates for controlling the effusion range from 60 to 90%, depending on the exact scope of the clinical study, the degree of lung expansion after the pleural fluid is drained, and the care with which the outcomes were reported. Figure 19-48 presents a decision algorithm for the management of malignant pleural effusion.

Table 19-36 Primary Organ Site or Neoplasm Type in Male Patients with Malignant Pleural Effusions		
Primary Site or Tumor Type	No. of Male Patients	Percentage of Male Patients
Lung	140	49.1
Lymphoma/leukemia	60	21.1
Gastrointestinal tract	20	7.0
Genitourinary tract	17	6.0
Melanoma	4	1.4
Miscellaneous less common tumors	10	3.5
Primary site unknown	31	10.9

Empyema

Thoracic empyema is defined by a purulent pleural effusion. The most common causes are parapneumonic, but postsurgical or posttraumatic empyema also is common (Table 19-38). The finding of grossly purulent, foul-smelling pleural fluid makes the diagnosis of empyema obvious on visual examination at the bedside. In the early stage, small to moderate turbid pleural effusions in the setting of a pneumonic process may require further pleural fluid analysis. Close clinical follow-up also is imperative to determine if progression to empyema is occurring. A deteriorating clinical course or a pleural pH of <7.20 and a glucose level of <40 mg/dL indicates the need to drain the fluid.

Table 19-38 Pathogenesis of Empyema
Contamination from a source contiguous to the pleural space (50–60%)
Lung
Mediastinum
Deep cervical area
Chest wall and spine
Subphrenic area
Direct inoculation of the pleural space (30–40%)
Minor thoracic interventions
Postoperative infections
Penetrating chest injuries
Hematogenous infection of the pleural space from a distant site (<1%)

Source: Reproduced with permission from Paris F, et al: Empyema and bronchopleural fistula, in Pearson FG, et al (eds): *Thoracic Surgery*, 2nd ed. New York: Churchill Livingstone, 2002, p 1177. Copyright Elsevier.

Patients of all ages can develop empyema, but the frequency is increased in older or debilitated patients. Common associated conditions include a pneumonic process in patients with pulmonary disorders and neoplasms, cardiac problems, diabetes mellitus, drug and alcohol abuse, neurologic impairments, postthoracotomy problems, and immunologic impairments. The mortality rate for empyema frequently depends on the degree of severity of the comorbidity; it may range from as low as 1% to >40% in immunocompromised patients.

PATHOPHYSIOLOGY

The spectrum of organisms involved in pneumonic processes that progress to empyema is changing. Pneumococci and staphylococci continue to be the most common, but gram-negative aerobic bacteria and anaerobes are becoming more prevalent. Cases involving mycobacteria or fungi are rare. Multiple organisms may be isolated in up to 50% of patients, but cultures may be sterile if antibiotic therapy was initiated before specimens were obtained for culture or if the culture process was not efficient. Therefore, it is imperative that the choice of antibiotics be guided by the clinical scenario and not just the organisms found on culture. Broad-spectrum coverage may still be required even when cultures have failed to grow out an organism or when a single organism is grown but the clinical picture is more consistent with a multiorganism process. Commonly identified gram-negative organisms include *E. coli*, *Klebsiella* and *Pseudomonas* species, and Enterobacteriaceae. Anaerobic organisms may be fastidious and difficult to document by culture and are associated with infections in patients with periodontal diseases, aspiration syndromes, alcoholism or drug abuse, or gastroesophageal reflux as well as patients undergoing general anesthesia.

The route of organism entry into the pleural cavity may be by contiguous spread from pneumonia, lung abscess, liver abscess, or another infectious process with contact with the pleural space. Organisms also may enter the pleural cavity by direct contamination from thoracentesis, thoracic surgical procedures, esophageal injuries, or trauma.

As organisms enter the pleural space, an influx of polymorphonuclear cells occurs, with a subsequent release of inflammatory mediators and toxic oxygen radicals. In attempting to control the invading organisms, these mechanisms lead to variable degrees of endothelial injury and capillary instability. An influx of fluid into the pleural space then occurs, followed by a process that overwhelms the normal exit avenues of the pleural lymphatic network. This early effusion is watery and free flowing in the pleural cavity. Thoracentesis at this stage yields fluid with a pH typically >7.3, a glucose level of >60 mg/dL, and a low LDH level (<500 units/L). At this stage, the decision to use antibiotics alone or to perform a repeat thoracentesis, chest tube drainage, thoracoscopy, or open thoracotomy depends on the amount of pleural fluid, its consistency, the clinical status of the patient, the degree of expansion of the lung after drainage, and the presence of loculated fluid in the pleural space (vs. free-flowing purulent fluid). If relatively thin, purulent pleural fluid is found early in the setting of a pneumonic process, the fluid often can be completely drained with simple large-bore thoracentesis. If complete lung expansion is obtained and the pneumonic process is responding to antibiotics, no further drainage may be necessary. A finding of pleural fluid with a pH <7.2 and with a low glucose level means that a more aggressive approach to drainage should be pursued.

The pleural fluid may become thick and loculated over the course of hours to days and may be associated with fibrinous adhesions (the fibrinopurulent stage). At this stage, chest tube insertion with closed-system drainage or drainage with thoracoscopy may be necessary to remove the fluid and adhesions and to allow complete lung expansion.¹⁸⁰ Further progression of the inflammatory process leads to the formation of a pleural peel, which may be flimsy and easy to remove early on. As the process progresses, however, a thick pleural rind may develop, leaving a trapped lung. Complete lung decortication by thoracotomy or, in some patients, thoracoscopy would then be necessary.

MANAGEMENT

If there is a residual space, persistent pleural infection is likely to occur. A persistent pleural space may be secondary to contracted, but intact, underlying lung; or it may be secondary to surgical lung resection. If the space is small and well drained by chest tubes, a conservative approach may be possible. This requires leaving the chest tubes in place and attached to closed-system drainage until symphysis of the visceral and parietal surfaces takes place. At this point, the chest tubes can be removed from suction. If the residual pleural space remains stable, the tubes can be cut and advanced out of the chest over the course of several weeks. If the patient's condition is stable, tube removal frequently can be done in the outpatient setting, guided by the degree of drainage and the size of the residual space visualized on serial CT scans. The presence of larger spaces may require open thoracotomy and decortication in an attempt to re-expand the lung to fill this residual space. If re-expansion fails or appears to carry too high a risk, then open drainage, rib resection, and prolonged packing may be required, with delayed closure with muscle flaps or thoracoplasty.¹⁸¹ Most chronic pleural space problems can be avoided by early specialized thoracic surgical consultation and complete drainage of empyemas, which allows space obliteration by the reinflated lung.

Chylothorax

Chylothorax develops most commonly after surgical trauma to the thoracic duct or a major branch but may also be associated with a number of other conditions (Table 19-39).¹⁸² It generally is unilateral; for example, it may occur on the right after esophagectomy, in which the duct is most frequently injured during dissection of the distal esophagus. The esophagus comes into close proximity to the thoracic duct as it enters the chest from its origin in the abdomen

at the cisterna chyli (Fig. 19-49). If the mediastinal pleura is disrupted on both sides, bilateral chylothoraces may occur. Left-sided chylothorax may develop after a left-sided neck dissection, especially in the region of the confluence of the subclavian and internal jugular veins. Chylothorax also may follow nonsurgical trauma, including penetrating or blunt injuries to the chest or neck area, central line placements, and other surgical misadventures. It is also seen in neonates, probably secondary to birth trauma. It may be seen in association with a variety of benign and malignant diseases that generally involve the lymphatic system of the mediastinum or neck. Given the significant variability of the course of the thoracic duct within the chest, some injuries are inevitable. The direct relationship of chylothorax to a surgical procedure, traumatic event, or neoplastic process may not always be obvious. Understanding the anatomy and course of the thoracic duct and some of its more common variants is helpful.

Table 19-39 Etiology of Chylothorax
Congenital
Atresia of thoracic duct
Thoracic duct–pleural space fistula
Birth trauma
Traumatic and/or iatrogenic

Normal thoracic duct anatomy. The esophagus comes into close proximity to the thoracic duct (d.) as it enters the chest from its origin in the abdomen at the cisterna chyli.

PATHOPHYSIOLOGY

Most commonly, the thoracic duct originates in the abdomen from the cisterna chyli, which is located in the midline, near the level of the second lumbar vertebra. From this origin, the thoracic duct ascends into the chest through the aortic hiatus at the level of T10 to T12 and courses just to the right of the aorta (see Fig. 19-49). As the thoracic duct courses cephalad above the diaphragm, it most commonly remains in the right chest, lying just behind the esophagus, between the aorta and azygos vein. The duct continues superiorly, lying just to the right of the vertebral column. Then, at about the level of the fifth or sixth thoracic vertebra, it crosses behind the aorta and the aortic arch into the left posterior mediastinum. From this location, it again courses superiorly, staying near the esophagus and mediastinal pleura as it exits the thoracic inlet. As it exits the thoracic inlet, it passes just to the left, just behind the carotid sheath and anterior to the inferior thyroid and vertebral bodies. Just medial to the anterior scalene muscle, it courses inferiorly and drains into the union of the internal jugular and subclavian veins. Given the extreme variability in the position of the main duct and its branches, accumulation of chyle in the chest or flow from penetrating wounds may be seen in association with a variety of traumatic events and medical conditions.¹⁸³

The main function of the duct is to transport fat absorbed from the digestive system. The composition of normal chyle is fat, with variable amounts of protein and lymphatic material (Table 19-40). Given the high volumes of chyle that flow through the thoracic duct, significant injuries can cause leaks in excess of 2 L/d. If this leakage is left untreated, protein, volume, and lymphocyte depletion can lead to serious metabolic effects and death. The diagnosis generally requires thoracentesis, the results of which may be grossly suggestive; often the pleural fluid is milky and nonpurulent. However, if the patient is under *nil per os* (nothing by mouth, or NPO) orders, the pleural fluid may not be grossly abnormal. Laboratory analysis of the pleural fluid shows a high lymphocyte count and high triglyceride levels. If the triglyceride level is >110 mg/100 mL, a chylothorax is almost certainly present (99% accuracy rate). If the triglyceride level is <50 mg/100 mL, there is only a 5% chance of chylothorax. In many clinical situations, the accumulation of chyle may be slow because minimal digestive fat is flowing through the GI tract after major trauma or surgery, so the diagnosis may be more difficult to establish.

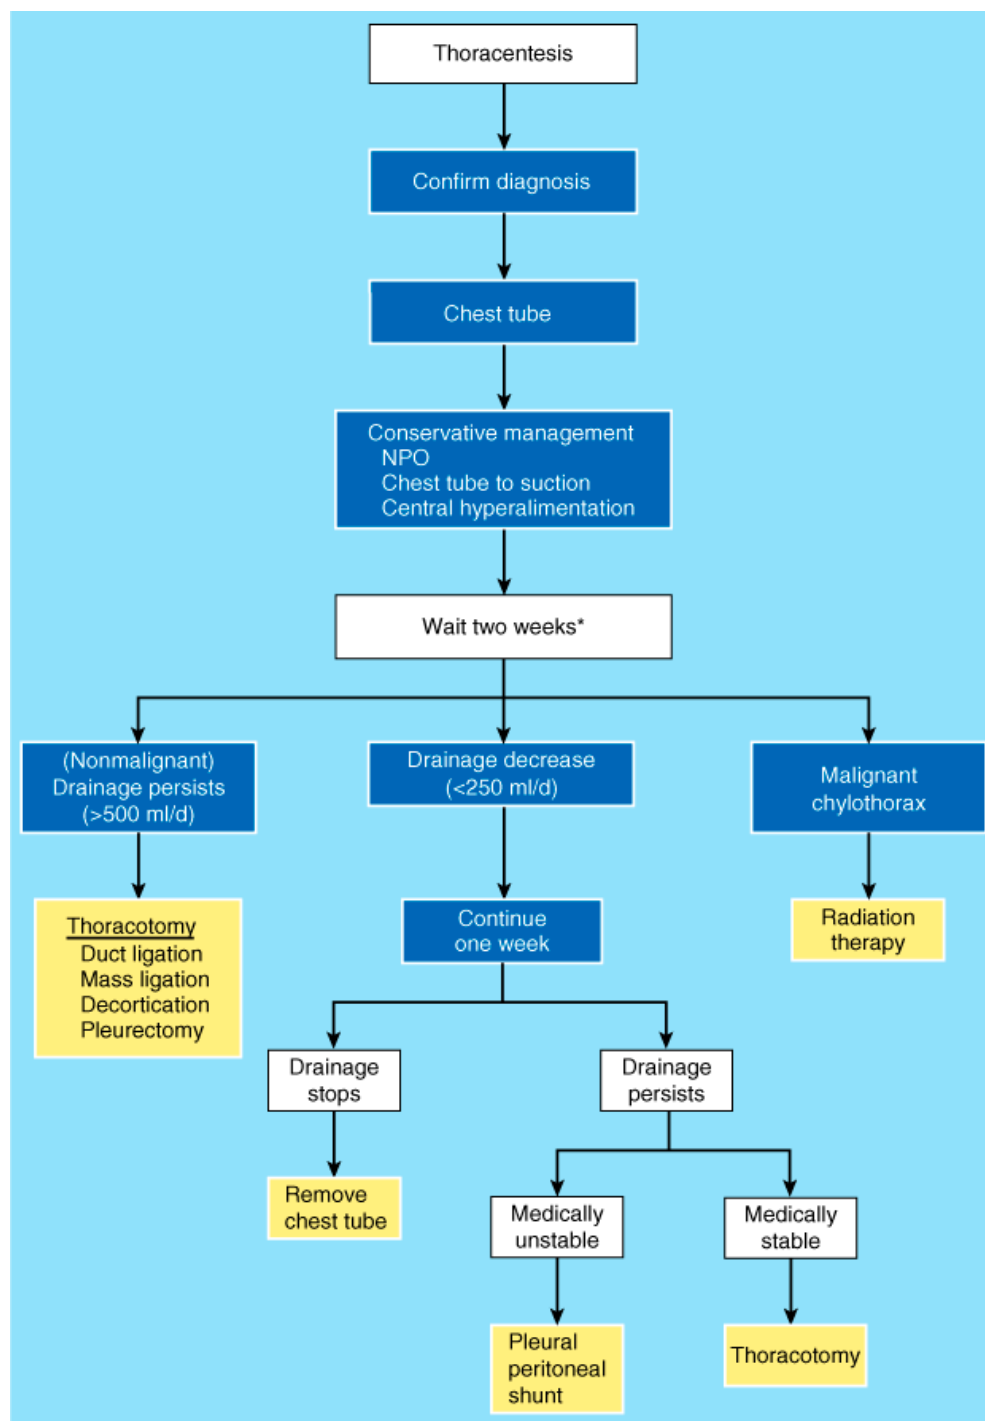

Table 19-40 Composition of Chyle	
Component	Amount (per 100 mL)
Total fat	0.4–5 g
Total cholesterol	65–220 mg
Total protein	2.21–5.9 g
Albumin	1.1–4.1 g
Globulin	1.1–3.1 g
Fibrinogen	16–24 g
Sugars	48–200 g
Electrolytes	Similar to levels in plasma
Cellular elements	
Lymphocytes	400–6800/mm ³
Erythrocytes	50–600/mm ³
Antithrombin globulin	>25% of plasma concentration
Prothrombin	>25% of plasma concentration
Fibrinogen	>25% of plasma concentration

MANAGEMENT

The treatment plan for any chylothorax depends on its cause, the amount of drainage, and the clinical status of the patient (Fig. 19-50). In general, the treatment for most patients is a short period of chest tube drainage, NPO orders, TPN, and observation. Chest cavity drainage must be adequate to allow complete lung re-expansion. The use of somatostatin has been advocated by some authors, with variable results.¹⁸⁴ If significant chyle drainage (>500 mL/d in an adult, >100 mL/d in an infant) continues despite TPN and good lung expansion, early surgical ligation of the duct is recommended. Ligation can be approached best by right thoracotomy and, in some experienced centers, by right VATS. Chylothoraces due to malignant conditions often respond to radiotherapy and/or chemotherapy and less commonly require surgical ligation. Untreated chylothoraces are associated with significant nutritional and immunologic depletion that leads to significant mortality. Before the introduction of surgical ligation of the thoracic duct, the mortality rate from chylothorax exceeded 50%. With the availability of TPN for nutritional supplementation and surgical ligation for persistent leaks, the mortality rate of chylothorax is <10%.

Algorithm for the management of chylothorax. *If high output persists (>50 mL/d), early surgical ligation of the thoracic duct may be considered. NPO = nothing by mouth.

Access and Drainage of Pleural Fluid Collections

APPROACHES AND TECHNIQUES

Once the decision is made to invasively access a pleural effusion, the next step is to determine if a sample of the fluid is required or if complete drainage of the pleural space is desired. This step is influenced by the clinical history, the type and amount of fluid present, the nature of the collection (such as free flowing or loculated), the cause, and the likelihood of recurrence. For small, free-flowing effusions, outpatient thoracentesis with a relatively small-bore needle or catheter (14- to 16-gauge) can be performed (Fig. 19-51). This approach can be used to sample fluid or to completely drain free-flowing pleural effusions. Fluid should be grossly examined as it is drained. Clear straw-colored fluid is often transudative; turbid or bloody fluid is often exudative.

Fig. 19-51.

Techniques for aspiration and drainage of a pleural effusion. **A.** Needle aspiration. With careful appraisal of the radiographic findings, the best interspace is selected, and fluid is aspirated with a needle and syringe. Large volumes of fluid can be removed with a little patience and a large-bore needle. **B.** Chest tube insertion. After careful skin preparation, draping, and administration of local anesthesia, a short skin incision is made over the correct interspace. The incision is deepened into the intercostal muscles, and the pleura is penetrated (usually with a clamp). When any doubt exists about the status of the pleural space at the site of puncture, the wound is enlarged bluntly to admit a finger, which can be swept around the immediately adjacent pleural space to assess the situation and break down any adhesions. The tube is inserted, with the tip directed toward the optimal position suggested by the chest radiographs. In general, a high anterior tube is best for air (pneumothorax) and a low posterior tube is best for fluid. A 28 to 32F tube is adequate for most situations. A 36F tube is preferred for hemothorax or for a viscous empyema. Many surgeons prefer a very small tube (16F to 20F) for drainage of simple pneumothorax. **C.** The tube is connected to a water-seal drainage system. Suction is added, if necessary, to expand the lung. Suction usually will be required in a patient with a substantial air leak (bronchopleural fistula).

The site of entry for drainage of a pleural effusion or pneumothorax may be based on the chest radiograph alone if the effusion is demonstrated to be free flowing. For large, free-flowing effusions, a low posterolateral approach at the eighth or ninth intercostal space affords good access. If the effusion is more complex with loculations, an approach guided by CT scan or ultrasound may be indicated. If complete drainage is the goal and the fluid is nonbloody and nonviscous, a small-bore (14- to 16-gauge) pigtail catheter is inserted and connected to a closed drainage system with applied suction (typically -20 cm H_2O) or water seal. If the fluid is bloody or turbid, a larger-diameter drainage tube (such as a 28F chest tube) may be required. In general, the smallest-bore drainage catheter that will effectively drain the pleural space should be chosen. The use of smaller-diameter catheters significantly decreases the pain associated with the placement of chest tubes.^{185,186} For clinical situations requiring biopsy or for potential interventions such as adhesiolysis or pleurodesis, minimally invasive surgery using a VATS approach may be indicated.

COMPLICATIONS OF PLEURAL DRAINAGE

The most common complication of invasive procedures to access the pleural space is inadvertent access to another cavity or organ. Examples include puncture of the underlying lung, with air leakage and pneumothorax; subdiaphragmatic entry, with damage to the liver, spleen, or other intra-abdominal viscera; bleeding secondary to intercostal vessel injury or, most commonly, larger vessel injury; and even cardiac puncture. Sometimes bleeding may be the result of an underlying coagulopathy or anticoagulant therapy. Other technical complications include loss of a catheter, guidewire, or fragment in the pleural space, and infections. Occasionally, rapid drainage of a large effusion can be followed by shortness of breath, clinical instability, and a phenomenon referred to as *postexpansion pulmonary edema*. For this reason, it is recommended to drain only up to 1 L initially. Most complications can be avoided by consulting with a clinician experienced in pleural drainage techniques.

Tumors of the Pleura

MALIGNANT MESOTHELIOMA

Malignant mesothelioma is the most common type of tumor of the pleura. The annual incidence in the United States is approximately 3000 cases. Other tumors of the pleura are much less common and include benign and malignant fibrous tumors of the pleura, lipomas, and cysts. In 20% of malignant mesotheliomas, the tumor arises from the peritoneum. Exposure to asbestos is the major known risk factor and can be established in over 50% of patients. Geographic areas of increased incidence are frequently the sites of industries using asbestos in the manufacturing process, such as shipbuilding. The risk extends beyond the worker directly exposed to the asbestos; family members exposed to the dust from clothing or the work environment are also at risk. Other risk factors have been identified, including exposure to fibers with physical properties similar to those of amphibole and exposure to radiation. Cigarette smoking does not appear to increase the risk of malignant mesothelioma, even though asbestos exposure and smoking synergistically increase the risk for lung cancer. Malignant mesotheliomas have a male predominance of 2:1 and are most common after the age of 40.

Pathophysiology

The exact etiologic role of asbestos fibers has not been elucidated; however, the physical characteristics of specific fibers (referred to as *serpentine* or *amphibole*) have been shown to be important. The serpentine fibers are large and curly and generally are not able to travel beyond larger airways. However, the narrow, straight amphibole fibers, in particular the crocidolite fibers, may navigate distally into the pulmonary parenchyma and are most clearly associated with mesotheliomas. The latency period between asbestos exposure and the development of mesothelioma is at least 20 years. The tumor generally is multicentric, with multiple pleura-based nodules coalescing to form sheets of tumor. This process initially involves the parietal pleura, generally with early spread to the visceral surfaces and with a variable degree of invasion of surrounding structures. Autopsy studies have shown that most patients have distant metastases, but the natural history of the disease in untreated patients culminates in death due to local extension.

Clinical Presentation

Most patients present with dyspnea and chest pain. Over 90% have a pleural effusion. Results of thoracentesis are diagnostic in <10% of patients. Frequently, thoracoscopy or open pleural biopsy with special staining of tumor samples is required to differentiate mesotheliomas from adenocarcinomas (Table 19-41). Once the diagnosis is confirmed, cell types can be distinguished (e.g., epithelial, sarcomatous, and mixed). Epithelial types are associated with a more favorable prognosis, and in some patients long-term survival may be seen with no treatment. Sarcomatous and mixed tumors share a more aggressive course.

Table 19-41 Differentiation of Mesothelioma from Adenocarcinoma		
	Mesothelioma	Adenocarcinoma
Immunohistochemical results		
Carcinoembryonic antigen	Negative	Positive
Vimentin	Positive	Negative
Low molecular weight cytokeratins	Positive	Negative
Electron microscopic features	Long, sinuous villi	Short, straight villi with fuzzy glycocalyx

Management

The treatment of malignant mesotheliomas remains controversial. It has been the subject of a number of recent clinical trials, the vast majority showing limited success.¹⁸⁷ A new staging system has been devised that has clearly shown prognostic value (Table 19-42).¹⁸⁸ However, although prognosis does depend on the stage of the disease, the problem is that many patients present with advanced local or distant disease beyond curative potential. Treatment options include supportive care only, surgical resection, and multimodality approaches (using a combination of surgery, chemotherapy, and radiation therapy).

Table 19-42 International Mesothelioma Interest Group Staging System for Diffuse Malignant Pleural Mesothelioma		
<i>T Tumor</i>		
T1	T1a	Tumor limited to the ipsilateral parietal ± mediastinal ± diaphragmatic pleura
		No involvement of the visceral pleura
	T1b	Tumor involving the ipsilateral parietal ± mediastinal ± diaphragmatic pleura
		Tumor also involving the visceral pleura
T2	Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features:	
	Involvement of diaphragmatic muscle	
	Extension of tumor from visceral pleura into the underlying pulmonary parenchyma	
T3	Describes locally advanced but potentially resectable tumor	
	Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features:	
	Involvement of the endothoracic fascia	
	Extension into the mediastinal fat	
	Solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall	
	Nontransmural involvement of the pericardium	
T4	Describes locally advanced technically unresectable tumor	
	Tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleurae) with at least one of the following features:	
	Diffuse extension or multifocal masses of tumor in the chest wall, with or without associated rib destruction	

	Direct transdiaphragmatic extension of tumor to the peritoneum		
	Direct extension of tumor to the contralateral pleura		
	Direct extension of tumor to mediastinal organs		
	Direct extension of tumor into the spine		
	Tumor extending through to the internal surface of the pericardium with or without a pericardial effusion; or tumor involving the myocardium		
N Lymph Nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes		
N2	Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes including the ipsilateral internal mammary nodes		
N3	Metastases in the contralateral mediastinal, contralateral internal mammary, or ipsilateral or contralateral supraclavicular lymph nodes		
M Metastases			
MX	Presence of distant metastases cannot be assessed		
M0	No distant metastases		
M1	Distant metastases present		
Staging			
Stage I			
IA	T1a	N0	M0
IB	T1b	N0	M0
Stage II	T2	N0	M0
Stage III	Any T3	Any N1	M0
		Any N2	
Stage IV	Any T4	Any N3	Any M1

Surgical options include palliative approaches such as pleurectomy or talc pleurodesis. Palliative approaches may lead to local control and a modest improvement in short-term survival. More radical surgical approaches (such as extrapleural pneumonectomy followed by adjuvant chemotherapy and radiotherapy) have an increased morbidity rate; moreover, the mortality rate exceeds 10% in all but the most experienced centers. In one Japanese review, extrapleural pneumonectomy yielded no improvement in survival compared with debulking surgery and showed no benefit over adjuvant therapy: the overall 5-year survival in all groups was <10%.¹⁸⁹ However, several reports of trials of radical surgery combined with multimodality adjuvant therapy have shown reasonable improvements in survival for patients with early-stage tumors (compared with historical controls). In one series of 183 patients undergoing extrapleural pneumonectomy and adjuvant chemotherapy and radiotherapy, a subset of 31 patients had favorable prognostic features (i.e., tumors of the epithelial cell type, negative resection margins, and negative extrapleural node status). This patient subset with favorable indicators had a 5-year survival rate of 46%, compared with 15% for the entire group.¹⁹⁰

In another series, 88 patients with mesotheliomas were studied prospectively. Adjuvant radiation therapy was given to 54 patients after extrapleural pneumonectomy; the median survival was 17 months. However, for patients with stage I and II disease, the median survival was significantly longer at 33.0 months.¹⁹¹

The authors' current approach to malignant mesotheliomas is based on tumor stage and pulmonary performance status. For patients with early-stage mesotheliomas and good pulmonary function, extrapleural pneumonectomy is recommended, especially for those with epithelial mesotheliomas. Patients are referred for clinical trials of multimodality therapy, if available. If disease is more advanced, or if patients have less than optimal pulmonary function or performance status, talc pleurodesis or supportive therapy is recommended.

Intrapleural therapy has been explored to improve the locoregional control of malignant mesotheliomas. In a phase II trial, 37 patients underwent pleurectomy with decortication, followed by intrapleural and systemic therapy with cisplatin and mitomycin C. Their median survival was 17 months, with a locoregional recurrence rate of 80%.¹⁹² According to another study, the addition of hyperthermic intrapleural perfusion seems to be pharmacokinetically advantageous; of seven patients, three underwent pleurectomy with decortication and received hyperthermic cisplatin. Systemic drug concentrations were greater after pleurectomy with decortication than after pleuropneumonectomy. The ratio of local tissue platinum concentration to perfusate platinum concentration tended to be higher after hyperthermic perfusion than after normothermic perfusion.¹⁹³

Another promising alternative to enhance the local efficacy of chemotherapy against malignant mesotheliomas is L-NDDP (cis-bis-neodecanoato-trans-R,R-

1,2-diaminocyclohexane platinum), a new lipophilic cisplatin analogue produced by the University of Texas M. D. Anderson Cancer Center in Houston, Texas. A phase II trial of L-NDDP enrolled 38 patients to receive a thorascopic biopsy and cytologic examination before and after treatment. Of the 33 patients who received treatment, 14 (42%) had a complete pathologic response; of the patients with positive cytologic results, 18 (78%) had a complete cytologic response.¹⁹⁴

FIBROUS TUMORS OF THE PLEURA

Fibrous tumors of the pleura are unrelated to asbestos exposure or malignant mesotheliomas. They generally occur as a single pedunculated mass arising from the visceral pleura. Frequently, they are discovered incidentally on routine chest radiographs without an associated pleural effusion. Fibrous tumors of the pleura may be benign or malignant. Symptoms such as cough, chest pain, and dyspnea occur in 30 to 40% of patients. Less common are fever, hypertrophic pulmonary osteoarthropathy, hemoptysis, and hypoglycemia. Hypoglycemia occurs in only approximately 4% of patients and resolves with surgical resection, as do the other symptoms. Given the localized, pedunculated nature of both benign and malignant fibrous tumors of the pleura, most are cured by complete surgical resection. Incompletely resected malignant tumors may recur locally or metastasize; frequently, they are fatal within 2 to 5 years.¹⁹⁵

ACKNOWLEDGMENT

The authors wish to thank Shannon Wyszomierski and Holly Rorabaugh for their invaluable help in compiling this chapter for the ninth edition. The authors also express appreciation to their spouses, Chris and Lee.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 20. Congenital Heart Disease >

KEY POINTS

1. Congenital heart disease comprises a wide morphologic spectrum. In general, lesions can be conceptualized as those which can be completely repaired, those that should be palliated, and those that can be either repaired or palliated depending on particular patient and institutional characteristics.
2. Percutaneous therapies for congenital heart disease are quickly becoming important adjuncts, and in some cases, alternatives, to standard surgical therapy. Important examples include percutaneous closure of atrial and ventricular septal defects, the hybrid approach to hypoplastic left heart syndrome, radiofrequency perforation of the pulmonary valve, and percutaneous pulmonary valve placement. Further studies are necessary to establish criteria and current benchmarks for the safe integration of these novel approaches into the care of patients with congenital heart surgery.
3. Outcomes have improved substantially over time in congenital heart surgery, and most complex lesions can be operated in early infancy. Neurologic protection, however, remains a key issue in the care of neonates undergoing surgery with cardiopulmonary bypass and deep hypothermic circulatory arrest. New monitoring devices and perioperative strategies are currently under investigation. Attention in the field has shifted currently from analyses of perioperative mortality, which for most lesions is under 10%, to longer-term outcomes, including quality of life and neurologic function.

PARADIGM SHIFT

Congenital heart surgery is a constantly evolving field. The last 20 years have brought about rapid developments in the technologic realm as well as a more thorough understanding of both the anatomy and pathophysiology of congenital heart disease (CHD), leading to the improved care of patients with this challenging disease.^{1,2}

These new advancements created a paradigm shift in the field of pediatric heart surgery. The traditional strategy of initial palliation followed by definitive correction at a later age, which had pervaded the thinking of most surgeons, began to evolve to one emphasizing early repair, even in the tiniest patients.² Furthermore, some of the defects that were virtually uniformly fatal [such as hypoplastic left-heart syndrome (HLHS)] now can be successfully treated with aggressive forms of palliation using cardiopulmonary bypass (CPB), resulting in outstanding survival for many of these children.

Because the goal in most cases of CHD is now early repair, as opposed to subdividing lesions into cyanotic or noncyanotic lesions, a more appropriate classification scheme divides particular defects into three categories based on the feasibility of achieving this goal: (a) defects that have no reasonable palliation and for which repair is the only option; (b) defects for which repair is not possible and for which palliation is the only option; and (c) defects that can either be repaired or palliated in infancy.³ It bears mentioning that all defects in the second category are those in which the appropriate anatomic components either are not present, as in HLHS, or cannot be created from existing structures.

DEFECTS WHERE REPAIR IS THE ONLY OR BEST OPTION

Atrial Septal Defect

An atrial septal defect (ASD) is defined as an opening in the interatrial septum that enables the mixing of blood from the systemic

venous and pulmonary venous circulations.

EMBRYOLOGY

The atrial and ventricular septa form between the third and sixth weeks of fetal development. After the paired heart tubes fuse into a single tube folded onto itself, the distal portion of the tube causes an indentation to form in the roof of the common atrium. Near this portion of the roof, the septum primum arises and extends into a crescentic formation toward the atrioventricular (AV) junction. The gap remaining between the septum primum and the developing tissues of the AV junction is called the *ostium primum*. Before the septum primum fuses completely with the endocardial cushions, a series of fenestrations appear in the septum primum that coalesce into the ostium secundum. During this coalescence, the septum secundum grows downward from the roof of the atrium, parallel to and to the right of the septum primum. The septum primum does not fuse, but creates an oblique pathway, called the *foramen ovale*, within the interatrial septum. After birth, the increase in left atrial (LA) pressure normally closes this pathway, obliterating the interatrial connection.⁴

ANATOMY

ASDs can be classified into three different types: (a) sinus venosus defects, comprising approximately 5 to 10% of all ASDs; (b) ostium primum defects, which are more correctly described as partial AV canal defects; and (c) ostium secundum defects, which are the most prevalent subtype, comprising 80% of all ASDs (Fig. 20-1).⁵

Fig. 20-1.

The anatomy of atrial septal defects. In the sinus venosus type (**A**), the right upper and middle pulmonary veins frequently drain to the superior vena cava or right atrium. **B**. Secundum defects generally occur as isolated lesions. **C**. Primum defects are part of a more complex lesion and are best considered as incomplete atrioventricular septal defects.

PATHOPHYSIOLOGY

ASDs result in an increase in pulmonary blood flow secondary to left-to-right shunting through the defect. The direction of the intracardiac shunt is predominantly determined by the compliance of the respective ventricles. In utero, the distensibility, or compliance, of the right and left ventricles (LVs) is equal, but postnatally the LV becomes less compliant than the right ventricle (RV). This shift occurs because the resistance of the downstream vascular beds changes after birth. The pulmonary vascular resistance (PVR) falls with the infant's first breath, decreasing RV pressure, whereas the systemic vascular resistance rises dramatically, increasing LV pressure. The increased LV pressure creates a thicker muscle mass, which offers a greater resistance to diastolic filling than does the RV; thus, the majority of flow through the ASD occurs from left to right. The greater volume of blood returning to the right atrium causes volume overload in the RV, but because of its lower muscle mass and low-resistance output, it easily distends to accommodate this load.^{5,6}

The long-term consequences of RV volume overload include hypertrophy with elevated RV end-diastolic pressure and a relative pulmonary stenosis across the pulmonary valve, because it cannot accommodate the increased RV flow. The resistance at the level of the pulmonary valve then contributes a further pressure load on the RV, which accelerates RV hypertrophy. Compliance gradually decreases as the right ventricular pressure approaches systemic pressure, and the size of the left-to-right shunt decreases. Patients at this stage have a balanced circulation and may deceptively appear less symptomatic.

A minority of patients with ASDs develop progressive pulmonary vascular changes as a result of chronic overcirculation. The increased PVR in these patients leads to an equalization of left and right ventricular pressures, and their ratio of pulmonary (Q_p) to systemic flow (Q_s), $Q_p:Q_s$, will approach 1.^{5,7} This does not mean, however, that there is no intracardiac shunting, only that the ratio between the left-to-right component and the right-to-left component is equal.

The ability of the RV to recover normal function is related to the duration of chronic overload, because those undergoing ASD closure before age 10 years have a better likelihood of achieving normal RV function in the postoperative period.³

The physiology of sinus venosus ASDs is similar to that discussed above for simple ASDs except that these are frequently accompanied by anomalous pulmonary venous drainage. This often results in significant hemodynamic derangements that accelerate the clinical course of these infants.

The same increase in symptoms is true for those with ostium primum defects because the associated mitral insufficiency from the "cleft" mitral valve can lead to more atrial volume load and increased atrial level shunting.

DIAGNOSIS

Patients with ASDs may present with few physical findings. Auscultation may reveal prominence of the first heart sound with fixed splitting of the second heart sound. This results from the relatively fixed left-to-right shunt throughout all phases of the cardiac cycle. A diastolic flow murmur indicating increased flow across the tricuspid valve may be discerned, and, frequently, an ejection flow murmur can be heard across the pulmonary valve. A right ventricular heave and increased intensity of the pulmonary component of the second heart sound indicates pulmonary hypertension and possible unrepairability.

Chest radiographs in the patient with an ASD may show evidence of increased pulmonary vascularity, with prominent hilar markings and cardiomegaly. The electrocardiogram (ECG) shows right axis deviation with an incomplete bundle-branch block. When right bundle-branch block is associated with a leftward or superior axis, an AV canal defect should be strongly suspected.⁸

Diagnosis is clarified by two-dimensional echocardiography, and use of color flow mapping facilitates an understanding of the physiologic derangements created by the defects.⁹ Older children and adults with unrepaired ASDs may present with stroke or systemic embolism from paradoxical embolism or atrial arrhythmias from dilation of the right atrium.

Echocardiography also enables the clinician to estimate the amount of intracardiac shunting, can demonstrate the degree of mitral

regurgitation in patients with ostium primum defects, and with the addition of microcavitation, can assist in the detection of sinus venosus defects.⁵

The advent of two-dimensional echocardiography with color flow Doppler has largely obviated the need for cardiac catheterization because the exact nature of the ASD can be precisely defined by echo alone. However, in cases where the patient is older than age 40 years, catheterization can quantify the degree of pulmonary hypertension present, because those with a fixed PVR greater than 12 U/mL are considered inoperable.¹⁰ Cardiac catheterization also can be useful in that it provides data that enable the calculation of Qp and Qs so that the magnitude of the intracardiac shunt can be determined. The ratio (Qp:Qs) can then be used to determine whether closure is indicated in equivocal cases, because a Qp:Qs greater than 1.5:1 is generally accepted as the threshold for surgical intervention. Finally, in patients older than age 40 years, cardiac catheterization can be important to disclose the presence of coronary artery disease.

In general, ASDs are closed when patients are between 4 and 5 years of age. Children of this size can usually be operated on without the use of blood transfusion and generally have excellent outcomes. Patients who are symptomatic may require repair earlier, even in infancy. Some surgeons, however, advocate routine repair in infants and children, as even smaller defects are associated with the risk of paradoxical embolism, particularly during pregnancy. In a review by Reddy and colleagues, 116 neonates weighing less than 2500 g who underwent repair of simple and complex cardiac defects with the use of CPB were found to have no intracerebral hemorrhages, no long-term neurologic sequelae, and a low operative-mortality rate (10%). These results correlated with the length of CPB and the complexity of repair.¹¹ These investigators also found an 80% actuarial survival at 1 year, and, more important, that growth following complete repair was equivalent to weight-matched neonates free from cardiac defects.¹¹

TREATMENT

ASDs can be repaired in a facile manner using standard CPB techniques through a midline sternotomy approach.⁷ The details of the repair itself are generally straightforward. An oblique atriotomy is made, the position of the coronary sinus and all systemic and pulmonary veins are determined, and the rim of the defect is completely visualized. Closure of ostium secundum defects is accomplished either by primary repair or by insertion of a patch that is sutured to the rim of the defect. The decision about whether patch closure is necessary can be determined by the size and shape of the defect as well as by the quality of the edges.

The type of repair used for sinus venosus ASDs associated with partial anomalous pulmonary venous connection is dictated by the location of the anomalous pulmonary veins. If the anomalous veins connect to the atria or to the superior vena cava (SVC) caudal to where the cava is crossed by the right pulmonary artery (RPA), the ASD can be repaired by inserting a patch, with redirection of the pulmonary veins behind the patch to the left atrium. Care must be taken with this approach to avoid obstruction of the pulmonary veins or the SVC, although usually the SVC is dilated and provides ample room for patch insertion. If the anomalous vein connects to the SVC cranial to the RPA an alternative technique, the Warden procedure, may be necessary. In this operation, the SVC is transected cranial to the connection of the anomalous vein (usually the right superior pulmonary vein). The caudal end of the transected cava is oversewn. The cranial end of the transected cava is anastomosed to the auricle of the right atrium. Inside the atrium, a patch is used to redirect pulmonary venous blood flow to the left atrium. In contrast to the repair for a defect where the pulmonary veins enter the right atrium or the SVC below the right PA, the patch covers the superior vena caval right atrial junction so that blood from the anomalous pulmonary vein that enters the cava is directed to the left atrium. Blood returning from the upper body enters the right atrium via the anastomosis between the SVC and the right auricle.

These operative strategies have been well established, with a low complication rate and a mortality rate approaching zero. As such, attention has shifted to improving the cosmetic result and minimizing hospital stay and convalescence. Multiple new strategies have been described to achieve these aims, including the right submammary incision with anterior thoracotomy, limited bilateral submammary incision with partial sternal split, transxiphoid window, and limited midline incision with partial sternal split.^{4,12–14}

Some centers use video-assisted thoracic surgery in the submammary and transxiphoid approaches to facilitate closure within a constricted operative field. The morbidity and mortality of all of these approaches are comparable to those of the traditional median sternotomy; however, each has technical drawbacks. The main concern is that operative precision be maintained with limited exposure. Luo and associates described a prospective randomized study comparing ministernotomy (division of the upper sternum for aortic and pulmonary lesions, and the lower sternum for septal lesions) to full sternotomy in 100 consecutive patients undergoing repair of septal lesions.¹⁴ The patients in the ministernotomy group had longer procedure times (by 15 to 20 minutes), less bleeding, and shorter hospital stays. These results have been echoed by other investigators from Boston who maintain that ministernotomy provides a cosmetically acceptable scar without compromising aortic cannulation or limiting the exposure of crucial mediastinal structures.¹² This approach also can be easily extended to a full sternotomy should difficulty or unexpected anomalies be encountered.¹³

First performed in 1976, transcatheter closure of ASDs with the use of various occlusion devices is gaining widespread acceptance.¹⁵ Certain types of ASDs, including patent foramen ovale (PFO), secundum defects, and some fenestrated secundum defects, are amenable to device closure, as long as particular anatomic criteria (e.g., an adequate superior and inferior rim for device seating and distance from the AV valve) are met. Since the introduction of percutaneous closure (PC), there has been a dramatic rise in device closure prevalence to the point where device closure has supplanted surgical therapy as the dominant treatment modality for secundum ASD.¹⁶ A study from the author's group¹⁶ recently found that ASD/PFO closures per capita increased dramatically from 1.08 per 100,000 population in 1988 to 2.59 per 100,000 population in 2005, an increase of 139%. When analyzed by closure type, surgical closure increased by only 24% (from 0.86 per 100,000 population in 1988 to 1.07 per 100,000 in 2005) whereas PC increased by 3475% (from 0.04 per 100,000 population in 1988 to 1.43 per 100,000 in 2005). Importantly, this study determined that the paradigm shift favoring PC has occurred mainly due to increased prevalence of closure in adults over age 40 years rather than an increase in closure in infants or children. Complications reported to occur with transcatheter closure include air embolism (1 to 3%); thromboembolism from the device (1 to 2%); disturbed AV valve function (1 to 2%); systemic/pulmonary venous obstruction (PVO) (1%); perforation of the atrium or aorta with hemopericardium (1 to 2%); atrial arrhythmias (1 to 3%); and malpositioning/embolization of the device requiring intervention (2 to 15%).^{4,17} Thus, although percutaneous approaches are cosmetic and often translate into shorter periods of convalescence, their attendant risks are not trivial, especially because their use may not result in complete closure of the septal defect.

RESULTS

Surgical repair of ASDs is associated with a mortality rate near zero.^{4,5,7,8,11} Early repairs in neonates weighing less than 1000 g have been increasingly reported with excellent results.¹¹ Uncommonly, atrial arrhythmias or significant LA hypertension may occur soon after repair. The latter is caused by the noncompliant small, LA chamber and generally resolves rapidly.

Aortic Stenosis

ANATOMY AND CLASSIFICATION

The spectrum of aortic valve abnormality represents the most common form of CHD, with the great majority of patients being asymptomatic until midlife. Obstruction of the left ventricular outflow tract (LVOT) occurs at multiple levels: subvalvular, valvular, and supra-valvular (Fig. 20-2). The critically stenotic aortic valve in the neonate or infant is commonly unicommissural or bicommissural, with thickened, dysmorphic, and myxomatous leaflet tissue and a reduced cross-sectional area at the valve level. Associated left-sided lesions are often present. In a review of 32 cases from the Children's Hospital in Boston, 59% had unicommissural valves and 40% had bicommissural valves.¹⁸ Associated lesions were frequent, occurring in 88% of patients, most commonly patent ductus arteriosus (PDA), mitral regurgitation, and hypoplastic LV. Endocardial fibroelastosis also is common among infants with critical aortic stenosis (AS).¹⁹ In this condition, the LV is largely nonfunctional, and these patients are not

candidates for balloon valvotomy, simple valve replacement, or repair, because the LV is incapable of supporting the systemic circulation. Often, the LV is markedly hypertrophic with a reduced cavity size, but on rare occasion, a dilated LV, reminiscent of overt heart failure, is encountered.²⁰

PATHOPHYSIOLOGY

The unique intracardiac and extracardiac shunts present in fetal life allow even neonates with critical AS to survive. In utero, left ventricular hypertrophy and ischemia cause LA hypertension, which reduces the right-to-left flow across the foramen ovale. In severe cases, a reversal of flow may occur, causing right ventricular volume loading. The RV then provides the entire systemic output via the PDA (ductal-dependent systemic blood flow). Although cardiac output is maintained, the LV suffers continued damage as the intracavitary pressure precludes adequate coronary perfusion, resulting in LV infarction and subendocardial fibroelastosis. The presentation of the neonate with critical AS is then determined by both the morphology of the LV and other left-sided heart structures, the degree of left ventricular dysfunction, and the completeness of the transition from a parallel circulation to an in-series circulation (i.e., on closure of the foramen ovale and the ductus arteriosus). Those infants with mild-to-moderate AS in which LV function is preserved are asymptomatic at birth. The only abnormalities may be a systolic ejection murmur and ECG evidence of left ventricular hypertrophy. However, those neonates with severe AS and compromised LV function are unable to provide adequate cardiac output at birth, and will present in circulatory collapse once the ductus closes, with dyspnea, tachypnea, irritability,

narrowed pulse pressure, oliguria, and profound metabolic acidosis.^{7,21} If ductal patency is maintained, systemic perfusion will be provided by the RV via ductal flow, and cyanosis may be the only finding.

DIAGNOSIS

Neonates and infants with severe valvular AS may have a relatively nonspecific history of irritability and failure to thrive. Angina, if present, is usually manifested by episodic, inconsolable crying that coincides with feeding. As discussed previously, evidence of poor peripheral perfusion, such as extreme pallor, indicates severe left ventricular outflow tract obstruction (LVOTO). Differential cyanosis is an uncommon finding, but is present when enough antegrade flow occurs only to maintain normal upper body perfusion, while a large PDA produces blue discoloration of the abdomen and legs.

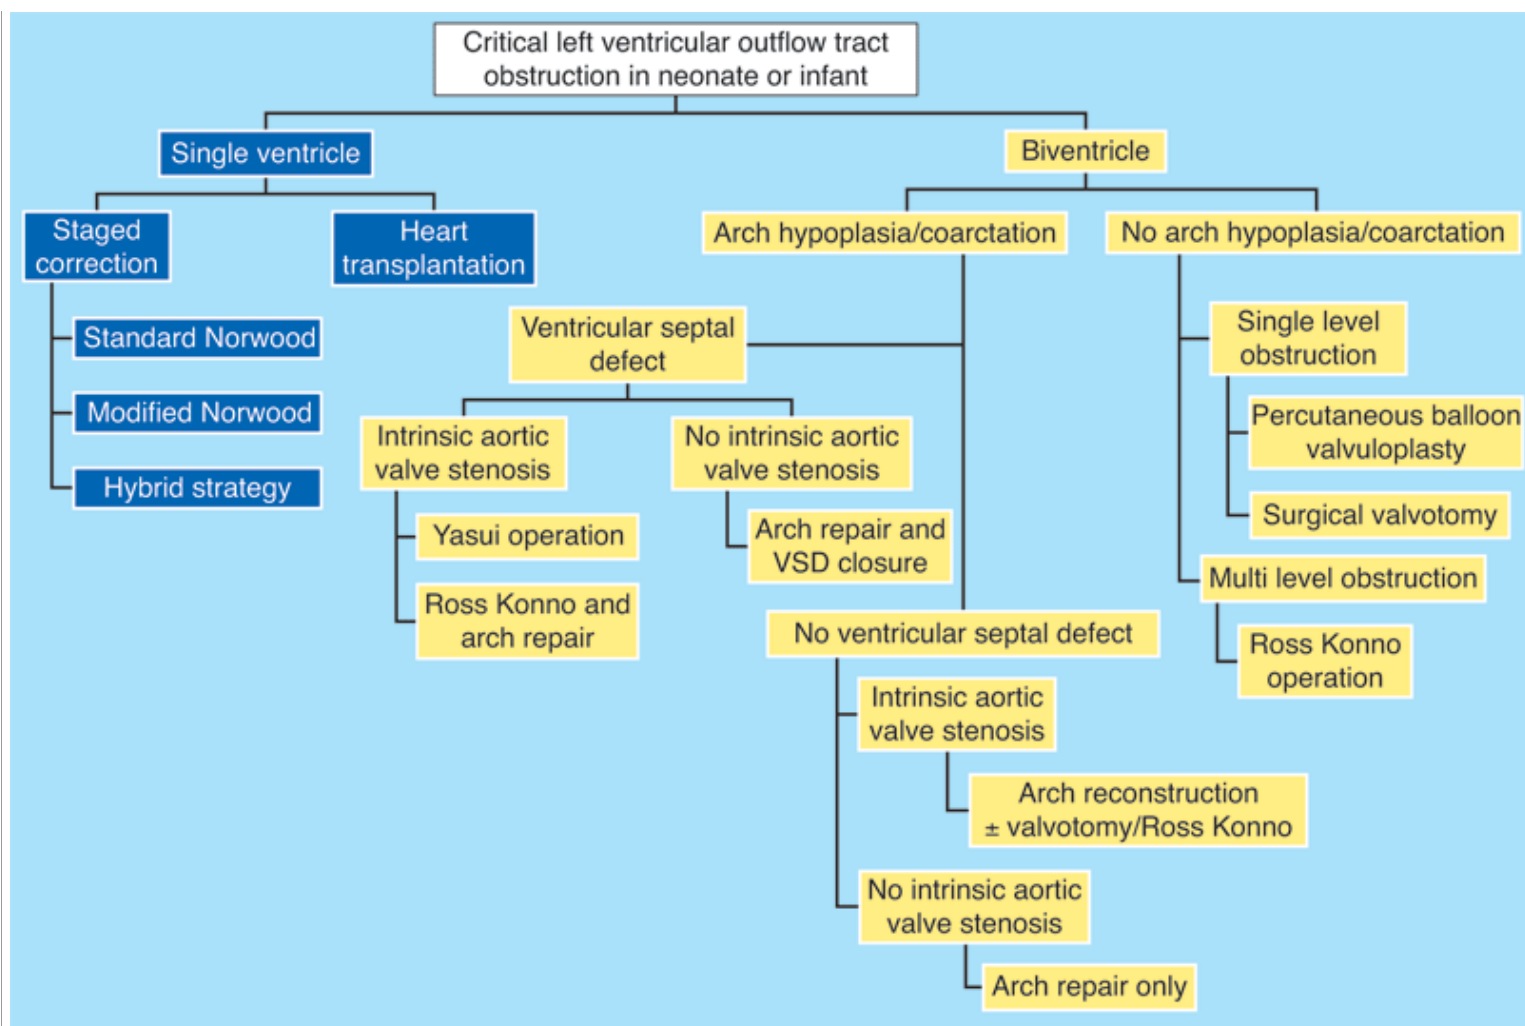

Physical findings include a systolic ejection murmur, although a quiet murmur may paradoxically indicate a more severe condition with reduced cardiac output. A systolic click correlates with a valvular etiology of obstruction. As LV dysfunction progresses, evidence of congestive heart failure (CHF) occurs.

The chest radiograph is variable, but may show dilatation of the aortic root, and the ECG often demonstrates LV hypertrophy. Echocardiography with Doppler flow is extremely useful in establishing the diagnosis, as well as quantifying the transvalvular gradient.²² Furthermore, echocardiography can facilitate evaluation for the several associated defects that can be present in critical neonatal AS, including mitral stenosis, LV hypoplasia, LV endocardial fibroelastosis, subaortic stenosis, ventricular septal defect (VSD), or coarctation. The presence of any or several of these defects has important implications related to treatment options for these patients. Although cardiac catheterization is not routinely performed for diagnostic purposes, it can be invaluable as part of the treatment algorithm if the lesion is amenable to balloon valvotomy.

TREATMENT

The first decision that must be made in the neonate with critical LVOTO is whether the patient is a candidate for biventricular or univentricular repair. Central to this decision is assessment of the degree of hypoplasia of the LV and other left-sided structures. Alsoufi and colleagues²³ recently described a rational approach to the neonate with critical LVOTO (Fig. 20-3). The infant with severe AS requires urgent intervention. Preoperative stabilization, however, has dramatically altered the clinical algorithm and outcomes for this patient population.^{19,21} The preoperative strategy begins with endotracheal intubation and inotropic support. Prostaglandin infusion is initiated to maintain ductal patency, and confirmatory studies are performed before operative intervention.

Treatment algorithm for neonates and infants with critical left ventricular outflow tract obstruction. Patients can be initially triaged to either a single or a biventricular approach depending on presenting morphologic, demographic, and institutional factors. VSD = ventricular septal defect.

(From Alsoufi et al,²³ Fig. 1, with permission. Copyright Elsevier.)

Therapy is generally indicated in the presence of a transvalvular gradient of 50 mmHg with associated symptoms including syncope, CHF, or angina, or if a gradient of 50 to 75 mmHg exists with concomitant ECG evidence of LV strain or ischemia. In the critically ill neonate, there may be little gradient across the aortic valve because of poor LV function. These patients depend on patency of the ductus arteriosus to provide systemic perfusion from the RV, and all ductal-dependent patients with critical AS require treatment. However, the decision regarding treatment options must be based on a complete understanding of associated defects. For example, in the presence of a hypoplastic LV (left ventricular end-diastolic volume <20 mL/m²), or a markedly abnormal mitral valve, isolated aortic valvotomy should not be performed because studies have demonstrated high mortality in this population following isolated valvotomy.²⁴

Patients who have a LV capable of providing systemic output are candidates for intervention to relieve AS, generally through balloon valvotomy. Very rarely, if catheter-based therapy is not an option, relief of valvular AS in infants and children can be accomplished with surgical valvotomy using standard techniques of CPB and direct exposure to the aortic valve. A transverse incision is made in the ascending aorta (AA) above the sinus of Valsalva, extending close to, but not into, the noncoronary sinus.

Exposure is attained with placement of a retractor into the right coronary sinus. After inspection of the valve, the chosen commissure is incised to within 1 to 2 mm of the aortic wall (Fig. 20-4).

Balloon valvotomy performed in the catheterization lab is the procedure of choice for reduction of transvalvular gradients in symptomatic infants and children. This procedure is an ideal palliative option because mortality from surgical valvotomy can be high due to the critical nature of these patients' condition. Furthermore, balloon valvotomy provides relief of the valvular gradient and allows future surgical intervention (which is generally required in most patients when a larger prosthesis can be implanted) to be performed on an unscarred chest. An important issue when planning aortic valvotomy, whether percutaneously or via open surgical technique, is the risk of inducing hemodynamically significant aortic regurgitation. Induction of more than moderate aortic regurgitation is poorly tolerated in the infant with critical AS, and may require an urgent procedure to replace or repair the aortic valve.

In general, catheter-based balloon valvotomy has supplanted open surgical valvotomy. The decision regarding the most appropriate method to use depends on several factors including the available medical expertise, the patient's overall status and hemodynamics, and the presence of associated cardiac defects requiring repair.²⁵ Although evidence is emerging to the contrary, simple valvotomy, whether performed using percutaneous or open technique, is generally considered a palliative procedure. The goal is to relieve

LVOTO without producing clinically significant regurgitation, to allow sufficient annular growth for eventual aortic valve replacement. The majority of infants who undergo aortic valvotomy will require further intervention on the aortic valve within 10 years following initial intervention.²⁶

Valvotomy may result in aortic insufficiency that, although not important enough to require intervention in infancy, alone or in combination with AS may result in the need for an aortic valve replacement. Neonates with severely hypoplastic LVs or significant LV endocardial fibroelastosis may not be candidates for two-ventricle repair and are treated the same as infants with the HLHS, which is discussed later (see Hypoplastic Left-Heart Syndrome below).

Many surgeons previously avoided aortic valve replacement for AS in early childhood because the more commonly used mechanical valves would be outgrown and require replacement later, and the obligatory anticoagulation for mechanical valves resulted in a substantial risk for complications. In addition, mechanical valves had an important incidence of bacterial endocarditis or perivalvular leak requiring reintervention.

The use of allografts and the advent of the Ross procedure have largely obviated these issues and made early definitive correction of critical AS a viable option.^{19,27,28} Donald Ross first described transposition of the pulmonary valve into the aortic position with allograft reconstruction of the pulmonary outflow tract in 1967.²⁷ The result of this operation is a normal trileaflet semilunar valve made of a patient's native tissue with the potential for growth to adult size in the aortic position in place of the damaged aortic valve (Fig. 20-5). The Ross procedure has become a useful option for aortic valve replacement in children, because it has improved durability and can be performed with acceptable morbidity and mortality rates. The placement of a pulmonary conduit, which does not grow and becomes calcified and stenotic over time, does obligate the patient to reoperation to replace the right-ventricle to PA conduit. Karamlou and colleagues²⁹ reviewed the outcomes and associated risk factors for aortic valve replacement in 160 children from the Hospital for Sick Children in Toronto. They found that younger age, lower operative weight, concomitant performance of aortic root replacement or reconstruction, and use of prosthesis type other than a pulmonary autograft were significant predictors of death, while the use of a bioprosthetic or allograft valve type and earlier year of operation were identified as significant risk factors for repeated aortic valve replacement. Autograft use was associated with a blunted progression of the peak prosthetic valve gradient and a rapid decrease in the left ventricular end-diastolic dimension (Fig. 20-6). In agreement with these findings, Lupinetti and Jones compared allograft aortic valve replacement with the Ross procedure and found a more significant transvalvular gradient reduction and regression of left ventricular hypertrophy in those patients who underwent the Ross procedure.³⁰ In some cases, the pulmonary valve may not be usable because of associated defects or congenital absence. These children are not candidates for the Ross procedure and are now most frequently treated with cryopreserved allografts (cadaveric human aortic valves). At times, there may be a size discrepancy between the right ventricular outflow tract (RVOT) and the LVOT, especially in cases of severe critical AS in infancy. For these cases, the pulmonary autograft is placed in a manner that also provides enlargement of the aortic annulus (Ross/Konno) (Fig. 20-7).

Subvalvular AS occurs beneath the aortic valve and may be classified as discrete or tunnel-like (diffuse). A thin, fibromuscular diaphragm immediately proximal to the aortic valve characterizes discrete subaortic stenosis. This diaphragm typically extends for 180° or more in a crescentic or circular fashion, often attaching to the mitral valve as well as the interventricular septum.²¹ The aortic valve itself is usually normal in this condition, although the turbulence imparted by the subvalvular stenosis may affect leaflet morphology and valve competence.

Diffuse subvalvular AS results in a long, tunnel-like obstruction that may extend to the left ventricular apex. In some individuals, there may be difficulty in distinguishing between hypertrophic cardiomyopathy and diffuse subaortic stenosis. Operation for subvalvular AS is indicated with a gradient exceeding 30 mmHg, the presence of aortic valve insufficiency, or when symptoms indicating LVOTO are present.³⁰ Given that repair of isolated, discrete, subaortic stenosis can be done with low rates of morbidity and mortality, some surgeons advocate repair in all cases of discrete AS, to avoid progression of the stenosis and the development of aortic insufficiency, although more recent data demonstrate that subaortic resection should be delayed until the LV gradient exceeds 30 mmHg because most children with an initial LV gradient less than 30 mmHg have quiescent disease.³¹ Diffuse AS is a more complex lesion and often requires aortoventriculoplasty as described in the previous paragraph. Results are generally excellent, with operative mortality less than 5%.³²

Supravalvular AS occurs more rarely, and also can be classified into a discrete type, which produces an hourglass deformity of the aorta, and a diffuse form that can involve the entire arch and brachiocephalic arteries. The aortic valve leaflets are usually normal, but in some cases, the leaflets may adhere to the supravalvular stenosis, thereby narrowing the sinuses of Valsalva in diastole and restricting coronary artery perfusion. In addition, accelerated intimal hyperplastic changes in the coronary arteries can be demonstrated in these patients because the proximal position of the coronary arteries subjects them to abnormally high perfusion pressures.

The signs and symptoms of supravalvular AS are similar to other forms of LVOTO. An asymptomatic murmur is the presenting manifestation in approximately one half of these patients. Syncope, poor exercise tolerance, and angina may all occur with nearly equal frequency. Supravalvular AS is associated with Williams syndrome, a constellation of elfin facies, mental retardation, and hypercalcemia.³³ Following routine evaluation, cardiac catheterization should be performed to delineate coronary anatomy, as well as to delineate the degree of obstruction. A gradient of 50 mmHg or greater is an indication for operation. However, the clinician must be cognizant of any coexistent lesions, most commonly pulmonic stenosis, which may add complexity to the repair.

The localized form of supravalvular AS is treated by creating an inverted Y-shaped aortotomy across the area of stenosis, straddling the right coronary artery. The obstructing shelf is then excised and a pantaloony-shaped patch is used to close the incision.²¹

The diffuse form of supravalvular stenosis is more variable, and the particular operative approach must be tailored to each specific patient's anatomy. In general, either an aortic endarterectomy with patch augmentation can be performed, or if the narrowing extends past the aorta arch, a prosthetic graft can be placed between the ascending and descending aorta. Operative results for discrete supravalvular AS are generally good, with a hospital mortality of less than 1% and an actuarial survival rate exceeding 90% at 20 years.³⁴ In contrast, however, the diffuse form is more hazardous to repair, and carried a mortality of 15% in a series.^{34,35}

Patent Ductus Arteriosus

ANATOMY

The ductus arteriosus is derived from the sixth aortic arch and normally extends from the main or left PA to the upper descending thoracic aorta, distal to the left subclavian artery. In the normal fetal cardiovascular system, ductal flow is considerable (approximately 60% of the combined ventricular output), and is directed exclusively from the PA to the aorta.³⁶ In infancy, the length of the ductus may vary from 2 to 8 mm, with a diameter of 4 to 12 mm.

Locally produced and circulating prostaglandin E₂ (PGE₂) and PGI₂ induce active relaxation of the ductal musculature, maintaining maximal patency during the fetal period.³⁷ At birth, increased pulmonary blood flow metabolizes these prostaglandin products, and absence of the placenta removes an important source of them, resulting in a marked decrease in these ductal-relaxing substances. In addition, release of histamines, catecholamines, bradykinin, and acetylcholine all promote ductal contraction. Despite all of these

complex interactions, the rising oxygen tension in the fetal blood is the main stimulus causing smooth muscle contraction and ductal closure within 10 to 15 hours postnatally.³⁸ Anatomic closure by fibrosis produces the ligamentum arteriosum connecting the PA to the aorta.

Delayed closure of the ductus is termed *prolonged patency*, whereas failure of closure causes *persistent patency*, which may occur as an isolated lesion or in association with more complex congenital heart defects. In many of these infants with more complex congenital heart defects, either pulmonary or systemic perfusion may depend on ductal flow, and these infants may decompensate if exogenous PGE is not administered to maintain ductal patency.

NATURAL HISTORY

The incidence of PDA is approximately 1 in every 2000 births; however, it increases dramatically with increasing prematurity.³⁹ In some series, PDAs have been noted in 75% of infants of 28 to 30 weeks gestation. Persistent patency occurs more commonly in females, with a 2:1 ratio.³⁹

PDA is not a benign entity, although prolonged survival has been reported. The estimated death rate for infants with isolated, untreated PDA is approximately 30%.⁴⁰ The leading cause of death is CHF, with respiratory infection as a secondary cause. Endocarditis is more likely to occur with a small ductus and is rarely fatal if aggressive antibiotic therapy is initiated early.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

After birth, in an otherwise normal cardiovascular system, a PDA results in a left-to-right shunt that depends on both the size of the ductal lumen and its total length. As the PVR falls 16 to 18 weeks postnatally, the shunt will increase, and its flow will ultimately be determined by the relative resistances of the pulmonary and systemic circulations.

The hemodynamic consequences of an unrestrictive ductal shunt are left ventricular volume overload with increased LA and PA pressures, and right ventricular strain from the augmented afterload. These changes result in increased sympathetic discharge, tachycardia, tachypnea, and ventricular hypertrophy. The diastolic shunt results in lower aortic diastolic pressure and increases the potential for myocardial ischemia and underperfusion of other systemic organs, while the increased pulmonary flow leads to increased work of breathing and decreased gas exchange. Unrestrictive ductal flow may lead to pulmonary hypertension within the first year of life. These changes will be significantly attenuated if the size of the ductus is only moderate, and completely absent if the ductus is small.

Physical examination of the afflicted infant will reveal evidence of a hyperdynamic circulation with a widened pulse pressure and a hyperactive precordium. Auscultation demonstrates a systolic or continuous murmur, often termed a *machinery murmur*. Cyanosis is not present in uncomplicated isolated PDA.

The chest radiograph may reveal increased pulmonary vascularity or cardiomegaly, and the ECG may show LV strain, LA enlargement, and possibly RV hypertrophy. Echocardiogram with color mapping reliably demonstrates the patency of the ductus as well as estimates the shunt size. Cardiac catheterization is necessary only when pulmonary hypertension is suspected.

THERAPY

The presence of a persistent PDA is sufficient indication for closure because of the increased mortality and risk of endocarditis.^{2,4} In older patients with pulmonary hypertension, closure may not improve symptoms and is associated with much higher mortality.

In premature infants, aggressive intervention with indomethacin or ibuprofen to achieve early closure of the PDA is beneficial unless contraindications such as necrotizing enterocolitis or renal insufficiency are present.⁴¹ Term infants, however, are generally unresponsive to pharmacologic therapy with indomethacin, so mechanical closure must be undertaken once the diagnosis is established. This can be accomplished either surgically or with catheter-based therapy.^{12,42,43} Currently, transluminal placement of

various occlusive devices, such as the Rashkind double-umbrella device or embolization with Gianturco coils, is in widespread use. However, there are a number of complications inherent with the use of percutaneous devices, such as thromboembolism, endocarditis, incomplete occlusion, vascular injury, and hemorrhage secondary to perforation.⁴³ In addition, these techniques may not be applicable in very young infants, as the peripheral vessels do not provide adequate access for the delivery devices.

Surgical closure can be achieved via either open or video-assisted approaches. The open approach uses a posterior lateral thoracotomy in the fourth or fifth intercostal space on the side of the aorta (generally the left). The lung is then retracted anteriorly. In the neonate, the PDA is singly ligated with a surgical clip or permanent suture. In older patients the PDA is triply ligated. Care must be taken to avoid the recurrent laryngeal nerve that courses around the PDA. The PDA also can be ligated via a median sternotomy; however, this approach generally is reserved for patients who have additional cardiac or great vessel lesions requiring repair. Occasionally, a short, broad ductus, in which the dimension of its width approaches that of its length, will be encountered. In this case, division between vascular clamps with oversewing of both ends is advisable (Fig. 20-8). In extreme cases, the use of CPB to decompress the large ductus during ligation is an option.

(From Castaneda et al,⁷ p 208, with permission. Copyright Elsevier.)

Video-assisted thoracoscopic occlusion, using metal clips, also has been described, although it offers few advantages over the

standard surgical approach.¹² Preterm newborns and children may do well with the thoracoscopic technique, while older patients (older than age 5 years) and those with smaller ducts (<3 mm) do well with coil occlusion. In fact, Moore and colleagues concluded from their series that coil occlusion is the procedure of choice for ducts smaller than 4 mm.⁴⁴ Complete closure rates using catheter-based techniques have steadily improved. Comparative studies of cost and outcome between open surgery and transcatheter duct closure, however, have shown no overwhelming choice between the two modalities.¹² Burke prospectively reviewed coil occlusion and video-assisted thoracic surgery at Miami Children's Hospital, and found both options to be effective and less morbid than traditional thoracotomy.¹²

OUTCOMES

In premature infants, the surgical mortality is very low, although the overall hospital death rate is significant as a consequence of other complications of prematurity. In older infants and children, mortality is less than 1%. Bleeding, chylothorax, vocal cord paralysis, and the need for reoperation occur infrequently. With the advent of muscle-sparing thoracotomy, the risk of subsequent arm dysfunction or breast abnormalities is virtually eliminated.⁴⁵

Aortic Coarctation

ANATOMY

Coarctation of the aorta (COA) is defined as a luminal narrowing in the aorta that causes an obstruction to blood flow. This narrowing is most commonly located distal to the left subclavian artery. The embryologic origin of COA is a subject of some controversy. One theory holds that the obstructing shelf, which is largely composed of tissue found within the ductus, forms as the ductus involutes.⁴⁶ The other theory holds that a diminished aortic isthmus develops secondary to decreased aortic flow in infants with enhanced ductal circulation.

Extensive collateral circulation develops, predominantly involving the intercostals and mammary arteries as a direct result of aortic flow obstruction. This translates into the well-known finding of "rib-notching" on chest radiograph, as well as a prominent pulsation underneath the ribs.

Other associated anomalies, such as VSD, PDA, and ASD, may be seen with COA, but the most common is that of a bicuspid aortic valve, which can be demonstrated in 25 to 42% of cases.⁴⁷

PATHOPHYSIOLOGY

Infants with COA develop symptoms consistent with left ventricular outflow obstruction, including pulmonary overcirculation and, later, biventricular failure. In addition, proximal systemic hypertension develops as a result of mechanical obstruction to ventricular ejection, as well as hypoperfusion-induced activation of the renin–angiotensin–aldosterone system. Interestingly, hypertension is often persistent after surgical correction despite complete amelioration of the mechanical obstruction and pressure gradient.⁴⁸ It has been shown that early surgical correction may prevent the development of long-term hypertension, which undoubtedly contributes to many of the adverse sequelae of COA, including the development of circle of Willis aneurysms, aortic dissection and rupture, and an increased incidence of coronary arteriopathy with resulting myocardial infarction.⁴⁹

DIAGNOSIS

COA is likely to become symptomatic either in the newborn period if other anomalies are present or in the late adolescent period with the onset of left ventricular failure. Physical examination will demonstrate a hyperdynamic precordium with a harsh murmur localized to the left chest and back. Femoral pulses will be dramatically decreased when compared to upper extremity pulses, and differential cyanosis may be apparent until ductal closure.

Echocardiography will reliably demonstrate the narrowed aortic segment, as well as define the pressure gradient across the stenotic

segment. In addition, detailed information regarding other associated anomalies can be gleaned. Aortography is reserved for those cases in which the echocardiographic findings are equivocal.

THERAPY

The routine management of hemodynamically significant COA in all age groups has traditionally been surgical. Transcatheter repairs are used with increasing frequency in older patients and those with recoarctation following surgical repair. Balloon dilatation of native coarctation in neonates has been used with poor results. The most common surgical techniques in current use are resection with end-to-end anastomosis or extended end-to-end anastomosis, taking care to remove all residual ductal tissue.^{50,51} Extended end-to-end anastomosis may also allow the surgeon to treat transverse arch hypoplasia which is commonly encountered in infants with aortic coarctation.^{52,53} The subclavian flap aortoplasty is another repair, although it is used less frequently in the modern era because of the risk of late aneurysm formation and possible underdevelopment of the left upper extremity or ischemia.⁵¹ In this method, the left subclavian artery is transected and brought down over the coarcted segment as a vascularized patch. The main benefit of these techniques is that they do not involve the use of prosthetic materials, and evidence suggests that extended end-to-end anastomosis may promote arch growth, especially in infants with the smallest initial aortic arch diameters.⁵²

Despite the benefits, however, extended end-to-end anastomosis may not be feasible when there is a long segment of coarctation or in the presence of previous surgery, because sufficient mobilization of the aorta above and below the lesion may not be possible. In this instance, prosthetic materials, such as a patch aortoplasty, in which a prosthetic patch is used to enlarge the coarcted segment, or an interposition tube graft must be used.

The most common complications after COA repair are late restenosis and aneurysm formation at the repair site.^{54–56} Aneurysm formation is particularly common after patch aortoplasty when using Dacron material. In a large series of 891 patients, aneurysms occurred in 5.4% of the total, with 89% occurring in the group who received Dacron-patch aortoplasty, and only 8% in those who received resection with primary end-to-end anastomosis.⁵⁴ A further complication, although uncommon, is lower-body paralysis resulting from ischemic spinal cord injury during the repair. This dreaded outcome complicates 0.5% of all surgical repairs, but its incidence can be lessened with the use of some form of distal perfusion, preferably left heart bypass with the use of femoral arterial or distal thoracic aorta for arterial inflow and the femoral vein or left atrium for venous return.⁵⁰ These techniques are generally reserved for older patients with complex coarctations that may need prolonged aortic cross-clamp times for repair, often in the setting of large collateral vessels and/or previous surgery.

Hypertension is also well recognized following repair of COA. Bouchart and colleagues reported that in a cohort of 35 hypertensive adults (mean age 28 years) undergoing repair, despite a satisfactory anatomic outcome, only 23 patients were normotensive at a mean follow-up period of 165 months.⁵⁵ Likewise, Bhat and associates reported that in a series of 84 patients (mean age at repair was 29 years), 31% remained hypertensive at a mean follow-up of 5 years following surgery.⁵⁶

Although operative repair is still the gold standard, treatment of COA by catheter-based intervention has become more widespread. Both balloon dilatation and primary stent implantation have been used successfully. The most extensive study of the results of balloon angioplasty reported on 970 procedures: 422 native and 548 recurrent COAs. Mean gradient reduction was $74 \pm 24\%$ for native and $70 \pm 31\%$ for recurrent COA.⁵⁷ This demonstrated that catheter-based therapy could produce equally effective results both in recurrent and in primary COA, a finding with far-reaching implications in the new paradigm of multidisciplinary treatment algorithms for CHD. In the valvuloplasty and angioplasty of congenital anomalies report, higher preangioplasty gradient, earlier procedure date, older patient age, and the presence of recurrent COA were independent risk factors for suboptimal procedural outcome.⁵⁷

The gradient after balloon dilatation in most series is generally acceptable. However, there is a significant minority (0 to 26%) for whom the procedural outcome is suboptimal, with a postprocedure gradient of 20 mmHg or greater. These patients may be ideal

candidates for primary stent placement. Restenosis is much less common in children, presumably reflecting the influence of vessel wall scarring and growth in the pediatric age group.

Deaths from the procedure also are infrequent (less than 1% of cases), and the main major complication is aneurysm formation, which occurs in 7% of patients.⁵⁰ With stent implantation, many authors have demonstrated improved resolution of stenosis compared with balloon dilatation alone, yet the long-term complications on vessel wall compliance remain largely unknown because only midterm data are widely available.

In summary, children younger than age 6 months with native COA should be treated with surgical repair, while those requiring intervention at later ages may be ideal candidates for balloon dilatation or primary stent implantation.⁵⁰ Additionally, catheter-based therapy should be used for those cases of restenosis following either surgical or primary endovascular management.

Truncus Arteriosus

ANATOMY

Truncus arteriosus is a rare anomaly, comprising between 1 and 4% of all cases of CHD.⁵⁸ It is characterized by a single great artery that arises from the heart, overrides the ventricular septum, and supplies the pulmonary, systemic, and coronary circulations.

The two major classification systems are those of Collett and Edwards, described in 1949, and Van Praagh and Van Praagh, described in 1965 (Fig. 20-9).^{59,60} The Collett and Edwards classification focuses mainly on the origin of the pulmonary arteries from the common arterial trunk, whereas the Van Praagh system is based on the presence or absence of a VSD, the degree of formation of the aorticopulmonary septum, and the status of the aortic arch.

Fig. 20-9.

There are similarities between the Collett and Edwards and the Van Praagh classifications of truncus arteriosus. Type I is the same as A1. Types II and III are grouped as a single type A2 because they are not significantly distinct embryologically or therapeutically. Type A3 denotes unilateral pulmonary artery with collateral supply to the contralateral lung (hemitruncus). Type A4 is truncus associated with interrupted aortic arch (13% of all cases of truncus arteriosus).

As adapted with permission from Hernanz-Schulman M, Fellows KE: Persistent truncus arteriosus: Pathologic, diagnostic and therapeutic considerations. *Semin Roentgenol* 20:121, 1985. Copyright Elsevier.]

During embryonic life, the truncus arteriosus normally begins to separate and spiral into a distinguishable anterior PA and posterior aorta. Persistent truncus, therefore, represents an arrest in embryologic development at this stage.⁶¹ Other implicated events include twisting of the dividing truncus because of ventricular looping, subinfundibular atresia, and abnormal location of the semilunar valve anlagen.⁶²

The neural crest may also play a crucial role in the normal formation of the great vessels, as experimental studies in chick embryos have shown that ablation of the neural crest results in persistent truncus arteriosus.⁶³ The neural crest also develops into the pharyngeal pouches that give rise to the thymus and parathyroids, which likely explains the prevalent association of truncus arteriosus and DiGeorge syndrome.⁶⁴

The annulus of the truncal valve usually straddles the ventricular septum in a "balanced" fashion; however, it is not unusual for it to be positioned predominantly over the RV, which increases the potential for LVOT obstruction following surgical repair. In the great majority of cases, the leaflets are thickened and deformed, which leads to valvular insufficiency. There are usually three leaflets (60%), but occasionally a bicuspid (50%), or even a quadricuspid valve (25%), is present.⁶⁵

In truncus arteriosus, the pulmonary trunk bifurcates, with the left and right pulmonary arteries forming posteriorly and to the left in most cases. The caliber of the pulmonary arterial branches is usually normal, with stenosis or diffuse hypoplasia occurring in rare instances.

The coronary arteries may be normal; however, anomalies are not unusual and occur in 50% of cases.^{65,66} Many of these are relatively minor, although two variations are of particular importance, because they have implications in the conduct of operative repair. The first is that the left coronary ostium may arise high in the sinus of Valsalva or even from the truncal tissue at the margin of the PA tissue. This coronary artery can be injured during repair when the pulmonary arteries are removed from the trunk or when the resulting truncal defect is closed. The second is that the right coronary artery can give rise to an important accessory anterior descending artery, which often passes across the RV in the exact location where the right ventriculotomy is commonly performed during repair.^{65,66}

PHYSIOLOGY AND DIAGNOSIS

The main pathophysiologic consequences of truncus arteriosus are (a) the obligatory mixing of systemic and pulmonary venous blood at the level of the VSD and truncal valve, which leads to arterial saturations near 85%, and (b) the presence of a nonrestrictive left-to-right shunt, which occurs during both systole and diastole, the volume of which is determined by the relative resistances of the pulmonary and systemic circulations.⁶⁵ Additionally, truncal valve stenosis or regurgitation, the presence of important LVOTO, and stenosis of PA branches can further contribute to both pressure- and volume loading of the ventricles. The presence of these lesions often results in severe heart failure and cardiovascular instability early in life. PVR may develop as early as 6 months of age, leading to poor results with late surgical correction.

Patients with truncus arteriosus usually present in the neonatal period, with signs and symptoms of CHF and mild to moderate cyanosis. A pan-systolic murmur may be noted at the left sternal border, and occasionally a diastolic murmur may be heard in the presence of truncal regurgitation.

Chest radiography will be consistent with pulmonary overcirculation, and a right aortic arch can be appreciated 35% of the time. The ECG is usually nonspecific, demonstrating normal sinus rhythm with biventricular hypertrophy.

Echocardiography with Doppler color flow or pulsed Doppler is diagnostic, and usually provides sufficient information to determine the type of truncus arteriosus, the origin of the coronary arteries, and their proximity to the pulmonary trunk, the character of the truncal valves, and the extent of truncal insufficiency.⁶⁵ Cardiac catheterization can be helpful in cases where pulmonary hypertension is suspected, or to further delineate coronary artery anomalies before repair.

The presence of truncus is an indication for surgery. Repair should be undertaken in the neonatal period, or as soon as the diagnosis is established. Eisenmenger's physiology, which is found primarily in older children, is the only absolute contraindication to correction.

REPAIR

Truncus arteriosus was first managed with PA banding as described by Armer and colleagues in 1961.⁶⁷ However, this technique led to only marginal improvements in 1-year survival rates because ventricular failure inevitably occurred. In 1967, however, complete repair was accomplished by McGoon and his associates based on the experimental work of Rastelli, who introduced the idea that an extracardiac valved conduit could be used to restore ventricular-to-PA continuity.⁶⁸ Over the next 20 years, improved survival rates led to uniform adoption of complete repair even in the youngest and smallest infants.^{58,65,69}

Surgical correction entails the use of CPB. Repair is completed by separation of the pulmonary arteries from the aorta, closure of the aortic defect (occasionally with a patch) to minimize coronary flow complications, placement of a valved cryopreserved allograft or jugular venous valved conduit (Contegra) to reconstruct the RVOT, and ventricular septal defect closure. Important branch pulmonary arterial stenosis should be repaired at the time of complete repair, and can usually be accomplished with longitudinal allograft patch arterioplasty. Severe truncal valve insufficiency occasionally requires truncal valve replacement, which can be accomplished with a cryopreserved allograft.⁷⁰

RESULTS

The results of complete repair of truncus have steadily improved. Ebert reported a 91% survival rate in his series of 77 patients who were younger than 6 months of age; later reports by others confirmed these findings and demonstrated that excellent results could be achieved in even smaller infants with complex-associated defects.^{11,69}

Newer extracardiac conduits also have been developed and used with success, which has widened the repertoire of the modern congenital heart surgeon and improved outcomes.⁷¹ Severe truncal regurgitation, interrupted aortic arch (IAA), coexistent coronary anomalies, chromosomal or genetic anomalies, and age younger than 100 days are risk factors associated with perioperative death and poor outcome.

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC) occurs in 1 to 2% of all cardiac malformations and is characterized by abnormal drainage of the pulmonary veins into the right heart, whether through connections into the right atrium or into its tributaries.⁷² Accordingly, the only mechanism by which oxygenated blood can return to the left heart is through an ASD, which is almost uniformly present with TAPVC.

Unique to this lesion is the absence of a definitive form of palliation. Thus, TAPVC with concomitant obstruction represents one of the only true surgical emergencies across the entire spectrum of congenital heart surgery.

ANATOMY AND EMBRYOLOGY

The lungs develop from an outpouching of the foregut, and their venous plexus arises as part of the splanchnic venous system.

TAPVC arises when the pulmonary vein evagination from the posterior surface of the left atrium fails to fuse with the pulmonary venous plexus surrounding the lung buds. In place of the usual connection to the left atrium, at least one connection of the pulmonary plexus to the splanchnic plexus persists. Accordingly, the pulmonary veins drain to the heart through a systemic vein (Fig. 20-10).

Fig. 20-10.

Total anomalous pulmonary venous connection results when the primordial pulmonary vein fails to unite with the plexus of veins that surround the lung buds and is derived from the splanchnic venous plexus, including the cardinal veins and umbilicovitelline veins.

(From Castaneda et al,⁷ p 158, with permission. Copyright Elsevier.)

Darling and colleagues classified TAPVC according to the site or level of connection of the pulmonary veins to the systemic venous system⁷³: type I (45%), anomalous connection at the supracardiac level; type II (25%), anomalous connection at the cardiac level; type III (25%), anomalous connection at the infracardiac level; and type IV (5%), anomalous connection at multiple levels.⁷⁴ Within each category, further subdivisions can be implemented, depending on whether PVO exists. Obstruction to pulmonary venous drainage is a powerful predictor of adverse natural outcome and occurs most frequently with the infracardiac type, especially when the pattern of infracardiac connection prevents the ductus venosus from bypassing the liver.⁷⁵

PATHOPHYSIOLOGY AND DIAGNOSIS

Because both pulmonary and systemic venous blood return to the right atrium in all forms of TAPVC, a right-to-left intracardiac shunt must be present for the afflicted infant to survive. This invariably occurs via a nonrestrictive PFO. Because of this obligatory mixing, cyanosis is usually present, and its degree depends on the ratio of pulmonary to systemic blood flow. Decreased pulmonary blood flow is a consequence of PVO, the presence of which is unlikely if the right ventricular pressure is less than 85% of systemic pressure.⁷⁶

The child with TAPVC may present with severe cyanosis and respiratory distress necessitating urgent surgical intervention if a severe degree of PVO is present. However, in cases where there is no obstructive component, the clinical picture is usually one of

pulmonary overcirculation, hepatomegaly, tachycardia, and tachypnea with feeding. In a child with serious obstruction, arterial blood gas analysis reveals severe hypoxemia (PO_2 less than 20 mmHg), with metabolic acidosis.⁷⁷

Chest radiography will show normal heart size with generalized pulmonary edema. Two-dimensional echocardiography is very useful in establishing the diagnosis, and also can assess ventricular septal position, which may be leftward secondary to small left ventricular volumes, as well as estimate the right ventricular pressure based on the height of the tricuspid regurgitant jet. Echocardiography can usually identify the pulmonary venous connections (types I–IV), and it is rarely necessary to perform other diagnostic tests.

Cardiac catheterization is not recommended in these patients because the osmotic load from the IV contrast can exacerbate the degree of pulmonary edema.⁷⁸ When cardiac catheterization is performed, equalization of oxygen saturations in all four heart chambers is a hallmark finding in this disease because the mixed blood returned to the right atrium gets distributed throughout the heart.

THERAPY

Operative correction of TAPVC requires anastomosis of the common pulmonary venous channel to the left atrium, obliteration of the anomalous venous connection, and closure of the ASD.^{77,79}

All types of TAPVC are approached through a median sternotomy, and many surgeons use deep hypothermic circulatory arrest to achieve an accurate and widely patent anastomosis. The technique for supracardiac TAPVC includes early division of the vertical vein, retraction of the aorta and the SVC laterally to expose the posterior aspect of the left atrium and the pulmonary venous confluence, and a side-to-side anastomosis between a long, horizontal biatrial incision and a longitudinal incision within the pulmonary venous confluence. The ASD can then be closed with an autologous pericardial or synthetic patch.

In patients with TAPVC to the coronary sinus without obstruction, a simple unroofing of the coronary sinus can be performed through a single right atriotomy with concomitant closure of the ASD. If PVO is present, the repair should include generous resection of roof of the coronary sinus.⁷⁷

Repair of infracardiac TAPVC entails ligation of the vertical vein at the diaphragm, followed by construction of a proximal, patulous longitudinal venotomy. This repair is usually performed by "rolling" the heart toward the left, thus exposing the left atrium where it usually overlies the descending vertical vein (Fig. 20-11).

Operative exposure obtained with infradiaphragmatic total anomalous pulmonary venous connection, using an approach from the right.

(From Castaneda et al,⁷ p 161, with permission. Copyright Elsevier.)

The perioperative care of these infants is crucial because episodes of pulmonary hypertension can occur within the first 48 hours, which contribute significantly to mortality following repair.^{6,78,79} Muscle relaxants and narcotics should be administered during this period to maintain a constant state of anesthesia. Arterial partial pressure of carbon dioxide should be maintained at 30 mmHg with use of a volume ventilator and the fraction of inspired oxygen should be increased to keep the pulmonary arterial pressure at less than two thirds of the systemic pressure.

RESULTS

Results of TAPVC in infancy have markedly improved, with an operative mortality of 5% or less in some series.⁷⁷⁻⁸⁰ This improvement is probably multifactorial, mainly as a consequence of early noninvasive diagnosis and aggressive perioperative management. The routine use of echocardiography; improvements in myocardial protection with specific attention to the RV; creation of a large, tension-free anastomosis with maximal use of the venous confluence and atrial tissue; careful geometric alignment of the pulmonary venous sinus with the body of the left atrium avoiding tension and rotation of the pulmonary veins; and prevention of pulmonary hypertensive events have likely played a major role in reducing operative mortality. The importance of risk factors for early mortality, such as venous obstruction at presentation, urgency of operative repair, and infradiaphragmatic anatomic type, has been debated.^{79,81}

Bando and colleagues⁸² made the controversial statement that both preoperative PVO and anatomic type had been neutralized as

potential risk factors beyond calendar year 1991. Hyde and associates⁸⁰ similarly reported that connection type was not related to outcome. However, a recent, large, single institution report of 377 children with TAPVC by the author from the Hospital for Sick Children in Toronto⁸³ found that, although outcomes had improved over time, patient anatomic factors were still important determinants of both survival and the need for subsequent reoperation. Risk factors for postrepair death were earlier operation year, younger age at repair, cardiac connection type, and postoperative PVO. Risk-adjusted estimated 1-year survival for a patient repaired at birth with unfavorable morphology in 2006 is 37% (95% confidence intervals: 8 to 80%) compared to 96% (95% confidence intervals: 91 to 99%) for a patient with favorable morphology repaired at age 1 year. Freedom from reoperation was $82\% \pm 6\%$ at 11 years postrepair, with increased risk associated with mixed connection and postoperative PVO. (Fig. 20-12).

Fig. 20-12.

a. Risk-adjusted survival from repair improved significantly with increasing year of operation, indicating a strong era effect. Solid lines are continuous point estimates enclosed by dashed 95% confidence limits showing three different solutions to the multivariable equation for death after repair. All other predictors have been set to mean values to illustrate the favorable influence of later operation year on survival after repair. **b.** Risk-adjusted nomograms show 1-year survival after repair expressed as a function of increasing year of operation for two different patients. The top line (A) shows the multivariable solution for a patient with favorable anatomic characteristics (noncardiac connection without pulmonary venous obstruction) undergoing repair at 1 year of age; the bottom line (B) shows the solution for a patient with unfavorable characteristics (cardiac connection with pulmonary venous obstruction) undergoing operation at birth. The nomograms show that the more recent era has improved survival in all patients, especially within the last few decades. However, unfavorable anatomic characteristics have not been neutralized as important determinants of postrepair survival despite improvements in perioperative care. Numbers in parentheses represent parametric estimates of median survival at 1 year after repair in 2005.

[From Karamlou et al,⁸³ (Fig. 2), with permission.]

The most significant postoperative complication of TAPVC repair is PVO, which occurs 9 to 11% of the time, regardless of the surgical technique used. Mortality varies between 30 and 45% and alternative catheter interventions do not offer definitive solutions.⁷⁸ Recurrent PVO can be localized at the site of the pulmonary venous anastomosis (extrinsic), which can usually be cured with patch enlargement or balloon dilatation, or it may be secondary to endocardial thickening of the pulmonary venous ostia frequently resulting in diffuse pulmonary venous sclerosis (intrinsic), which carries a 66% mortality rate because few good solutions exist.⁷⁵ More commonly, postrepair left ventricular dysfunction can occur as the noncompliant LV suddenly is required to handle an increased volume load from redirected pulmonary venous return. This can manifest as an increase in PA pressure but is distinguishable from primary pulmonary hypertension (another possible postoperative complication following repair of TAPVC) from the elevated LA pressure and LV dysfunction along with echocardiographic evidence of poor LV contractility. In pulmonary hypertension, the LA pressure may be low, the LV may appear "underfilled" (by echocardiography), and the RV may appear dilated. In either case, postoperative support for a few days with extracorporeal membrane oxygenation may be lifesaving, and TAPVC should be repaired in centers that have this capacity.

Some investigators have speculated that preoperative PVO is associated with increased medial thickness within the pulmonary vasculature, which may predispose these infants to intrinsic pulmonary venous stenosis despite adequate pulmonary venous decompression.⁸⁰ The majority of studies demonstrating that preoperative PVO is a predictor of subsequent need for reoperation to correct recurrent PVO lend credence to this notion. Another complication following repair of TAPVC is the development of atrial arrhythmias secondary to altered atrial geometry and LA enlargement procedures. These arrhythmias may be asymptomatic, and certain surgeons therefore advocate routine long-term follow-up with 24-hour ECG monitoring to facilitate their detection and treatment.⁸¹

Cor Triatriatum

ANATOMY

Cor triatriatum is a rare CHD characterized by the presence of a fibromuscular diaphragm that partitions the left atrium into two chambers: a superior chamber that receives drainage from the pulmonary veins, and an inferior chamber that communicates with the mitral valve and the LV (Fig. 20-13). An ASD frequently exists between the superior chamber and the right atrium, or, more rarely, between the right atrium and the inferior chamber.⁸⁴

Source: Brunicki FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Variants of cor triatriatum with imperforate membrane between common pulmonary venous chamber (CPVC) and left atrium (LA).
A. Common chamber draining to right atrium directly. **B.** Common chamber draining into systemic venous circulation via anomalous vein. RA = right atrium.

[Adapted with permission from Lucas RV: Anomalous venous connections, pulmonary and systemic, in Adams FH, Emmanouilides GC (eds): *Moss' Heart Disease in Infants, Children, and Adolescents*, 3rd ed. Baltimore: Lippincott Williams & Wilkins, 1983.]

PATHOPHYSIOLOGY AND DIAGNOSIS

Cor triatriatum results in obstruction of pulmonary venous return to the left atrium. The degree of obstruction is variable and depends on the size of fenestrations present in the LA membrane, the size of the ASD, and the existence of other associated anomalies. If the communication between the superior and inferior chambers is less than 3 mm, patients usually are symptomatic during the first year of life. The afflicted infant will present with the stigmata of low cardiac output and pulmonary venous hypertension, as well as CHF and poor feeding.

Physical examination may demonstrate a loud pulmonary S₂ sound and a right ventricular heave, as well as jugular venous distention and hepatomegaly. Chest radiography will show cardiomegaly and pulmonary vascular prominence, and the ECG will suggest right ventricular hypertrophy. Two-dimensional echocardiography provides a definitive diagnosis in most cases, with catheterization necessary only when echocardiographic evaluation is equivocal.

THERAPY

Operative treatment for cor triatriatum is fairly simple. CPB and cardioplegic arrest are used. A right atriotomy usually allows access to the LA membrane through the existing ASD, because it is dilated secondary to communication with the pulmonary venous chamber. The membrane is then excised, taking care not to injure the mitral valve or the interatrial septum, and the ASD is closed with a patch. Alternatively, if the right atrium is small, the membrane can be exposed through an incision directly into the superior LA chamber, just anterior to the right pulmonary veins.^{7,82} Surgical results are uniformly excellent for this defect, with survival approaching 100%.

The use of catheter-based intervention for this diagnosis remains controversial, although there have been two recent reports of successful balloon dilatation.⁸³

Aortopulmonary Window

EMBRYOLOGY AND ANATOMY

Aortopulmonary window (APW) is a rare congenital lesion, occurring in about 0.2% of patients, characterized by incomplete development of the septum that normally divides the truncus into the aorta and the PA.⁸⁵

In the vast majority of cases, APW occurs as a single defect of minimal length, which begins a few millimeters above the semilunar valves on the left lateral wall of the aorta (Fig. 20-14). Coronary artery anomalies, such as aberrant origin of the right or left coronary artery from the main PA, are occasionally present.

Fig. 20-14.

A through C. Classification of aortopulmonary window.

(Reproduced with permission from Mori K, Ando M, Takao A: Distal type of aortopulmonary window: report of 4 cases. *Br Heart J* 40:681, 1978. With permission from the BMJ Publishing Group.)

PATHOPHYSIOLOGY AND DIAGNOSIS

The dominant pathophysiology of APW is that of a large left-to-right shunt with increased pulmonary flow and the early development of CHF. Like other lesions with left-to-right flow, the magnitude of the shunt is determined by the size of the defect, as well as the PVR.

Infants with APW present with frequent respiratory tract infections, tachypnea with feeding, and failure to thrive. Cyanosis is usually absent because these infants deteriorate before the onset of significant pulmonary hypertension. The rapid decline with this defect occurs because shunt flow continues during both phases of the cardiac cycle, which limits systemic perfusion and increases ventricular work.⁸⁶

The diagnosis of APW begins with the physical examination, which may demonstrate a systolic flow murmur, a hyperdynamic precordium, and bounding peripheral pulses. The chest radiograph will show pulmonary overcirculation and cardiomegaly, and the ECG will usually demonstrate either left ventricular hypertrophy or biventricular hypertrophy. Echocardiography can detect the defect and also provide information about associated anomalies. Retrograde aortography will confirm the diagnosis, but is rarely necessary.

THERAPY

All infants with APW require surgical correction once the diagnosis is made. Repair is undertaken through a median sternotomy and the use of CPB. The pulmonary arteries are occluded once the distal aorta is cannulated, and a transaortic repair using a prosthetic patch for PA closure is then carried out. The coronary ostia must be carefully visualized and included on the aortic side of the patch. Alternatively, a two-patch technique can be used, which may eliminate recurrent fistulas from suture line leaks that occasionally

occur with the single-patch method (Fig. 20-15).⁸⁵

Fig. 20-15.

Two-patch repair of aortopulmonary window. **A.** The aorta and right atrium are cannulated through a median sternotomy and, once the patient is on cardiopulmonary bypass, the right and left pulmonary arteries are occluded with snares. The ducts arteriosus (when present) can be ligated. The aorta is cross-clamped and the heart arrested with cardioplegia. The aortopulmonary window is then divided, with the left coronary ostia being carefully protected. **B.** A piece of previously prepared pulmonary homograft material is used to patch the aortic defect. In older children polytetrafluoroethylene material can be safely used. **C.** Once the aortic portion of the defect has been safely repaired, the aortic cross-clamp may be removed to restore perfusion to the heart. During rewarming the pulmonary portion of the defect is repaired using a similar piece of homograft or polytetrafluoroethylene. **D.** At the completion of repair, the patient is easily weaned from cardiopulmonary bypass, and the cannulas are removed. This type of repair restores normal anatomy, with a reduced likelihood of long-term fistula formation.

(From Gaynor et al,⁸⁷ with permission.)

RESULTS

Results are generally excellent, with an operative mortality in most large series of less than 5%.⁸⁵

DEFECTS REQUIRING PALLIATION

Tricuspid Atresia

Tricuspid atresia occurs in 2 to 3% of patients with CHD and is characterized by atresia of the tricuspid valve. This results in discontinuity between the right atrium and RV. The RV is generally hypoplastic, and left-heart filling is dependent on an ASD. Tricuspid atresia is the most common form of the single-ventricle complex, indicating that there is functionally only one ventricular chamber.

ANATOMY

As mentioned, tricuspid atresia results in a lack of communication between the right atrium and the RV, and in the majority of patients there is no identifiable valve tissue or remnant.⁸⁸ The right atrium is generally enlarged and muscular, with a fibrofatty floor. An unrestrictive ASD is usually present. The LV is often enlarged as it receives both systemic and pulmonary blood flow, but the left AV valve usually is normal.

The RV, however, usually is severely hypoplastic, and there is sometimes a ventricular septal defect in its trabeculated or infundibular portion. In many cases, the interventricular communication is a site of obstruction to pulmonary blood flow, but obstruction may also occur at the level of the outlet valve or in the subvalvular infundibulum.⁸⁷ In most cases, pulmonary blood flow is dependent on the presence of a PDA, and there may be no flow into the pulmonary circulation except for this PDA.

Tricuspid atresia is classified according to the relationship of the great vessels and by the degree of obstruction to pulmonary blood flow (Fig. 20-16). Because of the rarity of tricuspid atresia with transposed great arteries, this chapter will focus solely on tricuspid atresia with normally related great vessels.

Fig. 20-16.

Classification of tricuspid atresia. Type I, normally related great arteries with: **IA**, pulmonary atresia with virtual absence of right ventricle; **IB**, pulmonary stenosis with small ventricular septal defect; **IC**, normal pulmonary valve, large ventricular septal defect. Type II, transposed great arteries with: **IIA**, pulmonary atresia; **IIB**, pulmonary or subpulmonary stenosis; **IIC**, normal or enlarged pulmonary valve and artery without subpulmonary stenosis.

[Reproduced with permission from Tricuspid atresia, in Mavroudis C and Backer CL (eds): *Pediatric Cardiac Surgery*, 2nd ed. St. Louis: Mosby, 1994, p 381.]

PATHOPHYSIOLOGY

The main pathophysiology in tricuspid atresia is that of a univentricular heart of left ventricular morphology. That is, the LV must receive systemic blood via the interatrial communication, and then distribute it to both the pulmonary circulation and the systemic circulation. Unless there is a VSD (as is found in some cases), pulmonary flow is dependent upon the presence of a PDA. As the ductus begins to close shortly after birth, infants become intensely cyanotic. Re-establishing ductal patency (with PGE1) restores pulmonary blood flow and stabilizes patients for surgical intervention. Pulmonary hypertension is unusual in tricuspid atresia.

However, occasional patients have a large VSD between the LV and the infundibular portion of the RV (just below the pulmonary valve). If there is no obstruction at the level of this VSD or at the valve, these infants may actually present with heart failure from excessive pulmonary blood flow. Regardless of whether these infants are "ductal-dependent" for pulmonary blood flow or have pulmonary blood flow provided across a VSD, they will be cyanotic because the obligatory right-to-left shunt at the atrial level will provide complete mixing of systemic and pulmonary venous return so that the LV ejects a hypoxemic mixture into the aorta.

DIAGNOSIS

The signs and symptoms of tricuspid atresia are dependent on the underlying anatomic variant, but most infants are cyanotic and hypoxic as a result of decreased pulmonary blood flow and the complete mixing at the atrial level. When pulmonary blood flow is provided through a VSD, there may be a prominent systolic murmur. Tricuspid atresia with pulmonary blood flow from a PDA may present with the soft, continuous murmur of a PDA in conjunction with cyanosis.

In the minority of patients with tricuspid atresia, symptoms of CHF will predominate. This is often related to excessive flow across a VSD. The natural history of the muscular VSDs in these infants is that they will close and the CHF will dissipate and transform into cyanosis with reduced pulmonary blood flow. Chest radiography will show decreased pulmonary vascularity. The ECG is strongly suggestive, because uncharacteristic left axis deviation will be present, owing to underdevelopment of the RV. Two-dimensional echocardiography readily confirms the diagnosis and the anatomic subtype.

TREATMENT

The treatment for tricuspid atresia in the earlier era of palliation was aimed at correcting the defect in the pulmonary circulation. That is, patients with too much pulmonary flow received a pulmonary band, and those with insufficient flow received a systemic-to-PA shunt. Systemic-to-PA shunts, or Blalock-Taussig (B-T) shunts, were first applied to patients with tricuspid atresia in the 1940s and 1950s.⁸⁹ Likewise PA banding was applied to patients with tricuspid atresia and congestive failure in 1957. However, despite the initial relief of either cyanosis or CHF, long-term mortality was high, as the single ventricle was left unprotected from either volume or pressure overload.⁹⁰

Recognizing the inadequacies of the initial repairs, Glenn described the first successful cavopulmonary anastomosis, an end-to-side RPA-to-SVC shunt in 1958, and later modified this to allow flow to both pulmonary arteries.⁹¹ This end-to-side RPA-to-SVC anastomosis was known as the *bidirectional Glenn*, and is the first stage to final Fontan repair in widespread use today (Fig. 20-17). The Fontan repair was a major advancement in the treatment of CHD, as it essentially bypassed the right heart, and allowed separation of the pulmonary and systemic circulations. It was first performed by Fontan in 1971, and consisted of a classic Glenn anastomosis, ASD closure, and direct connection of the right atrium to the proximal end of the left PA using an aortic homograft.⁹² The main PA was ligated, and a homograft valve was inserted into the orifice of the IVC.

Superior vena cava–pulmonary artery shunts. **A.** Classic Glenn shunt. End-to-side right pulmonary artery (RPA)-to-superior vena cava (SVC) anastomosis with ligation of SVC–right atrial junction. **B.** Method of takedown of classic Glenn shunt and creation of total cavopulmonary anastomosis during Fontan operation. **C.** Bidirectional Glenn shunt (bidirectional SVC–pulmonary artery shunt), end-to-side SVC-to-RPA anastomosis. **D.** Method of construction of bidirectional Glenn shunt, one cannula in the high SVC or innominate vein and another cannula in the right atrium connected to a Y-connector.

[Reproduced with permission from Tricuspid atresia, in Mavroudis C, Backer CL (eds): *Pediatric Cardiac Surgery*, 2nd ed. St. Louis: Mosby, 1994, p 383.]

Multiple modifications of this initial repair were performed over the next 20 years. One of the most important was the description by deLeval and colleagues of the creation of an interatrial lateral tunnel that allowed the inferior vena caval blood to be channeled exclusively to the SVC.⁹³ A total cavopulmonary connection could then be accomplished by dividing the SVC and suturing the superior portion to the upper side of the RPA and the inferior end to the augmented undersurface of the RPA. Pulmonary flow then occurs passively, in a laminar fashion, driven by the central venous pressure. This repair became known as the *modified Fontan operation*.

Another important modification, the fenestrated Fontan repair, was introduced in 1988.^{94–96} In this procedure, a residual 20 to 30% right-to-left shunt is either created or left unrepaired at the time of cavopulmonary connection to help sustain systemic output in the face of transient elevations in the PVR postoperatively (Fig. 20-18).⁹⁴

The fenestrated Fontan procedure. Using a polytetrafluoroethylene patch, a tunnel is created in the lateral wall of the right atrium to direct inferior vena cava (IVC) flow to the superior vena cava (SVC) that is anastomosed to the pulmonary artery (PA). A 4- to 5-mm fenestration in the baffle diminishes systemic venous pressure and improves cardiac output at the expense of a small decrease in systemic arterial oxygen saturation.

(Reproduced with permission from Kopf GS, Kleinman CS, Hijazi ZM, et al: Fenestrated Fontan operation with delayed transcatheter closure of atrial septal defect: Improved results in high-risk patients. *J Thorac Cardiovasc Surg* 103:1039, 1992. Copyright Elsevier.)

The last notable variation on the original Fontan repair uses an extracardiac prosthetic tube graft, usually 20 mm in diameter, as the conduit directing IVC blood to the pulmonary arteries.⁹⁵ This technique has the advantages of decreasing atrial geometric alterations by avoiding intra-atrial suture lines, and improving flow dynamics in the systemic venous pathway by maximizing laminar

flow. Several investigators have shown a decrease in supraventricular arrhythmias, as well as an improvement in ventricular function, which may be secondary to decreased atrial tension and alleviation of chronic elevations in coronary sinus pressure.^{95,96} The extracardiac Fontan operation can be completed without the use of CPB in selected cases, which may further improve outcomes.⁹⁷

One potential disadvantage of the extracardiac Fontan is that it delays performance of the Fontan to allow placement of a conduit of sufficient size. Despite these innovative approaches, the current strategy for operative management still relies on the idea of palliation. Patients are approached in a staged manner, to maximize their physiologic state so that they will survive to undergo a Fontan operation. The therapeutic strategy must begin in the neonatal period and should be directed toward reducing the patient's subsequent risk factors for a Fontan procedure. Accordingly, small systemic pulmonary shunts, which are usually performed through a median sternotomy, should be constructed for palliation of ductus-dependent univentricular physiology. This can easily be replaced with a bidirectional Glenn shunt or hemi-Fontan operation at 6 months of life. In non-ductus-dependent univentricular physiology, the infant can be managed medically until primary construction of a bidirectional cavopulmonary anastomosis becomes feasible. This is possible in the majority of cases because the physiologically elevated PVR prevents pulmonary overcirculation during the neonatal period.

Occasionally, if a previous B-T shunt was performed, arterioplasty of the RPA may be required to ensure adequate size and unobstructed bilateral flow.² The bidirectional Glenn shunt or hemi-Fontan operation effectively avoids recirculation of both systemic and pulmonary venous return, thus preventing volume overload of the single ventricle and its attendant sequelae.⁹⁵ PA banding is necessary in 10 to 15% of patients with markedly increased pulmonary blood flow and florid CHF.

The Fontan is usually performed when the child is between 2 and 4 years of age, and it is generally successful if the infant was staged properly, with a protected single ventricle, and there is adequate PA growth. The PVR should be below 4 Wood's units, and the ejection fraction should be more than 45% to ensure success.⁹⁸ In patients with high PA pressure, fenestration of the atrial baffle may be helpful because their PVR may preclude adequate cardiac output postoperatively.^{92,96}

RESULTS

Reports of the Fontan procedure for tricuspid atresia have been encouraging, with an overall survival of 86% and an operative mortality of 2%.^{8,99} The main complications following repair are atrial arrhythmias, particularly atrial flutter; conduit obstruction requiring reoperation; protein-losing enteropathy; and decreased exercise tolerance.

A prospective multi-institutional study from the Congenital Heart Surgeons' Society reported the outcomes of 150 neonates with tricuspid atresia and normally related great vessels.⁹⁹ Five-year survival was 86%, and by the age of 2 years, 89% had undergone cavopulmonary anastomosis, and 75% of those surviving cavopulmonary anastomosis underwent a Fontan operation within 3 years. Competing risks methodology was used in this study to determine the rates of transition to end states and their associated determinants (Fig. 20-19). Risk factors for death without cavopulmonary anastomosis in this study included the presence of mitral regurgitation and palliation with systemic-to-pulmonary artery shunts not originating from the innominate artery. Factors associated with decreased transition rate to cavopulmonary anastomosis included patient variables (younger age at admission to a participating institution and noncardiac anomalies) and procedural variables (larger systemic-to-pulmonary arterial shunt diameter and previous palliation).⁹⁹

Competing risks depiction of events after diagnosis in 150 patients with tricuspid atresia. All patients began alive and thereafter migrated to one of four mutually exclusive end states [death, bidirectional cavopulmonary anastomosis (BDCPA), single-stage Fontan completion, or remaining alive without BDCPA] at time-dependent rates defined by the underlying hazard functions. At any point in time, the sum of proportions of children in each state is 100%. For example, estimated prevalences after 2 years from diagnosis are as follows: 89% BDCPA, 6% dead without BDCPA, 4% alive without BDCPA, and 1% single-stage Fontan completion. Solid lines represent parametric point estimates; dashed lines enclose 70% confidence intervals; circles with error bars represent nonparametric estimates; numbers in parentheses indicate the estimated proportion of patients in each state at 2 years from diagnosis.

Hypoplastic Left-Heart Syndrome

HLHS comprises a wide spectrum of cardiac malformations, including hypoplasia or atresia of the aortic and mitral valves and hypoplasia of the LV and AA.¹⁰⁰ HLHS has a reported prevalence of 0.2 per 1000 live births and occurs twice as often in boys as in girls. Left untreated, HLHS is invariably fatal and is responsible for 25% of early cardiac deaths in neonates.¹⁰¹ However, the evolution of palliative surgical procedures has dramatically improved the outlook for patients with HLHS, and an improved understanding of anatomic and physiologic alterations have spurred advances in parallel arenas such as intrauterine diagnosis and fetal intervention, echocardiographic imaging, and neonatal critical care.

ANATOMY

As implied by its name, HLHS involves varying degrees of underdevelopment of left-sided structures, including the LV and the aortic and mitral valves. Thus, HLHS can be classified into four anatomic subtypes based on the valvular morphology: (a) aortic and mitral stenosis; (b) aortic and mitral atresia; (c) aortic atresia and mitral stenosis; and (d) AS and mitral atresia. Aortic atresia tends to be associated with more severe degrees of hypoplasia of the AA than does AS.

Even in cases without frank aortic atresia, however, the aortic arch is generally hypoplastic and, in severe cases, may even be

interrupted. There is an associated coarctation shelf in 80% of patients with HLHS, and the ductus itself is usually quite large, as is the main PA.⁷ The segmental pulmonary arteries, however, are small, secondary to reduced intrauterine pulmonary blood flow, which is itself a consequence of the left-sided outflow obstruction. The LA cavity is generally smaller than normal, and is accentuated because of the leftward displacement of the septum primum. There is almost always an interatrial communication via the foramen ovale, which can be large, but more commonly restricts right-to-left flow. In rare cases, there is no atrial-level communication, which can be lethal for these infants because there is no way for pulmonary venous return to cross over to the RV.

Associated defects can occur with HLHS, and many of them have importance with respect to operative repair. For example, if a ventricular septal defect is present, the LV can retain its normal size during development even in the presence of mitral atresia. This is because a right-to-left shunt through the defect impels growth of the LV.¹⁰² This introduces the feasibility of biventricular repair for this subset of patients.

Although HLHS undoubtedly results from a complex interplay of developmental errors in the early stages of cardiogenesis, many investigators have hypothesized that the altered blood flow is responsible for the structural underdevelopment that characterizes HLHS. In other words, if the stimulus for normal development of the AA from the primordial aortic sac is high-pressure systemic blood flow from the LV through the aortic valve, then an atretic or stenotic aortic valve, which impedes flow and leads to only low-pressure diastolic retrograde flow via the ductus, will change the developmental signals and result in hypoplasia of the downstream structures. Normal growth and development of the LV and mitral valve can be secondarily affected, resulting in hypoplasia or atresia of these structures.¹⁰⁰

PATHOPHYSIOLOGY AND DIAGNOSIS

In HLHS, pulmonary venous blood enters the left atrium, but atrial systole cannot propel blood across the stenotic or atretic mitral valve into the LV. Thus, the blood is shunted across the foramen ovale into the right atrium, where it contributes to volume loading of the RV. The end result is pulmonary venous hypertension from outflow obstruction at the level of the left atrium, as well as pulmonary overcirculation and right ventricular failure. As the PVR falls postnatally, the condition is exacerbated because right ventricular output is preferentially directed away from the systemic circulation, resulting in profound underperfusion of the coronary arteries and the vital organs. Closure of the ductus is incompatible with life in these neonates.

Neonates with severe HLHS receive all pulmonary, systemic, and coronary blood flow from the RV. Generally, a child with HLHS will present with respiratory distress within the first day of life, and mild cyanosis may be noted. These infants must be rapidly triaged to a tertiary center, and echocardiography should be performed to confirm the diagnosis. PGE1 must be administered to maintain ductal patency, and the ventilatory settings adjusted to avoid excessive oxygenation and increase carbon dioxide tension. These maneuvers will maintain PVR and promote improved systemic perfusion.^{2,7,100} Cardiac catheterization generally should be avoided because it is not usually helpful and might result in injury to the ductus and compromised renal function secondary to the osmotic dye load.

TREATMENT

In 1983, Norwood and colleagues described a two-stage palliative surgical procedure for relief of HLHS¹⁰³ that was later modified to the currently used three-stage method of palliation.¹⁰⁴ Stage 1 palliation, also known as the *modified Norwood procedure*, bypasses the LV by creating a single outflow vessel, the neo-aorta, which arises from the RV.¹⁰⁵

The current technique of arch reconstruction involves completion of a connection between the pulmonary root, the native AA, and a piece of pulmonary homograft used to augment the diminutive native aorta. There are several modifications of this anastomosis, most notably the Damus-Kaye-Stansel (DKS) anastomosis, which involves dividing both the aorta and the PA at the sinotubular junction. The proximal aorta is anastomosed to the proximal PA creating a "double-barreled" outlet from the heart. This outlet is anastomosed to the distal aorta, which can be augmented with homograft material if there is an associated coarctation. At the

completion of arch reconstruction, a 3.5- or 4-mm shunt is placed from the innominate artery to the right PA. The interatrial septum is then widely excised, thereby creating a large interatrial communication and preventing pulmonary venous hypertension (Fig. 20-20).

Fig. 20-20.

Current techniques for first-stage palliation of the hypoplastic left-heart syndrome. **A.** Incisions used for the procedure, incorporating a cuff of arterial wall allograft. The distal divided main pulmonary artery may be closed by direct suture or with a patch. **B.** Dimensions of the cuff of the arterial wall allograft. **C.** The arterial wall allograft is used to supplement the anastomosis between the proximal divided main pulmonary artery and the ascending aorta, aortic arch, and proximal descending aorta. **D** and **E.** The procedure is completed by atrial septectomy and a 3- to 5-mm modified right Blalock shunt. **F.** When the ascending aorta is particularly small, an alternative procedure involves placement of a complete tube of arterial allograft. The tiny ascending aorta may be left in situ, as indicated, or implanted into the side of the neo-aorta. a. = artery.

(From Castaneda et al,⁷ p 371, with permission. Copyright Elsevier.)

The DKS connection, as described in the previous paragraph, might avoid postoperative distortion of the tripartite connection in the neo-aorta, and thus decrease the risk of coronary insufficiency.^{105,106} It can be used when the aorta is 4 mm or larger. Unfortunately, in many infants with HLHS, especially if there is aortic atresia, the aorta is diminutive and often less than 2 mm in diameter.

The postoperative management of infants following stage 1 palliation is complex because favorable outcomes depend on establishing a delicate balance between pulmonary and systemic perfusion. Literature suggests that these infants require adequate postoperative cardiac output to supply both the pulmonary and the systemic circulations and that the use of oximetric catheters to monitor Sv-O₂ aids clinicians in both the selection of inotropic agents and in ventilatory management.^{106,107} The introduction of a modification that includes arch reconstruction and placement of the shunt between the RV and the PA (Sano shunt) diminishes the diastolic flow created by the classical aortopulmonary shunt and may augment coronary perfusion, resulting in improved postoperative cardiac function. A current prospective, randomized, multi-institutional trial sponsored by the National Institutes of Health, the systemic ventricle reconstruction trial, is currently evaluating the outcomes of neonates having either a modified B-T shunt or a Sano shunt.^{107,108}

Although surgical palliation with the Norwood procedure is still the mainstay of therapy for infants with HLHS, a combined surgical and percutaneous option (hybrid procedure), which consists of bilateral PA banding and placement of a ductal stent, has emerged as a promising alternative that obviates the need for CPB in the fragile neonatal period.^{109,110} The hybrid procedure can also be used as a bridge to heart transplantation in those infants with severe AV valve regurgitation or otherwise unsuitable single-ventricle anatomy.

Following stage 1 palliation, the second surgical procedure is the creation of a bidirectional cavopulmonary shunt or hemi-Fontan, generally at 3 to 6 months of life when the PVR has decreased to normal levels. This is the first step in separating the pulmonary and systemic circulations, and it decreases the volume load on the single ventricle. The existing innominate artery-to-pulmonary shunt (or RV-pulmonary shunt) is eliminated during the same operation (Fig. 20-21).

Technique of a bidirectional Glenn shunt. The divided right superior vena cava has been anastomosed at the previous site of the distal anastomosis of the modified right Blalock shunt. The cardiac end of the divided superior vena cava may also be anastomosed to the right pulmonary artery, with the internal orifice being closed with a Gore-Tex patch.

(From Castaneda et al,⁷ p 376, with permission. Copyright Elsevier.)

The third stage of surgical palliation, known as the *modified Fontan procedure*, completes the separation of the systemic and pulmonary circulations and is performed between 18 months and 3 years of age, or when the patient experiences increased cyanosis (i.e., has outgrown the capacity to perfuse the systemic circulation with adequately oxygenated blood). This has traditionally required a lateral tunnel within the right atrium to direct blood from the IVC to the PA, allowing further relief of the volume load on the RV, and providing increased pulmonary blood flow to alleviate cyanosis. More recently, many favor using an extracardiac conduit (e.g., 20-mm tube graft) to connect the IVC to the PA.

Not all patients with HLHS require this three-stage palliative repair. Some infants afflicted with a milder form of HLHS, recently described as *hypoplastic left-heart complex*, have aortic or mitral hypoplasia without intrinsic valve stenosis and antegrade flow in the AA. In this group, a two-ventricle repair can be achieved with a reasonable outcome. Tchervenkov recently published the results of 12 patients with hypoplastic left-heart complex who underwent biventricular repair at a mean age of 7 days.¹⁰⁷ The operative technique consisted of a pulmonary homograft patch aortoplasty of the aortic arch and AA and closure of the interatrial and interventricular communications.^{110,111} The left heart was capable of sustaining systemic perfusion in 92% of patients, and early

mortality was 15.4%. Four patients required reoperations to relieve LVOTO, most commonly between 12 and 39 months following repair.

Although the Norwood procedure is the most widely performed initial operation for HLHS, transplantation can be used as a first-line therapy and may be preferred when anatomic or physiologic considerations exist that preclude a favorable outcome with palliative repair. Significant tricuspid regurgitation, intractable PA hypertension, or progressive right ventricular failure, are cases where cardiac replacement may be advantageous. Widespread adaptation of transplantation as first-line treatment for HLHS has been limited by improved Norwood survival rates as the operation and pre- and postoperative management of the patient have evolved, as well as limited organ availability. Organ availability should be considered before electing transplantation, as 24% of infants died awaiting transplantation in the largest series to date.^{111,112}

RESULTS

Outcomes for HLHS are still significantly worse than those for other complex cardiac defects. However, with improvements in perioperative care and modifications in surgical technique, the survival following the Norwood procedure now exceeds 80% in experienced centers.^{100,106,108,110} The outcome for low-birth-weight infants has improved, but low weight still remains a major predictor of adverse survival, especially when accompanied by additional cardiac defects, such as systemic outflow obstruction, or extracardiac anomalies.¹¹⁰

DEFECTS THAT MAY BE PALLIATED OR REPAIRED

Ebstein's Anomaly

ANATOMY

Ebstein's anomaly is a rare defect, occurring in less than 1% of CHD patients. The predominant maldevelopment in this lesion is the inferior displacement of the tricuspid valve into the RV, although Bove and others¹¹³ have emphasized that Ebstein's anomaly is primarily a defect in right ventricular morphology rather than an isolated defect in the tricuspid valve. The anterior leaflet is usually attached in its normal position to the annulus, but the septal and posterior leaflets are displaced toward the ventricle. This effectively divides the RV into two parts: the inlet portion (atrialized RV) and the outlet portion (true or trabeculated RV). The atrialized RV is usually thin and dilated. Similarly, the tricuspid annulus and the right atrium are extremely dilated, and the tricuspid valve is usually regurgitant with a "sail-like" leaflet. There is commonly an ASD present, which results in a right-to-left shunt at the atrial level. Occasionally, there is true anatomic pulmonary atresia or milder forms of RVOT obstruction. A Wolff-Parkinson-White (WPW) syndrome type of accessory pathway with associated pre-excitation is present in 15% of patients.^{109,110}

PATHOPHYSIOLOGY

Right ventricular dysfunction occurs in patients with Ebstein's anomaly because of two basic mechanisms: the inflow obstruction at the level of the atrialized ventricle, which produces ineffective RV filling and contractile dysfunction. Inflow obstruction and tricuspid regurgitation, which is exacerbated by progressive annular dilatation, both produce ineffective RV filling. Contractile dysfunction of the RV is a result of a decrease in the number of myocardial fibers, as well as the discordant contraction of the large atrialized portion.

The lack of forward flow at the right ventricular level may lead to physiologic or functional pulmonary atresia, and the infant is dependent on ductal patency for survival. All systemic venous return must be directed through an ASD to the left atrium, where it can be shunted through the ductus for gas exchange. However, the left ventricular function is usually compromised in infants with severe Ebstein's anomaly as well, because the enormous RV and the to-and-fro flow within the atrialized RV prevent adequate intracardiac mixing. Left ventricular function may also be severely compromised in Ebstein's anomaly because the large RV causes left ventricular compression.

DIAGNOSIS

There is a spectrum of clinical presentation in the infants with Ebstein's anomaly that mirrors the anatomic spectrum of this anomaly. Some infants with less severe forms may present with a mild degree of cyanosis, whereas the onset of clinical symptoms in patients' surviving childhood is gradual, with the average age of diagnosis in the mid-teens.

However, the infant with severe atrialization and pulmonary stenosis will be both cyanotic and acidotic at birth. The chest radiograph may demonstrate the classic appearance, which consists of a globular "wall-to-wall" heart, similar to that seen with pericardial effusion. The ECG may show right bundle-branch block and right axis deviation. WPW syndrome, as mentioned above in Anatomy under Ebstein's Anomaly, is a common finding in these patients. Echocardiography will confirm the diagnosis, as well as provide critical information, including tricuspid valvular function, size of the atrialized portion of the RV, degree of pulmonary stenosis, and the atrial size.^{6,113,114}

The Great Ormond Street Score,¹¹⁵ which consists of the area of the right atrium plus the area of the atrialized portion of the RV divided by the diastolic area of the remaining cardiac chambers, has been proposed as a useful prognostic tool to stratify neonates with Ebstein's. A score greater than unity is essentially 100% mortality. Electrophysiology study with radiofrequency ablation is indicated in patients with evidence of WPW syndrome, or in children with a history of supraventricular tachycardia, undefined wide-complex tachycardia, or syncope.

TREATMENT

Surgery is indicated for symptomatic infants and for older children and adults with arrhythmias, progressive cyanosis, or New York Heart Association class III or IV. However, the operative repair may be different, depending on the patient's age, because older children usually are candidates for a biventricular or one-and-a-half ventricle repair, whereas moderate survival has been reported for neonates, using a procedure that converts the anatomy to a single ventricle physiology, as described by Starnes and coworkers.^{115,116}

The surgical approach in widespread use today for patients surviving infancy was described by Danielson and colleagues in 1992.^{6,114,117} This procedure entails excision of redundant right atrial tissue and patch closure of any associated ASD, plication of the atrialized portion of the ventricle with obliteration of the aneurysmal cavity, posterior tricuspid annuloplasty to narrow the tricuspid annulus, reconstruction of the tricuspid valve if the anterior leaflet is satisfactory, or replacement of the tricuspid valve if necessary.¹¹⁷ If the tricuspid valve is not amenable to reconstruction, valve replacement should be considered. Care must be taken when performing the posterior annuloplasty, or during the conduct of tricuspid valve replacement, to avoid the conduction system, because complete heart block can complicate this procedure. In addition, patients who demonstrated preoperative evidence of pre-excitation should undergo electrophysiologic mapping and ablation.

Neonatal Ebstein's anomaly is a separate entity. Results with surgical correction have been poor, and many neonates are not candidates for operative repair as described in the paragraph above. Surgical options for the symptomatic neonate include palliative procedures, the one-and-a-half ventricle repair, or conversion to single-ventricle physiology.^{1,7,118} Arguably, the most favorable outcomes in symptomatic neonatal Ebstein's or repair in slightly older infants has been using the right ventricular exclusion premise. This technique, known as the *Starnes procedure*,¹¹⁶ uses a fenestrated patch to close the tricuspid valve orifice coupled with systemic-to-pulmonary artery shunt. The patch must be fenestrated to allow decompression of the RV in instances of anatomic pulmonary atresia. Although Knott-Craig and colleagues^{118,119} have described tricuspid valve repair for the full spectrum of neonates and infants with excellent short- and midterm results, these have not been reproduced in other institutions. The one-and-a-half ventricle repair was first described by Billingsly and coworkers as an attempt to achieve a more physiologic "pulsatile" pulmonary circulation in those patients with a hypoplastic or dysplastic RV.¹²⁰ This is accomplished by diverting the superior vena

caval blood directly into the pulmonary arterial system by a bidirectional cavopulmonary shunt while recruiting the RV to propel the inferior vena caval blood directly to the pulmonary arteries via the RVOT. Thus, the hemodynamics of the one-and-a-half ventricle repair are characterized by separate systemic and pulmonary circulations in series. The systemic circulation is fully supported by a systemic ventricle, and the pulmonary circulation is supported by both the bidirectional Glenn shunt and the hypoplastic (pulmonary) ventricle. Proponents of this approach report a decreased right atrial pressure and a decrease in IVC hypertension, which is theorized to be responsible for many of the dreaded complications of the Fontan circulation, including protein-losing encephalopathy, hepatic congestion, atrial arrhythmias, and systemic ventricular failure. In addition, the maintenance of pulsatile pulmonary blood flow, as opposed to continuous laminar flow as in the Fontan circulation, may be advantageous to the pulmonary microcirculation, although it has not been proven in any studies thus far.^{120,121} Certain criteria, most notably an adequate tricuspid valve Z score, as well as the absence of severe pulmonary hypertension or concomitant defects requiring intricate intracardiac repair, should be satisfied before electing the one-and-a-half ventricle approach.^{121,122} Patients who do not fulfill these criteria may be approached with a two-ventricle repair and atrial fenestration, or a Fontan repair.

In the infant with severe Ebstein's anomaly, initial stabilization with prostaglandin to maintain ductal patency, mechanical ventilation, and correction of cyanosis is mandatory. Metabolic acidosis, if present from compromised systemic perfusion, must be aggressively treated with afterload reduction. Many of these infants will improve over 1 to 2 weeks as PVR falls and they are able to improve antegrade flow into the pulmonary circulation through their abnormal RV and tricuspid valve. When stabilization and medical palliation fails, surgical management remains an option, although its success depends on numerous anatomic factors (e.g., adequacy of the tricuspid valve, RV, and pulmonary outflow tract), and surgery for symptomatic neonates with Ebstein's anomaly carries a high risk. Knott-Craig and associates reported three cases where two-ventricle repair was undertaken by subtotal closure of the ASD, extensive resection of the right atrium, and vertical plication of the atrialized chamber.^{117,118} Five-year follow-up revealed all patients to be asymptomatic and in sinus rhythm without medications.

RESULTS

In the neonatal period, the most common postoperative problem, whether after a simple palliative procedure such as a B-T shunt or following a more extensive procedure such as attempted exclusion of the RV, has been low cardiac output. Supraventricular tachycardia also has been problematic postoperatively. Complete heart blockage necessitating pacemaker implantation should be uncommon if the techniques described to avoid suturing between the coronary sinus and the tricuspid annulus are used.

There are few published reports of outcomes, owing to the rarity of this defect. However, based on the natural history of this condition, which is remarkably benign for the majority of older patients, the outlook should be excellent for patients who have survived ASD closure, plication, and tricuspid annuloplasty.^{7,113,117,118}

Transposition of the Great Arteries

ANATOMY

Complete transposition is characterized by connection of the atria to their appropriate ventricles with inappropriate ventriculoarterial connections. Thus, the aorta arises anteriorly from the RV, while the PA arises posteriorly from the LV. Van Praagh and coworkers introduced the term *D-transposition of the great arteries* (D-TGA) to describe this defect, while L-TGA describes a form of corrected transposition where there is concomitant AV discordance.^{123,124}

D-TGA requires an obligatory intracardiac mixing of blood, which usually occurs at both the atrial and the ventricular levels or via a patent ductus. Significant coronary anomalies occur frequently in patients with D-TGA.⁷ The most common pattern, occurring in 68% of cases, is characterized by the left main coronary artery arising from the leftward coronary sinus, giving rise to the left anterior descending and circumflex arteries. The most common variant is for the circumflex coronary artery to arise as a branch from the right coronary artery instead of from the left coronary artery.

PATHOPHYSIOLOGY

D-TGA results in parallel pulmonary and systemic circulations, with patient survival dependent on intracardiac mixing of blood. After birth, both ventricles are relatively noncompliant, and thus, infants initially have higher pulmonary flow owing to the decreased downstream resistance. This causes LA enlargement and a left-to-right shunt via the PFO.

Postnatally, the LV does not hypertrophy because it is not subjected to systemic afterload. The lack of normal extrauterine left ventricular maturation has important implications for the timing of surgical repair because the LV must be converted to the systemic ventricle and be able to function against systemic vascular resistance. If complete repair is done within the first few weeks of life the LV usually adapts easily to systemic resistance since it is conditioned to high intrauterine PVR. After a few weeks of life, the LV that is conditioned to the decrease in pulmonary resistance that occurs when the lungs inflate after birth may have difficulty adapting to systemic vascular resistance without preoperative preparation or postoperative support. Novel techniques of LV "preparation" using a pulmonary arterial band have been used in cases where complete repair has been delayed.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Infants with D-TGA and an intact ventricular septum are usually cyanotic at birth, with an arterial PO₂ between 25 and 40 mmHg. If ductal patency is not maintained, deterioration will be rapid with ensuing metabolic acidosis and death. Conversely, those infants with a coexisting VSD may be only mildly hypoxemic and may come to medical attention after 2 to 3 weeks, when the falling PVR leads to symptoms of CHF.

The ECG will reveal right ventricular hypertrophy, and the chest radiograph will reveal the classic egg-shaped configuration. Definitive diagnosis is made by echocardiography, which reliably demonstrates ventriculoarterial discordance and any associated lesions. Cardiac catheterization is rarely necessary, except in those infants requiring surgery after the neonatal period to assess the suitability of the LV to support the systemic circulation. Limited catheterization, however, is useful for performance of atrial septostomy in those neonates with inadequate intracardiac mixing.

SURGICAL REPAIR

Blalock and Hanlon introduced the first operative intervention for D-TGA with the creation of an atrial septectomy to enhance intracardiac mixing.¹²⁵ This initial procedure was feasible in the precardiopulmonary bypass era, but carried a high mortality rate. Later, Rashkind and Cuaso developed a catheter-based balloon septostomy, which largely obviated the need for open septectomy.⁴² These early palliative maneuvers, however, met with limited success, and it was not until the late 1950s, when Senning and Mustard developed the first "atrial repair," that outcomes improved. The Senning operation consisted of rerouting venous flow at the atrial level by incising and realigning the atrial septum over the pulmonary veins and using the right atrial free wall to create a pulmonary venous baffle (Fig. 20-22).¹²⁶ Although the Mustard repair was similar, it made use of either autologous pericardium or synthetic material to create the interatrial baffle.¹¹⁸ These atrial switch procedures resulted in a physiologic correction, but not an anatomic one, as the systemic circulation is still based on the RV. Still, survival rose to 95% in most centers by using an early balloon septostomy followed by an atrial switch procedure at 3 to 8 months of age.^{126,127}

Despite the improved early survival rates, long-term problems, such as SVC or PVO, baffle leak, arrhythmias, tricuspid valve regurgitation, and right ventricular failure, prompted the development of the arterial switch procedure by Jatene in 1975.¹²⁸ The arterial switch procedure involves the division of the aorta and the PA, posterior translocation of the aorta (Lecompte maneuver), mobilization of the coronary arteries, placement of a pantaloon-shaped pericardial patch, and proper alignment of the coronary arteries on the neo-aorta (Fig. 20-23).

Fig. 20-23.

Cardiac Surgery: State of the Art Review*, Vol. 5, no. 1. Philadelphia: Hanley & Belfus, 1991, p 108. Copyright Elsevier.]

The most important consideration is the timing of surgical repair, because arterial switch should be performed within 2 weeks after birth, before the LV loses its ability to pump against systemic afterload.^{2,4,7} In patients presenting later than 2 weeks, the LV can be retrained with preliminary PA banding and aortopulmonary shunt followed by definitive repair. Alternatively, the unprepared LV can be supported following arterial switch with a mechanical assist device for a few days while it recovers ability to manage systemic pressures. Echocardiography can be used to assess left ventricular performance and guide operative planning in these circumstances.

The subset of patients who present with D-TGA complicated by LVOTO and VSD may not be suitable for an arterial switch operation. The Rastelli operation, first performed in 1968, uses placement of an intracardiac baffle to direct left ventricular blood to the aorta and an extracardiac valved conduit to establish continuity between the RV and the PA, which has led to successful outcomes in these complex patients.¹²⁹

RESULTS

For patients with D-TGA, intact ventricular septum, and VSD, the arterial switch operation provides excellent long-term results with a mortality rate of less than 5%. Operative risk is increased when unfavorable coronary anatomic configurations are present, or when augmentation of the aortic arch is required. The most common complication is supravalvular pulmonary stenosis, occurring 10% of the time, which may require reoperation.^{4,7,130}

Results of the Rastelli operation have improved substantially, with an early mortality rate of 5% in a review.¹³¹ Late mortality rate

results were less favorable because conduit failure requiring reoperation, pacemaker insertion, or relief of LVOTO as frequent.

Double-Outlet Right Ventricle

ANATOMY

Double-outlet right ventricle (DORV) accounts for 5% of CHD and exists when both the aorta and PA arise wholly, or in large part, from the RV. DORV encompasses a spectrum of malformations, because the incomplete shift of the aorta toward the LV is often associated with other abnormalities of cardiac development, such as ventricular looping and infundibular-truncal spiraling.¹³² The vast majority of hearts exhibiting DORV have a concomitant VSD, which varies in its size and spatial association with the great vessels. The VSD is usually nonrestrictive and represents the only outflow for the LV; its location relative to the great vessels dictates the dominant physiology of DORV, which can be analogous to that of a large isolated VSD, tetralogy of Fallot, or D-TGA. In 1972, Lev¹³³ suggested considering DORV as a spectrum of hearts that "pass imperceptibly from tetralogy with VSD with overriding aorta into DORV with subaortic VSD." Thus, Lev and colleagues described a classification scheme for DORV based on the "commitment" of the VSD to either or both great arteries.^{7,133} The VSD can be subaortic, doubly committed, noncommitted, or subpulmonic.

The subaortic type is the most common (50%) and occurs when the VSD is located directly beneath the aortic annulus. Doubly committed VSD (10%) is present when the VSD lies beneath both the aorta and the PA, which are usually side by side in this lesion. The noncommitted VSD (10 to 20%) exists when the VSD is remote from the great vessels. The subset of DORV hearts with the VSD located beneath the pulmonary valve also are classified as the Taussig-Bing syndrome.¹³⁴ This occurs in 30% of cases of DORV with VSD, and it occurs when the aorta rotates more anteriorly, with the PA rotated more posteriorly (Fig. 20-24).

The relationship of the ventricular septal defect (VSD) to the great arteries in double-outlet right ventricle (DORV). **A.** Subaortic VSD without pulmonary stenosis. **B.** Subaortic VSD with pulmonary stenosis. **C.** Subpulmonary VSD (Taussig-Bing malformation). **D.** Doubly committed VSD. **E.** Noncommitted (remote) VSD. **F.** Intact interventricular septum. A = aorta; CS = coronary sinus; D = ventricular septal defect; FO = foramen ovale; IVC = inferior vena cava; PA = pulmonary artery; RV = right ventricle; SVC = superior vena cava.

(Adapted with permission from Zamora R, Moller JH, and Edwards JE: Double-outlet right ventricle. *Chest* 68:672, 1975.)

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with DORV typically present with one of the following three scenarios: (a) those with doubly committed or subaortic VSD present with CHF and a high propensity for pulmonary hypertension, much like those infants with a large single VSD; (b) those with a subaortic VSD and pulmonary stenosis present with cyanosis and hypoxia, much like those infants with tetralogy of Fallot; and (c) those with subpulmonic VSD present with cyanosis much like those with D-TGA, because streaming directs desaturated systemic venous blood to the aorta and oxygenated blood to the PA.¹³² Thus, the three critical factors influencing the clinical presentation and subsequent management of infants with DORV are the size and location of the VSD, the presence or absence of important RVOT obstruction, and the presence of other anomalies (especially associated hypoplasia of left-sided structures sometimes seen with subpulmonary VSD).

Echocardiography is the mainstay of diagnosis, and can also provide valuable information regarding the feasibility of biventricular repair. Specific anatomic questions that should be resolved to assist in surgical planning in addition to those mentioned above include the coronary anatomy (presence of a conal branch or left anterior descending from the right coronary coursing across the conus), the presence of additional muscular VSDs remote from either great vessel, and the distance between the tricuspid and pulmonary valve. Cardiac catheterization is rarely necessary in neonates or infants, except to determine the degree of pulmonary hypertension and to determine the effects of previous palliative procedures on the pulmonary arterial anatomy.

THERAPY

The goals of corrective surgery are to relieve pulmonary stenosis, to provide separate and unobstructed outflow pathways from each ventricle to the correct great vessel, and to achieve separation of the systemic and pulmonary circulations.

Double-Outlet Right Ventricle with Noncommitted Ventricular Septal Defect

The repair of hearts with DORV and noncommitted VSD can be accomplished by constructing an intraventricular tunnel connecting the VSD to the aorta, closing the PA, and placing a valved extracardiac conduit from the RV to the PA. In those patients without pulmonary stenosis who have intractable congestive failure, a PA band can be placed in the first 6 months to control PA overcirculation and prevent the development of pulmonary hypertension.

Those infants with pulmonary stenosis can be managed with a systemic-to-pulmonary shunt followed by biventricular repair as described by Belli and colleagues in 1999, or with a modified Fontan.¹³⁵ There is no consensus on the timing of repair, but literature suggests that repair within the first 6 months is associated with better outcome. However, in cases where an extracardiac valved conduit is necessary, it is better to delay definitive repair until the child is 2 to 3 years of age, because this allows placement of a larger conduit and possibly reduces the number of future obligatory conduit replacements.^{7,132}

Double-Outlet Right Ventricle with Subaortic or Doubly Committed Ventricular Septal Defect Without Pulmonary Stenosis

Patients with CORV with subaortic or doubly committed VSD without pulmonary stenosis can be treated by creating an intracardiac baffle that directs blood from the LV into the aorta. Enlargement of the VSD may be necessary to allow ample room for the baffle; this should be done anterosuperiorly to avoid injury to the conduction system that normally lies inferoposteriorly along the border of the VSD. In addition, other important considerations in constructing the LV outflow tunnel include the prominence of the conal septum, the attachments of the tricuspid valve to the conal septum, and the distance between the tricuspid and pulmonary valves. In some instances, unfavorable anatomy may preclude placement of an adequate intracardiac baffle, necessitating single ventricle repair.

Double-Outlet Right Ventricle with Subaortic or Doubly Committed Ventricular Septal Defect with Pulmonary Stenosis

Repair of DORV with subaortic or doubly committed VSD with pulmonary stenosis is similar to Double-Outlet Right Ventricle with Subaortic or Doubly Committed Ventricular Septal Defect without Pulmonary Stenosis described above except that concomitant RVOT reconstruction must be performed in addition to the intracardiac tunnel. The RVOT augmentation can be accomplished with the placement of a transannular patch or with placement of an extracardiac valved conduit when an anomalous left anterior descending artery precludes use of a patch.

Taussig-Bing Syndrome Without Pulmonary Stenosis

Infants with Taussig-Bing syndrome without pulmonary stenosis are best treated with a balloon septostomy during the neonatal period to improve mixing, followed by VSD closure baffling LV egress to the PA and an arterial switch operation. The Kawashima

procedure,¹³⁶ in which an intraventricular tunnel is used to baffle LV egress directly to the aorta, may alternatively be used when the aorta is more posterior or when there is associated pulmonary stenosis.

Taussig-Bing Syndrome with Pulmonary Stenosis

Taussig-Bing syndrome with pulmonary stenosis may be treated with a variety of techniques, depending on the specific anatomic details and the expertise of the treatment team. A Rastelli-type repair, which involves construction of an intraventricular tunnel through the existing VSD that connects the LV to both great vessels, followed by division of the PA at its origin and insertion of a valved conduit from the RV to the distal PA, can be performed.¹³⁷ Alternatively, a Yasui procedure, which involves baffling the VSD to the PA, creation of a DKS anastomosis between the PA and the aorta with patch augmentation can be accomplished concomitant with placement of a RV-PA conduit.¹³⁸

RESULTS

The results of DORV repairs are generally favorable, especially for the tetralogy-type DORV with subaortic VSD.^{139,140} However, more complex types of DORV, including noncommitted VSD and Taussig-Bing type, still carry important morbidity and mortality.^{125,139,140} Furthermore, repeated interventions for RVOT reconstruction or staged operations for patients triaged to single ventricle pathways pose late hazards for patients surviving initial repair. A recent single institution series evaluated 393 patients with DORV.¹³⁹ The authors found that the need for reintervention approached 37% at 15 years following repair. Arterial switch operation, as opposed to Rastelli-type repair, was associated with an increased risk of early postrepair mortality, but mitigated against the risk of late death. Patients with hypoplastic left-sided structures and a nonsubaortic VSD may fare better with a single-ventricle repair.

Tetralogy of Fallot

ANATOMY

The original description of TOF by Ettienne Louis Fallot,¹⁴¹ as the name implies, included four abnormalities: a large perimembranous VSD adjacent to the tricuspid valve; an overriding aorta; a variable degree of RVOT obstruction, which might include hypoplasia and dysplasia of the pulmonary valve as well as obstruction at the subvalvular and PA level; and right ventricular hypertrophy. More recently, Van Praagh and colleagues¹⁴² pointed out that TOF could be more correctly termed *monology of Fallot*, because the four components are explained by the malposition of the infundibular septum. When the infundibular septum is displaced anteriorly and leftward, the RVOT is narrowed and its anterior displacement results in failure of fusion of the ventricular septum between the arms of the trabecula-septomarginalis (Fig. 20-25).

Pathologic specimen of the heart in a patient with tetralogy of Fallot. The four anatomic components comprising tetralogy of Fallot can be conceptualized as a monology of Fallot, because they can be explained by malposition of the interventricular septum. AO = aorta; RV = right ventricle; RVOT = right ventricular outflow tract; TV = tricuspid valve; VSD = ventricular septal defect.

(From Van Praagh et al,¹⁴² with permission. © Elsevier Ltd.)

The morphology of TOF is markedly heterogeneous and includes an absent pulmonary valve, concomitant AV septal defects, and pulmonary atresia with major aortopulmonary collaterals. The present discussion will focus only on the so-called *classic presentation of TOF* without coexisting intracardiac defects.

Anomalous coronary artery patterns, related to either origin or distribution, have been described in TOF.¹⁴³ However, the most surgically important coronary anomaly occurs when the left anterior descending artery arises as a branch of the right coronary artery. This occurs in approximately 3% of cases of TOF and may preclude placement of a transannular patch, as the left anterior descending coronary artery crosses the RVOT at varying distances from the pulmonary valve annulus.¹⁴⁴

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The initial presentation of a child afflicted with TOF depends on the degree of RVOT obstruction. Those children with cyanosis at birth usually have severe pulmonary annular hypoplasia with concomitant hypoplasia of the peripheral pulmonary arteries. Most children, however, present with mild cyanosis at birth, which then progresses as the right ventricular hypertrophy further compromises the RVOT. Cyanosis usually becomes significant within the first 6 to 12 months of life, and the child may develop characteristic "tet" spells, which are periods of extreme hypoxemia. These spells are characterized by decreased pulmonary blood flow and an increase in aortic flow. They can be triggered by any stimulus that decreases systemic vascular resistance, such as fever or vigorous physical activity. Cyanotic spells increase in severity and frequency as the child grows, and older patients with uncorrected TOF may often squat, which increases peripheral vascular resistance and relieves the cyanosis.

Physical examination in the older patient with TOF may demonstrate clubbing, polycythemia, or brain abscesses. Chest radiography will demonstrate a boot-shaped heart, and ECG will show the normal pattern of right ventricular hypertrophy. Echocardiography confirms the diagnosis because it demonstrates the position and nature of the VSD, defines the character of the RVOT obstruction, and often visualizes the branch pulmonary arteries and the proximal coronary arteries. Cardiac catheterization is rarely necessary and is actually risky in TOF because it can create spasm of the RVOT muscle and result in a hypercyanotic episode (tet spell).

Occasionally, aortography is necessary to delineate the coronary artery anatomy.

TREATMENT

John Deanfield¹⁴⁵ said ". . . long follow-up inevitably means surgery in an earlier era: More recent surgery, at a younger age, with better preoperative, operative, and postoperative care, will improve long-term results. Data from the former (earlier) era will be overly pessimistic." This statement is particularly pertinent as surgical correction of TOF has evolved from a staged approach of antecedent palliation in infancy followed by intracardiac repair to primary repair during the first few months of life without prior palliative surgery.

However, systemic-to-pulmonary shunts, generally a B-T shunt, may still be preferred with an unstable neonate younger than 6 months of age, when an extracardiac conduit is required because of an anomalous left anterior descending coronary artery, or when pulmonary atresia, significant branch PA hypoplasia, or severe noncardiac anomalies coexist with TOF.

Traditionally, TOF was repaired through a right ventriculotomy, providing excellent exposure for closure of the VSD and relief of the RVOT obstruction, but concerns that the resultant scar would significantly impair right ventricular function or lead to lethal arrhythmias led to the development of a transatrial approach. Transatrial repair, except in cases when the presence of diffuse RVOT hypoplasia requires insertion of a transannular patch, is now being increasingly advocated by many, although its superiority has not been conclusively demonstrated.¹⁴⁶

The operative technique involves the use of CPB. All existing systemic-to-pulmonary arterial shunts, as well as the ductus arteriosus, are ligated. A right atriotomy is then made, and the anatomy of the VSD and the RVOT are assessed by retracting the tricuspid valve (Fig. 20-26). The outflow tract obstruction is relieved by resecting the offending portion of the infundibular septum as well as any muscle trabeculations. If necessary, a pulmonary valvotomy or, alternatively, a longitudinal incision in the main PA can be performed to improve exposure. The diameter of the pulmonary valve annulus is assessed by inserting Hegar dilators across the outflow tract; if the PA/AA diameter is less than 0.5, or the estimated RV/LV pressure is greater than 0.7, a transannular patch is inserted.^{21,147} Patch closure of the VSD is then accomplished, taking care when placing sutures along the posteroinferior portion to avoid the conduction system.

The anatomy from the perspective of the right atrial (RA) approach, shown as if the right atrial free wall and tricuspid valve were translucent. The free edge of the tricuspid leaflets is shown by dashed lines. **A.** The difference from the right ventricular (RV) perspective is in the apparent position of the parietal extension. From the RA perspective the surgeon looks *beneath* this, as the parietal extension arches *over* the right ventricular outflow tract. **B.** The same perspective without the outline of the tricuspid valve leaflets. The parietal extension is transected at its origin from the infundibular septum, dissected up toward the free wall, and amputated at the free wall. **C.** A pledgetted mattress suture is placed from the RA side through the base of the commissural tissue between septal and tricuspid leaflets and through the patch. **D.** The suturing is continued onto the parietal extension and infundibular septum, visualizing and staying close to the aortic valve leaflets to avoid leaving a hole between muscular bands. When working from the RA, it is particularly important to stay close to the aortic valve leaflets in the direction of the septum to avoid narrowing the RV outflow tract. **E.** The repair of the ventricular septal defect is completed. Note that the suture line is away from the bundle of His and its branches, except where it crosses the right bundle branch anteroinferiorly. ant. = anterior; ML = mitral leaflet; post. = posterior; TV = tricuspid valve.

RESULTS

Operative mortality for primary repair of TOF in infancy is less than 5% in most series.^{4,7,146,148} Previously reported risk factors such as transannular patch insertion or younger age at time of repair have been eliminated secondary to improved intraoperative and postoperative care.

A major complication of repaired TOF is the development of pulmonary insufficiency, which subjects the RV to the adverse effects of acute and chronic volume overload. This is especially problematic if residual lesions such as a VSD or peripheral pulmonary stenosis exist. Pulmonary valve regurgitation after repair of TOF is relatively well tolerated in the short term, partly because the hypertrophied RV usually adapts to the altered hemodynamic load.^{139,149} The detrimental effects of chronic pulmonary valve regurgitation are, however, numerous, and include progressive right ventricular dilatation and failure, tricuspid valve regurgitation, exercise intolerance, arrhythmia, and sudden death. Mechanoelectrical interaction, by which a dilated RV provides the substrate for electrical instability, might underlie the propensity toward ventricular arrhythmia.¹⁵⁰ In support of this contention, Gatzoulis and colleagues^{140,150} found that the risk of symptomatic arrhythmia was high in patients with marked right ventricular enlargement and QRS prolongation on resting ECG of more than 180 milliseconds. Karamlou and associates have shown that similar structural and hemodynamic abnormalities, including a larger right atrial volume and right ventricular chamber size, are also related to atrial arrhythmias in patients following TOF repair.¹⁵¹ The authors found that prolongation of the QRS duration, beyond a threshold of 160 milliseconds, increased the risk of atrial arrhythmias.¹⁵¹ Together, these data show that a similar mechanism could be responsible for both atrial and ventricular arrhythmias after repair in TOF patients.

When significant deterioration of ventricular function occurs, insertion of a pulmonary valve may be required, although this is rarely necessary in infants. Unfortunately, there are no universal criteria establishing the timing of pulmonary valve replacement, though dilation of the RV, prolongation of the QRS duration beyond 180 milliseconds, important atrial arrhythmias, or impaired ventricular function are widely used.

Arrhythmias are potentially the most serious late complication following TOF repair. In a multicenter cohort of 793 patients studied by Gatzoulis and colleagues,¹⁵⁰ a steady increase was documented in the prevalence of ventricular and atrial tachyarrhythmia and sudden cardiac death in the first 5 to 10 years following intracardiac repair. Clinical events were reported in 12% of patients at 35 years after repair. Prevalence of atrial arrhythmias from other studies, however, ranges from 1 to 11%,^{140,150} which is a reflection of the strong time dependence of arrhythmia onset.

Underlying causes of arrhythmia following repair are complex and multifactorial, resulting in poorly defined optimum screening and treatment algorithms. Older repair age has been associated with an increased frequency of both atrial and ventricular arrhythmias. Impaired ventricular function secondary to a protracted period of cyanosis before repair might contribute to the propensity for arrhythmia in older patients.

Ventricular Septal Defect

ANATOMY

VSD refers to a hole between the LVs and RVs. These defects are common, comprising 20 to 30% of all cases of CHD, and may occur as an isolated lesion or as part of a more complex malformation.¹⁵² VSDs vary in size from 3 to 4 mm to more than 3 cm, and are classified into four types based on their location in the ventricular septum: perimembranous, AV canal, outlet or supracristal, and muscular (Fig. 20-27).

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Classic anatomic types of ventricular septal defect (VSD). **A.** Type I (conal, infundibular, supracristal, subarterial) VSD. **B.** Type II or perimembranous VSD. **C.** Type III VSD (atrioventricular canal type or inlet septum type). **D.** Type IV VSD (single or multiple).

[Reproduced with permission from Ventricular septal defect, in Mavroudis C, Backer CL (eds): *Pediatric Cardiac Surgery*, 2nd ed. St. Louis: Mosby, 1994, p 70. Copyright Elsevier.]

Perimembranous VSDs are the most common type requiring surgical intervention, constituting approximately 80% of cases.¹⁵³ These defects involve the membranous septum and include the malalignment defects seen in TOF. In rare instances, the anterior and septal leaflets of the tricuspid valve adhere to the edges of the perimembranous defect, forming a channel between the LV and the right atrium. These defects result in a large left-to-right shunt owing to the large pressure differential between the two chambers.

AV canal defects, also known as *inlet defects*, occur when part or all of the septum of the AV canal is absent. The VSD lies beneath

the tricuspid valve and is limited upstream by the tricuspid annulus, without intervening muscle.

The supracristal or outlet VSD results from a defect within the conal septum. Characteristically, these defects are limited upstream by the pulmonary valve and are otherwise surrounded by the muscle of the infundibular septum.

Muscular VSDs are the most common type, and may lie in four locations: anterior, midventricular, posterior, or apical. These are surrounded by muscle, and can occur anywhere along the trabecular portion of the septum. The rare "Swiss-cheese" type of muscular VSD consists of multiple communications between the right and LVs, complicating operative repair.

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION

The size of the VSD determines the initial pathophysiology of the disease. Large VSDs are classified as nonrestrictive, and are at least equal in diameter to the aortic annulus. These defects allow free flow of blood from the LV to the RV, elevating right ventricular pressures to the same level as systemic pressure. Consequently, the pulmonary-to-systemic flow ratio ($Q_p:Q_s$) is inversely dependent on the ratio of PVR to systemic vascular resistance. Nonrestrictive VSDs produce a large increase in pulmonary blood flow, and the afflicted infant will present with symptoms of CHF. However, if untreated, these defects will cause pulmonary hypertension with a corresponding increase in PVR. This will lead to a reversal of flow (a right-to-left shunt), which is known as Eisenmenger's syndrome.

Small restrictive VSDs offer significant resistance to the passage of blood across the defect, and therefore, right ventricular pressure is either normal or only minimally elevated and $Q_p:Q_s$ rarely exceeds 1.5.^{4,7} These defects are generally asymptomatic because there are few physiologic consequences. However, there is a long-term risk of endocarditis, because endocardial damage from the jet of blood through the defect may serve as a possible nidus for colonization.

DIAGNOSIS

The child with a large VSD will present with severe CHF and frequent respiratory tract infections. Those children with Eisenmenger's syndrome may be deceptively asymptomatic until frank cyanosis develops.

The chest radiograph will show cardiomegaly and pulmonary overcirculation and the ECG will show signs of left ventricular or biventricular hypertrophy. Echocardiography provides definitive diagnosis, and can estimate the degree of shunting as well as pulmonary arterial pressures. Cardiac catheterization has largely been supplanted by echocardiography, except in older children where measurement of pulmonary resistance is necessary before recommending closure of the defect.

TREATMENT

VSDs may close or narrow spontaneously, and the probability of closure is inversely related to the age at which the defect is observed. Thus, infants at 1 month of age have an 80% incidence of spontaneous closure, whereas a child at 12 months of age has only a 25% chance of closure.¹⁵³ This has an important impact on operative decision making, because a small or moderate-size VSD may be observed for a period of time in the absence of symptoms. Large defects and those in severely symptomatic neonates should be repaired during infancy to relieve symptoms and because irreversible changes in PVR may develop during the first year of life.

Repair of isolated VSDs requires the use of CPB with moderate hypothermia and cardioplegic arrest. The right atrial approach is preferable for most defects, except apical muscular defects, which often require a left ventriculotomy for adequate exposure. Supracristal defects may alternatively be exposed via a longitudinal incision in the right ventricular outflow tract, below the pulmonary valve. Regardless of the type of defect present, a right atrial approach can be used initially to inspect the anatomy, as this may be abandoned should it offer inadequate exposure for repair. After careful inspection of the heart for any associated malformations, a patch repair is used, taking care to avoid the conduction system (Fig. 20-28). Routine use of intraoperative transesophageal echocardiography should be used to assess for any residual defects.

Fig. 20-28.

A. Right atrial incision and exposure of perimembranous ventricular septal defect (VSD) in the region of the tricuspid anterosseptal commissure. Stay sutures have been placed to slightly evert the atrial wall. Note that initially, the superior edge of this typical perimembranous defect is not visible. The atrioventricular node is in the muscular portion of the atrioventricular septum, just on the atrial side of the commissure between the tricuspid septal and anterior leaflets. The bundle of His thus penetrates at the posterior angle of the VSD, where it is vulnerable to injury. **B** and **C.** The repair of the perimembranous VSD is completed with use of a slightly oversized Dacron patch, taking care to place stitches 3 to 5 mm away from the edge of the defect itself to avoid injury to the conduction system.

Successful percutaneous device closure of VSDs using the Amplatzer muscular VSD has been described.¹⁵⁴ The device has

demonstrated a 100% closure rate in a small series of patients with isolated or residual VSDs, or as a collaborative treatment strategy for the VSD component in more complex congenital lesions. Proponents of device closure argue that their use can decrease the complexity of surgical repair, avoid reoperation for a small residual lesion, or avoid the need for a ventriculotomy.

Multiple or "Swiss-cheese" VSDs represent a special case, and many cannot be repaired during infancy. In those patients in whom definitive VSD closure cannot be accomplished, temporary placement of a PA band can be used to control pulmonary flow. This allows time for spontaneous closure of many of the smaller defects, thus simplifying surgical repair.

Some centers, however, have advocated early definitive repair of the Swiss-cheese septum, by using oversize patches, fibrin glue, and combined intraoperative device closure, as well as techniques to complete the repair transatrially.¹⁵⁵ At the University of California, San Francisco, 69% of patients with multiple VSDs underwent single-stage correction, and the repaired group had improved outcome as compared to the palliated group.¹⁵⁴

RESULTS

Even in very small infants, closure of VSDs can be safely performed with hospital mortality near 0%.^{4,7,155,156} The main risk factor remains the presence of other associated lesions, especially when present in symptomatic neonates with large VSDs.

Atrioventricular Canal Defects

ANATOMY

AV canal defects result from failure of fusion of the endocardial cushions in the central portion of the heart, causing a lesion that involves the atrial and the ventricular septum, as well as the anterior mitral and septal tricuspid valve leaflets. Defects involving primarily the atrial septum are known as *partial AV canal defects* and frequently occur in conjunction with a cleft anterior mitral leaflet. Complete AV canal defects have a combined deficiency of the atrial and ventricular septum associated with a common AV orifice rather than separate tricuspid and mitral valves. The common AV valve generally has five leaflets: three lateral (free wall) and two bridging (septal) leaflets. The defect in the ventricular septum can lie either between the two bridging leaflets, or beneath them. The relationship between the septal defect and the anterior bridging leaflet forms the basis of the Rastelli classification for complete AV canal defects (Fig. 20-29).¹⁵⁷

PATHOPHYSIOLOGY AND DIAGNOSIS

Partial AV canal defects, in the absence of AV valvular regurgitation, frequently resemble isolated ASDs. Left-to-right shunting predominates as long as PVR remains low. However, 40% of patients with partial AV canal defects have moderate-to-severe valve incompetence, and progressive heart failure occurs early in this patient population.¹⁵⁸ Complete AV canal defects produce more severe pathophysiologic changes, because the large intracardiac communication and significant AV valve regurgitation contribute to ventricular volume loading and pulmonary hypertension. Children with complete AV canal defects develop signs of CHF within the first few months of life.

Physical examination may reveal a right ventricular heave and a systolic murmur. Children may also present with endocarditis or paradoxical emboli as a result of the intracardiac communication. Chest radiography will be consistent with CHF, and the ECG demonstrates right ventricular hypertrophy with a prolonged PR interval.

Two-dimensional echocardiography with color-flow mapping is confirmatory, but cardiac catheterization can be used to define the status of the pulmonary vasculature, with a PVR greater than 12 Woods units indicating inoperability.¹⁵⁸

TREATMENT

The management of patients with AV canal defects can be especially challenging. Timing of operation is individualized. Those patients with partial defects can be electively repaired between 2 and 5 years of age, whereas complete AV canal defects should be repaired within the first year of life to prevent irreversible changes in the pulmonary circulation. Complete repair in infancy should be accomplished, with palliative procedures such as PA banding reserved for only those infants with other complex lesions, or who are too ill to tolerate CPB.

The operative technique requires the use of either continuous hypothermic CPB or, for small infants, deep hypothermic circulatory arrest. The heart is initially approached through an oblique right atriotomy, and the anatomy is carefully observed. In the case of a partial AV canal, the cleft in the mitral valve is repaired with interrupted sutures and the ASD is closed with a pericardial patch.¹⁵⁹ Complete AV canal defects are repaired by patch closure of the VSD, separating the common AV valve into tricuspid and mitral components and suspending the neovalves from the top of the VSD patch, and closing the ASD.

RESULTS

Partial AV canal defects have an excellent outcome, with a mortality rate of 0 to 2% in most series.¹⁵⁷ Complete AV canal defects are associated with a poorer prognosis, with an operative mortality of 3 to 13%.

The most frequently encountered postoperative problems are complete heart block (1 to 2%), right bundle-branch block (22%), arrhythmias (11%), RVOT obstruction (11%), and severe mitral regurgitation (13 to 24%).¹⁵⁷ The increasing use of intraoperative transesophageal echocardiography may positively influence outcomes, as the adequacy of repair can be assessed and treated without need for subsequent reoperation.^{157,158}

Interrupted Aortic Arch

ANATOMY

IAA is a rare defect, comprising approximately 1% of all cases of CHD.^{7,159} It is defined as an absence of luminal continuity between the ascending and descending aorta, and does not occur as an isolated defect in most cases, because a VSD or PDA is usually present. IAA is classified based on the location of the interruption (Fig. 20-30).

Fig. 20-30.

Anatomic types of interrupted aortic arch. **A.** Interruption distal to the left subclavian artery. **B.** Interruption between the left subclavian and left carotid arteries. **C.** Interruption between the left carotid and innominate arteries. Ao = aorta; IA = innominate artery; LPA, MPA, RPA = left, main, and right pulmonary arteries; LC = left carotid artery; LS = left subclavian artery; PDA = patent ductus arteriosus.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Infants with IAA have ductal-dependent systemic blood flow and will develop profound metabolic acidosis and hemodynamic collapse upon ductal closure. In the rare instance of failed ductal closure, the diagnosis may be missed during infancy, and the child will present with symptoms of CHF from a persistent left-to-right shunt.

Once definitive diagnosis is made in infants, usually with echocardiography, preparations are made for operative intervention, and PGE1 is infused to maintain ductal patency and correct acidosis. The infant's hemodynamic status should be optimized with mechanical ventilation and inotropic support. An effort should be made to increase PVR by decreasing the fractional inspired oxygen and avoiding hyperventilation, because this will preferentially direct blood into the systemic circulation.

TREATMENT

Initial strategies for the management of IAA involved palliation through a left thoracotomy by using one of the arch vessels as a conduit to restore aortic continuity. PA banding can be simultaneously performed to limit left-to-right shunting, because it is not feasible to repair the VSD or other intracardiac communications with this approach.

However, complete surgical repair in infants with IAA is now preferable. The operative technique involves use of a median sternotomy and CPB with short periods of circulatory arrest. Aortic arch reconstruction can be accomplished with either direct anastomosis or patch aortoplasty followed by closure of the VSD.¹⁵⁹

In certain cases, the defect will involve hypoplasia of the left heart, precluding attempts at definitive repair. These infants should be managed with a Norwood procedure followed by a Fontan repair.

RESULTS

Outcomes in infants with IAA have improved substantially over the last decades as a result of improved perioperative care. Operative mortality is now less than 10% in most series.¹⁵⁷ Some authors advocate the use of patch augmentation of the aorta to ensure adequate relief of LVOTO and to diminish anastomotic tension, thus reducing the subsequent risk of restenosis and tracheobronchial compression.^{7,157,160}

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 21. Acquired Heart Disease >

KEY POINTS

1. The long-term outcomes of coronary artery bypass graft surgery remain superior to coronary stenting for patients with left main disease and multivessel coronary artery disease in diabetic patients.
2. Congestive heart failure is reaching epidemic proportions. Effective surgical strategies exist for these patients, ranging from valve repair to ventricular assist devices.
3. Mitral valve repair rather than replacement affords superior long-term benefits to patients with degenerative mitral valve disease.
4. Aortic valve replacement is routinely and safely performed in patients over 80 years old.

CARDIAC ASSESSMENT

Clinical Evaluation

The importance of the history and physical examination when evaluating a patient with acquired heart disease for potential surgery cannot be overemphasized. It is imperative that the surgeon be well aware of the functional status of the patient and the clinical relevance of each symptom, because surgical decisions depend upon the accurate assessment of the significance of a particular pathologic finding. Likewise, as the number of diagnostic tests continues to increase, appropriate sequencing of the diagnostic work-up requires a clinical perspective that is obtained through the history and physical examination. Associated risk factors and coexisting conditions must be identified, as they significantly influence a patient's operative risk for cardiac or noncardiac surgery. Furthermore, the operative strategy is affected by specific physical findings and important history, such as previous cardiac or thoracic surgery, peripheral vascular occlusive disease, or prior saphenous vein stripping. The safe surgeon is one who can integrate clinical evidence and diagnostic information to establish a scientifically based operative plan.

SYMPTOMS

The classic symptoms of heart disease are fatigue, angina, dyspnea, edema, hemoptysis, palpitations, and syncope, as outlined by Braunwald.¹ When a patient describes or complains of any of these symptoms, the clinical scenario leading to it must be explored in detail, including symptom intensity, duration, provocation, and conditions that lead to relief. The initial goal is to determine whether a symptom is cardiac or noncardiac in origin, as well as to determine the clinical significance of the complaint. An important feature of cardiac disease is that myocardial function or coronary blood supply that may be adequate at rest may become completely inadequate with exercise or exertion. Thus, chest pain or dyspnea that occurs primarily during exertion is frequently cardiac in origin, while symptoms that occur at rest often are not.

In addition to evaluating the patient's primary symptoms, the history should include a family history, past medical history [prior surgery or myocardial infarction (MI), concomitant hypertension, diabetes, and other associated diseases], personal

habits (smoking, alcohol or drug use), functional capacity, and a detailed review of systems. After a careful assessment of a patient's symptoms, appropriate diagnostic studies are ordered and interpreted. The classic symptoms are reviewed in detail below.

Easy fatigability is a frequent but nonspecific symptom of cardiac disease that can arise from many causes. In some patients, this symptom reflects a generalized decrease in cardiac output or low-grade heart failure. The significance of subjective easy fatigability is vague and nonspecific.

Angina pectoris is the hallmark of myocardial ischemia secondary to coronary artery disease (CAD), although a variety of other conditions can produce chest pain, and the clinician must determine if chest pain is of cardiac or noncardiac origin. Classic angina is precordial pain described as squeezing, heavy, or burning in nature, lasting from 2 to 10 minutes. The pain is usually substernal, radiating into the left shoulder and arm, but occasionally occurs in the midepigastrium, jaw, right arm, or midscapular region. Angina usually is provoked by exercise, emotion, sexual activity, or eating, and is relieved by rest or nitroglycerin. Angina is present in its classic form in 75% of patients with coronary disease, while atypical symptoms occur in 25% of patients and more frequently in women. A small but significant number of patients have "silent" ischemia, typically occurring in diabetics. Angina also is a classic symptom of aortic stenosis, occurring secondary to a combination of left ventricular (LV) hypertrophy, increased intracardiac pressure, increased ventricular wall tension (leading to higher oxygen requirements), and decreased cardiac output. This combination results in a myocardial oxygen supply-demand mismatch with resultant ischemia and angina.

Noncardiac causes of chest pain that may be confused with angina include gastroesophageal reflux disease, esophageal spasm, musculoskeletal pain, peptic ulcer disease, pulmonary embolus, costochondritis (Tietze's syndrome), biliary tract disease, pleuritis, pulmonary hypertension, pericarditis, and aortic dissection.

The physiologic change in most patients with heart failure is a rise in LV end-diastolic pressure, followed by cardiac enlargement. While Starling's law describes the compensatory mechanism of the heart of increased work in response to increased diastolic fiber length, symptoms develop as this compensatory mechanism fails, resulting in a progressive rise in LV end-diastolic pressure. Because this development is eventually damaging to the myocardial muscle and may ultimately result in a dilated cardiomyopathy, data suggest that surgery should be considered for many patients before the development of dyspnea or congestive heart failure (CHF). Nevertheless, exertional dyspnea is often the first sign of LV dysfunction, and should prompt an evaluation for an underlying cardiac cause.

Dyspnea may appear as an early sign in patients with mitral stenosis due to restriction of flow from the left atrium into the left ventricle. However, with other forms of heart disease, dyspnea is a late sign, as it develops only after the left ventricle has failed and the end-diastolic pressure rises significantly. Dyspnea associated with mitral insufficiency, aortic valve disease, or coronary disease represents relatively advanced pathophysiology.

A number of other respiratory symptoms represent different degrees of pulmonary congestion. These include orthopnea, paroxysmal nocturnal dyspnea, cough, hemoptysis, and pulmonary edema. Occasionally, dyspnea represents an "angina equivalent," occurring secondary to ischemia-related LV dysfunction. This finding is more common in women and in diabetic patients.

Left-sided heart failure may result in fluid retention and pulmonary congestion, subsequently leading to pulmonary hypertension and progressive right-sided heart failure. A history of exertional dyspnea with associated edema is frequently due to heart failure. In contrast, primary right heart failure may result from right ventricular injury and dysfunction or from

primary tricuspid valve (TV) disease. Right atrial pressure, normally <5 to 8 mmHg, may be elevated to 15 to 30 mmHg or higher. Retention of >7 to 10 lb of fluid results in visible lower extremity edema, usually equal bilaterally. Additionally, jugular venous distention and hepatomegaly develop with severe right heart failure. In chronic, severe heart failure, generalized fluid retention may be quite severe, accompanied by ascites and massive hepatomegaly.

Palpitations are secondary to rapid, forceful, ectopic, or irregular heartbeats. Palpitations frequently are innocuous, but occasionally represent significant or potentially life-threatening arrhythmias. The underlying cardiac arrhythmia may range from premature atrial or ventricular contractions to atrial fibrillation, atrial flutter, paroxysmal atrial or junctional tachycardia, or sustained ventricular tachycardia.

Atrial fibrillation is one of the most common causes of palpitations. It is a common arrhythmia in patients with mitral stenosis, and results from left atrial enlargement that evolves from sustained elevation in left atrial pressure. With other forms of heart disease, arrhythmias are less common and occur sporadically. In general, arrhythmias are more frequent in older patients, resulting from intrinsic disease in sinus node (sick sinus syndrome) or disease of the atrioventricular (AV) conduction mechanism resulting in complete or intermittent heart block.

Severe, life-threatening forms of ventricular tachycardia or ventricular fibrillation may occur in any patient with ischemic disease, either from ongoing ischemia or from prior infarction and myocardial scarring.

Syncope, or sudden loss of consciousness, is usually a result of sudden decreased perfusion of the brain. The differential diagnosis includes: (a) third-degree heart block with bradycardia or asystole, (b) malignant ventricular tachyarrhythmias or ventricular fibrillation, (c) aortic stenosis, (d) hypertrophic cardiomyopathy, (e) carotid artery disease, (f) seizure disorders, and (g) vasovagal reaction. Any episode of syncope must be evaluated thoroughly, as many of these conditions can result in sudden death.

FUNCTIONAL DISABILITY AND ANGINA

An important part of the history is the assessment of the patient's overall cardiac functional disability, which is a good approximation of the severity of the patient's underlying disease. The New York Heart Association (NYHA) has developed a classification of patients with heart disease based on symptoms and functional disability (Table 21-1). The NYHA classification has been extremely useful in evaluating a patient's severity of disability, in comparing treatment regimens, and in predicting operative risk.

Table 21-1 New York Heart Association Functional Classification
Class I: Patients with cardiac disease but without resulting limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or angina pain.
Class II: Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or angina pain.
Class III: Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.
Class IV: Patients with cardiac disease resulting in an inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

The NYHA functional classification system is widely used and adequate for the majority of patients. However, when a more precise functional analysis is necessary, the specific activity scale proposed by Goldman and based upon the estimated

metabolic cost of various activities is used. A different grading system for patients with ischemic disease, developed by the Canadian Cardiovascular Society (CCS), is used to assess the severity of angina (Table 21-2).

Table 21-2 Canadian Cardiovascular Society Angina Classification
Class I: Ordinary physical activity, such as walking or climbing stairs, does not cause angina. Angina may occur with strenuous or rapid or prolonged exertion at work or recreation.
Class II: There is slight limitation of ordinary activity. Angina may occur with walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals or in the cold, in the wind, or under emotional stress, or walking more than two blocks on the level, or climbing more than one flight of stairs under normal conditions at a normal pace.
Class III: There is marked limitation of ordinary physical activity. Angina may occur after walking one or more blocks on the level or climbing one flight of stairs under normal conditions at a normal pace.
Class IV: There is inability to carry on any physical activity without discomfort; angina may be present at rest.

Cardiac Risk Assessment in General Surgery Patients

Cardiac risk stratification for patients undergoing noncardiac surgery is a critical part of the preoperative evaluation of the general surgery patient. The joint American College of Cardiology/American Heart Association task force, chaired by Eagle, recently reported guidelines and recommendations, which are summarized in this section. In general, the preoperative cardiovascular evaluation involves an assessment of clinical markers, the patient's underlying functional capacity, and various surgery-specific risk factors.

The *clinical markers* that predict an increased risk of a cardiac event during noncardiac surgery are divided into three grades. *Major* predictors include unstable coronary syndromes, including acute or recent MI and unstable angina (CCS class III or IV), decompensated heart failure (NYHA class IV), and significant arrhythmias and severe valvular disease. *Intermediate* predictors are mild angina (CCS class I or II), old MI, compensated heart failure (NYHA class II and III), diabetes, and renal insufficiency. *Mild* predictors are advanced age, uncontrolled systemic hypertension, irregular rhythm, prior stroke, abnormal electrocardiogram (ECG), and mild functional disability.

Specific *surgical risk factors or procedures* expose the patient to greater or lesser risk of a cardiovascular event. *High-risk* procedures include emergent, major procedures in the elderly; major vascular procedures (e.g., thoracic, abdominal aortic, or peripheral vascular); and long general surgical procedures with anticipated large fluid shifts and/or blood loss (e.g., pancreatectomy, hepatic resection, or abdominoperineal resection). *Intermediate-risk* procedures include any intraperitoneal or intrathoracic operation, carotid endarterectomy, and orthopedic, prostate, and head and neck procedures. *Low-risk* procedures include endoscopic, breast, cataract, and superficial operations.

Based upon the clinical markers, the functional class of the patient, and the proposed surgical procedure, the patient is assigned a high, intermediate, or low cardiac risk, and then managed appropriately. In some patients, further risk stratification is required, such as patients with intermediate cardiac risk factors who are undergoing a high-risk surgical procedure. These patients should undergo exercise stress testing or provocative testing (dipyridamole thallium or dobutamine stress echocardiography) before an operation. In patients who are considered high cardiac risk due to clinical markers or by virtue of noninvasive testing, coronary angiography may be recommended before surgery. CAD is then managed according to the classic indications. In patients who are thought to be low or moderate cardiac risk, medical management alone is sufficient.

Due to the common atherosclerotic etiology and the close association between clinically relevant CAD and peripheral vascular

disease (PVD), patients undergoing major vascular surgery should be screened closely, either by history or provocative stress testing. Those patients with symptoms suggestive of ischemia, with a decreased ejection fraction due to prior MI, or with provocative stress testing suggestive of ischemia should undergo coronary angiography or a newer cardiac computed tomography (CT) modality before vascular surgery. Any significant underlying coronary disease should be aggressively treated, either with intensive perioperative management or with coronary revascularization before surgery, using standard indications. This aggressive screening approach, followed by appropriate intervention in patients with significant CAD, has greatly lowered the operative risk of patients undergoing major vascular surgery.

Diagnostic Studies

ELECTROCARDIOGRAM AND CHEST X-RAY

ECG and the chest x-ray are two classic diagnostic studies. The ECG is used to detect rhythm disturbances, heart block, atrial or ventricular hypertrophy, ventricular strain, myocardial ischemia, and MI. Standard posterior-anterior and lateral chest x-rays are excellent for determining cardiac enlargement and pulmonary congestion, as well as for assessing associated pulmonary pathology.

ECHOCARDIOGRAPHY

Echocardiography has become the most widely used cardiac diagnostic study. This test incorporates the use of ultrasound and reflected acoustic waves for cardiac imaging. Blood flow velocities are assigned colors to help visually evaluate them. This information is superimposed onto the two-dimensional image, giving a graphic illustration of the directional intracardiac flow pattern and an assessment of valvular insufficiency.

Standard transthoracic echocardiography has become an excellent noninvasive screening test to evaluate cardiac size, wall motion, and valvular pathology. Corrective operation for valvular disease is now frequently performed on younger patients based on this study alone.

Transesophageal echocardiography (TEE), performed by the placement of a two-dimensional transducer in a flexible endoscope, improves the image quality by minimizing scatter from the chest wall. This test, although invasive, is particularly useful in the evaluation of valvular disease, and may elucidate exact leaflet pathology. Additionally, atherosclerotic disease of the aortic arch and descending aorta can be accurately assessed with this study. Moreover, TEE studies are used when more precise imaging is required or when the diagnosis is uncertain after a transthoracic study.

Dobutamine stress echocardiography has evolved as an important noninvasive provocative study. This study is used to assess cardiac wall motion in response to inotropic stimulation, as wall motion abnormalities reflect underlying ischemia. Several reports have documented the accuracy of dobutamine stress echocardiography in identifying patients with significant CAD. The predictive value of a positive test for MI or death after noncardiac surgery is approximately 10%, while 20 to 40% will have some cardiac event. A negative test is 93 to 100% predictive that no cardiac event will occur.

RADIONUCLIDE STUDIES

Currently the most widely used myocardial perfusion screening study is the thallium scan, which uses the nuclide thallium-201. Initial uptake of thallium-201 into myocardial cells is dependent upon myocardial perfusion, while delayed uptake depends on myocardial viability. Thus, reversible defects occur in underperfused, ischemic, but viable zones, while fixed defects occur in areas of infarction. Fixed defects on the thallium scan suggest nonviable myocardium and may be of prognostic value.

The exercise thallium test is widely used to identify inducible areas of ischemia and is 95% sensitive in detecting multivessel coronary disease. This is the best overall test to detect myocardial ischemia, but requires the patient to exercise on the treadmill. The study also gives excellent, specific information about the patient's cardiac functional status.

The dipyridamole thallium study is a provocative study using IV dipyridamole, which induces vasodilation and consequently unmasks myocardial ischemia in response to stress. This is the most widely used provocative study for risk stratification for patients who cannot exercise. In patients undergoing noncardiac surgery, the predictive value of a positive dipyridamole thallium study is 5 to 20% for MI or death, while a negative study is 99 to 100% predictive that a cardiac event will not occur. It is, therefore, a very effective screening study for moderate- to high-risk patients who require a general surgery procedure.

Global myocardial function is frequently evaluated by a gated blood pool scan (equilibrium radionuclide angiography) using technetium-99m. This study can detect areas of hypokinesis and measure left ventricular ejection fraction (LVEF), end-systolic volume, and end-diastolic volume. An exercise-gated blood pool scan is an excellent method to assess a patient's global cardiac response to stress. Normally, the ejection fraction will increase with exercise, but with significant CAD or valvular disease, the ejection fraction may remain unchanged or even decrease. The resting-gated blood pool scan determines the degree of prior cardiac injury and assesses baseline cardiac function, whereas the exercise-gated blood pool scan assesses the functional response to stress.

POSITRON EMISSION TOMOGRAPHY SCAN

The positron emission tomography (PET) scan is a radionuclide imaging technique used to assess myocardial viability in underperfused areas of the heart. The technique may be more sensitive than the thallium scan for this purpose.² The PET scan is based on the myocardial metabolism of glucose or other compounds tagged with positron-emitting isotopes. PET allows the noninvasive functional assessment of perfusion, substrate metabolism, and cardiac innervation in vivo. The PET scan may be most useful in determining whether an area of apparently infarcted myocardium may, in fact, be hibernating and capable of responding to revascularization. These data can be used to determine whether patients with CHF might improve with operative revascularization.

MAGNETIC RESONANCE IMAGING VIABILITY STUDIES

Magnetic resonance imaging (MRI) may be used to delineate the transmural extent of MI and to distinguish between reversible and irreversible myocardial ischemic injury.³ This test has proven to be useful in the assessment of patients with myocardial scarring and ventricular aneurysms, when ventricular remodeling surgery is an option.

CARDIAC CATHETERIZATION

The cardiac catheterization study remains an important part of cardiac diagnosis. Complete cardiac catheterization includes the measurement of intracardiac pressures and cardiac output, localization and quantification of intracardiac shunts, determination of internal cardiac anatomy and ventricular wall motion by cineradiography, and determination of coronary anatomy by coronary angiography. However, most cardiac catheterizations today are focused studies (e.g., coronary angiography alone), because echocardiography and other noninvasive studies can accurately evaluate valvular pathology and cardiac function.

During cardiac catheterization the cardiac output can be calculated using the Fick oxygen method, where cardiac index (1/min per square meter) = oxygen consumption (mL/min per square meter) arteriovenous oxygen content difference

(mL/min). For determining the arteriovenous oxygen difference, the oxygen content is calculated separately in the arterial and venous circulations by the formula:

$$\text{Oxygen content (mL oxygen/L blood)} = \text{hemoglobin (g/100 mL)} \times \text{percent hemoglobin saturation} \times 1.36 \text{ (mL oxygen/g hemoglobin)} \times 10.$$

Calculation of systemic vascular resistance (SVR) is by the formula:

$$\text{SVR} = (\text{mean systemic arterial pressure} - \text{mean right atrial pressure}) \times 80 / \text{systemic blood flow (cardiac output)}. \text{ The normal SVR is } 1200 \text{ dynes}\cdot\text{sec}\cdot\text{cm}^{-5}.$$

The pulmonary vascular resistance (PVR) is calculated by the formula:

$$\text{PVR} = (\text{mean pulmonary artery pressure} - \text{mean left atrial pressure}) \times 80 / \text{pulmonary blood flow (equal to the cardiac output when no shunt is present)}. \\ \text{The normal PVR is } 70 \text{ to } 80 \text{ dynes}\cdot\text{sec}\cdot\text{cm}^{-5}.$$

The area of a cardiac valve can be determined from measured cardiac output and intracardiac pressures using Gorlin's formula. This formula relates valve area to the flow across the valve divided by the square root of the transvalvular pressure gradient. The Gorlin formula indicates that a relatively small transvalvular pressure gradient may actually represent severe valvular stenosis when the patient's cardiac output is low, demonstrating the danger of basing a surgical decision on the transvalvular gradient alone. The significance of valvular stenosis should be based on the calculated valve area [the normal mitral valve (MV) area is 4 to 6 cm² and the normal aortic valve area is 2.5 to 3.5 cm² in adults].

Coronary angiography remains the primary diagnostic procedure for determining the degree of CAD (Fig. 21-1). The left coronary system supplies the major portion of the LV myocardium through the left main, left anterior descending, and circumflex coronary arteries. The right coronary artery supplies the right ventricle, and the posterior descending artery supplies the inferior wall of the left ventricle. The AV nodal artery arises from the right coronary artery in 80 to 85% of patients, termed *right dominant circulation*. In 15 to 20% of cases, the circumflex branch of the left coronary system supplies the posterior descending branch and the AV nodal artery, termed *left dominant*, while 5% are codominant.

Cardiac catheterization. **A.** Coronary angiogram demonstrating a severely stenotic atherosclerotic lesion in the right coronary artery. **B.** A systolic left ventriculogram of a patient with a normal ejection fraction (*arrows* indicate normal systolic contraction of LV walls).

COMPUTED TOMOGRAPHY CORONARY ANGIOGRAPHY

Technologic advances in CT now allow less invasive imaging of the coronary anatomy. Newer rapid CT coronary angiography has been shown to be extremely sensitive in detecting coronary stenoses. These tests initially assess luminal calcium and a "calcium score" is derived. CT angiography has provided comparable results to traditional angiography in some recent studies.⁴

Extracorporeal Perfusion

HISTORY

With initial intracardiac surgical procedures being performed by brief asystole and systemic hypothermia or cross-perfusion from a parent, reliable cardiopulmonary support of the patient became a necessary development.

The pioneering efforts of Gibbon were largely responsible for such a development of the extracorporeal circulation circuit (cardiopulmonary bypass or CPB). Starting in 1932, Gibbon's laboratory investigations continued until, in 1953, he performed the first successful open heart operation in a human supported by a CPB machine.⁵ Intrinsic to this device was the capacity for gas exchange with oxygenation and carbon dioxide (CO₂) removal. Subsequently, refinements in the circuit led to the development of bubble oxygenators and the now widely used membrane oxygenators which use a hollow fiber membrane for

the blood-gas interface.

In recent years, the focus of perfusion technology has been on the development of perfusion systems that inflict less trauma on the patient's blood. One such advance was the introduction of biocompatible circuits to perfusion technology. This concept involves coating the plastic circuits with biocompatible materials that result in less activation of complement and other inflammatory cytokines during extracorporeal perfusion.

TECHNIQUE

Heparin is the most important medication used during CPB; it allows the blood to transverse the CPB circuit without clotting. Typically, 3 to 4 mg/kg of heparin is given to elevate activated clotting time (ACT) above 500 seconds. In a typical modern circuit, vacuum-assisted venous drainage removes blood from a patient and a pump then pushes it thru a membrane oxygenator and filter before returning it to the patient. Traditionally, venous blood was drained from the right atrium by gravity through large bore cannulas, but more recently, vacuum-assisted venous drainage has been increasingly used, which allows use of smaller-diameter venous drainage cannulas. Systemic flow rates during extracorporeal perfusion depend on the body oxygen consumption requirements of the patient, which are dependent upon the patient's body temperature. Normothermic perfusion is done at a flow rate of about 2.5 to 3.5 L/min per square meter, which is the normal cardiac index. Because hypothermia decreases the metabolic rate [approximately 50% for each 7°C (12.6°F)], the necessary flow rates can be diminished as the patient is cooled. Safe bypass flow rates for 30°C (86°F) are 1.8 to 2.3 L/min per square meter, for 25°C (77°F) 1.5 to 1.8 L/min per square meter, and for 20°C (68°F) 1.2 to 1.5 L/min per square meter.

Gas flow through the oxygenator is adjusted to produce an arterial oxygen tension above 150 mmHg and the CO₂ tension 35 to 45 mmHg. Systemic temperature is controlled with a heat exchanger in the circuit; the temperature is usually lowered to 25 to 32°C (77° to 89.6°F), although colder temperatures are occasionally necessary for some complicated procedures. Free intrapericardial or intracardiac blood is aspirated with a suction apparatus, filtered, and returned to the pump circuit's reservoir. A cell-saving device is likewise used to reprocess spilled blood before and after the heparinization of CPB. This technique washes the blood and extracts the red blood cells for transfusion back to the patient.

Venous blood returning to the heart-lung machine will usually have an oxygen saturation >60%. With adequate flow rates and oxygen saturations, metabolic acidosis of a significant degree does not occur. Patients are constantly monitored for signs of underoxygenation. Heparin is gradually metabolized by the body, and so additional heparin is given to keep the ACT above 500 to 600 seconds.

Once the operation is completed and the patient is systemically rewarmed to normothermic levels, the perfusion is slowed and then stopped as the patient's blood is returned from the pump reservoir to the patient. Before discontinuing bypass, the surgeon checks several important variables: ECG (for rate, rhythm, and ST-segment changes), potassium level, hematocrit, myocardial contractility, and hemostasis of the suture lines. Both visual inspection and TEE are used to assess contractility. Postbypass, the patient's blood pressure and cardiac function are monitored closely. A Swan-Ganz catheter can measure the cardiac output and the pulmonary capillary wedge pressure to provide a guide to left atrial preload. If the cardiac output and blood pressure are inadequate despite an adequate preload, inotropic support is initiated. Hypotension from a low peripheral vascular resistance and normal myocardial contractility is treated with vasoconstrictors.

Once hemodynamic stability is achieved, heparin is neutralized with protamine. If a coagulopathy is present, the ACT may not return to prebypass levels, indicating the need for coagulation products, such as fresh-frozen plasma, platelets, or clotting factor concentrates. Although this is infrequent, it does occur in complex operations and longer pump runs.

SYSTEMIC RESPONSE

Systemic responses to extracorporeal perfusion mainly involve platelet dysfunction and a generalized systemic inflammatory response syndrome. This is apparently due to the activation of complement and other acute-phase inflammatory components by blood contact with the extracorporeal circuit. The severity of the inflammatory response and the level of subsequent end-organ dysfunction are related to the length of the pump time, with complement and cytokine activation leading to an upregulation of white blood cell adhesion molecules and the ability of white blood cells to release superoxide. White blood cell upregulation or "priming" produced by extracorporeal circulation results in increased capillary permeability throughout the body, with the "primed" white blood cells placing the patient in a potentially vulnerable state for 24 to 48 hours, during which any secondary insult may result in various levels of multiorgan dysfunction. Other effects may include mental confusion, renal insufficiency, decreased oxygen exchange (pulmonary dysfunction), transient hepatic dysfunction, and hyperamylasemia. Low levels of a consumptive coagulopathy and hyperfibrinolysis from plasmin activation may also be present. Current research is focused on minimizing the body's systemic inflammatory response during extracorporeal circulation by coating circuits with biocompatible materials or by blockading specific cytokines. Aprotinin and steroids may attenuate the inflammatory response to bypass, while aprotinin and ϵ -aminocaproic acid diminish coagulopathy. There remains controversy as to the risk-benefit ratio of aprotinin, with concerns about renal and neurologic adverse events. Zero-balance ultrafiltration (Z-BUF) is a method of ultrafiltration during CPB. This technique removes significant amounts of inflammatory mediators associated with CPB and potentially attenuates the adverse effects of bypass while maintaining the patient's volume status. Recent studies have shown that Z-BUF reduces pulmonary edema and protects against lung injury.⁶ Additionally, the use of Z-BUF has been shown to decrease the concentrations of interleukin-6 and interleukin-8 that are markers of systemic inflammation associated with CPB.

MYOCARDIAL PROTECTION

Cardioplegia was developed as a protective solution to induce both cardiac asystole and protect the myocardium from ischemic injury. When infused through the coronary circulation, cold high-potassium cardioplegic solution produces diastolic arrest and slows the metabolic activity, protecting the heart from ischemia. The arrested heart allows the surgeon to work precisely on the heart in a motionless, bloodless field. With current cardioplegic techniques the heart can be stopped and protected for 2 to 3 hours quite safely, allowing time for complicated procedures to be performed with good recovery of cardiac function.

Both crystalloid and blood cardioplegic solutions are widely used, with the exact composition of the cardioplegic mixture varying among different institutions. With periods of cardiac arrest up to 90 minutes, there is little measurable difference in the two techniques, although blood cardioplegia may allow the heart to be safely arrested for longer periods.

CORONARY ARTERY DISEASE

History

In the 1930s, investigators attempted to increase the blood supply to the ischemic heart by developing collateral circulation with vascular adhesions. Beck, the leading investigator, tried different methods for many years, but ultimately failed. An ingenious concept arose in 1946, when Vineberg developed the technique of implantation of the internal mammary artery (IMA) into a tunnel in the myocardium. This was applied clinically by Vineberg and Miller in 1951 and continued for many years. Interestingly, the artery remained patent in >90% of patients, but the amount of flow through the artery was small,

and the procedure was subsequently abandoned. Coronary artery endarterectomy for coronary revascularization was attempted by Longmire in 1956 with short-term success. Late results were poor, however, due to progressive restenosis and occlusion. Shortly thereafter, CPB was used to facilitate coronary revascularization, and Senning reported vein patch graft arterioplasty in 1961.

The development of the coronary artery bypass operation in the 1960s was a dramatic medical milestone. In the United States, the principal credit belongs to Favalaro and Effler from the Cleveland Clinic. In 1967, they began the first series of coronary bypass grafts with saphenous vein grafts using CPB. This launched the modern era of coronary bypass surgery. An additional breakthrough came in 1968 when Green and colleagues performed the first left IMA to left anterior descending artery (LAD) bypass, using CPB and an operative microscope. Kolessov had independently performed IMA to left coronary artery bypass grafting (CABG) on the beating heart in Russia in 1964, although his work was largely unknown for many years. Subsequently, coronary artery bypass surgery became one of the most widely applied surgical procedures in the United States and throughout the world.

Etiology and Pathogenesis

The etiology of CAD is primarily atherosclerosis. The disease is multifactorial, with the primary risk factors being hyperlipidemia, smoking, diabetes, hypertension, obesity, sedentary lifestyle, and male gender. Newly identified risk factors include elevated levels of C-reactive protein, lipoprotein (a), and homocysteine. The atherosclerotic process results in the formation of obstructive lesions in the aorta, the peripheral vessels, and the coronary arteries. Atherosclerosis is the leading cause of death in the Western world, and acute MI alone accounts for 25% of the deaths in the United States each year. The most important factor in the long-term treatment of coronary disease is modification of risk factors, including the immediate cessation of smoking, control of hypertension, weight loss, exercise, and reduction of serum cholesterol. If dietary control of cholesterol cannot be achieved in patients with coronary disease, evidence suggests that the early use of medications (such as statins) to lower cholesterol can significantly reduce cardiovascular risk.

The basic lesion is a segmental plaque within the coronary artery. Involvement of small distal vessels is usually less extensive, while arterioles and intramyocardial vessels are usually free of disease. This segmental localization makes CABG possible. Among the three major coronary arteries, the proximal LAD is frequently stenosed or occluded, with the distal half of the artery remaining patent. The right coronary artery is often stenotic or occluded throughout its course, but the posterior descending and left AV groove branches are almost always patent. The circumflex artery is often diseased proximally, but one or more distal marginal branches are usually patent. With progressive disease, platelet aggregation in the narrowed lumen or plaque hemorrhage or rupture may lead to unstable symptoms or to acute thrombosis and MI.

Clinical Manifestations

Myocardial ischemia from CAD may result in angina pectoris, MI, CHF, cardiac arrhythmias, and sudden death. Angina is the most frequent symptom, but MI may appear without prior warning. CHF usually results as a sequela of MI, with significant muscular injury resulting in an ischemic myopathy. Myocardial injury and scarring can then lead to serious ventricular arrhythmias that may result in sudden death.

Angina pectoris, the most common manifestation, manifests by periodic chest discomfort, usually substernal, and typically appears with exertion. These symptoms usually subside within 3 to 5 minutes and are relieved by sublingual nitroglycerin. In 20 to 25% of patients, the pain may be atypical and radiate to the jaw, shoulder, or epigastrium. Some patients, especially women or diabetics, have no symptoms of angina and experience primarily exertional dyspnea. Establishing a diagnosis of

myocardial ischemia in these patients is difficult and perhaps impossible without provocative diagnostic studies. The differential diagnosis in patients with atypical symptoms includes aortic stenosis, hypertrophic cardiomyopathy, musculoskeletal disorders, pulmonary disease, gastritis or peptic ulcer disease, gastroesophageal reflux, diffuse esophageal spasm, and anxiety.

MI is the most common serious complication of CAD, with 1.1 million infarcts occurring in the United States annually. Modern therapy, which involves early reperfusion with either thrombolytic therapy or emergent angioplasty, has lowered the mortality to <5%. MI may result in acute cardiac failure and cardiogenic shock, or in mechanical rupture of infarcted zones of the heart.

In a certain number of patients who have MI, CHF develops, resulting from significant loss of LV function. When areas of salvageable myocardium are still present, angina is associated with heart failure, and significant improvement can be obtained with CABG. In contrast, with patients with late-stage chronic congestive failure due to diffuse myocardial scarring, the outlook is ominous. Bypass grafting may not be beneficial in these patients unless viable myocardium is present with reversible ischemia. Surgical ventricular remodeling, long-term support with a ventricular assist device, or cardiac transplantation become the only options in such patients.

Preoperative Evaluation

A complete history and physical examination should be performed in every patient with suspected CAD, along with a chest x-ray, ECG, and baseline echocardiogram. In patients with atypical symptoms, provocative stress tests, such as adenosine thallium or dobutamine echocardiography, may be beneficial in deciding if a cardiac catheterization is indicated. CT angiography is now used to evaluate intraluminal calcium and also is accurate in the assessment of previous bypass grafts. However, cardiac catheterization remains the gold standard of evaluation, as it outlines the location and severity of the coronary disease and accurately assesses cardiac function. "Angiographically significant" coronary stenosis is considered to be present when the diameter is reduced by >50%, corresponding to a reduction in cross-sectional area >75%. Furthermore, the number, location, and severity of the coronary stenoses are used to determine the appropriate method of revascularization.

Ventricular function is expressed as the LVEF, with 0.55 to 0.70 considered as normal, 0.40 to 0.55 as mildly depressed, <0.40 as moderately depressed, and <0.25 as severely depressed. An ejection fraction <0.25 is usually associated with severe heart failure. The LVEF is used to determine operative risk and long-term prognosis. Regional wall motion may also be analyzed, either by cardiac catheterization or echocardiography.

Studies such as the PET scan, thallium scan, dobutamine echocardiogram, or MRI viability scan may be used to determine myocardial viability and the reversibility of ischemia in areas of the heart that might benefit from revascularization. A patient is not "inoperable" simply because the LV function is severely depressed, if a significant amount of myocardium has reversible ischemia and is thought to be viable but hibernating.

Coronary Artery Bypass Grafting

INDICATIONS

CABG may be indicated in patients with chronic angina, unstable angina, or postinfarction angina, and in asymptomatic patients with severe proximal lesions or patients with atypical symptoms who have easily provoked ischemia during stress testing.

Chronic Angina

In some patients with chronic angina, CABG is associated with improved survival and improved complication-free survival when compared to medical management. In general, patients with more severe angina (CCS class III or IV symptoms) are most likely to benefit from bypass. For patients with less severe angina (CCS class I or II), other factors, such as the anatomic distribution of disease (left main coronary disease or triple-vessel) and the degree of LV dysfunction, are used to determine which patients will most benefit from surgical revascularization.

Three historic randomized trials were conducted to determine which patients with mild degrees of chronic angina would have improved survival from coronary bypass surgery. These studies provided the initial background data to support the widespread use of CABG.

The Veterans Administration Cooperative Study. This study involved 668 males with mild to moderate angina, treated between 1972 and 1974, and demonstrated improved long-term survival in patients with left main disease treated with surgical therapy.⁷ Largely based on this trial, surgery has been recommended for virtually all patients with significant left main arterial disease. Subsequent studies have shown that patients with left main arterial disease treated with surgery have a median survival of 13.3 years, vs. 6.6 years in those treated medically.⁸

The European Coronary Surgery Study Group. This study, done between 1973 and 1976, randomized male patients with mild to moderate angina into medical or surgical therapy.⁹ Surgery was found to be associated with improved survival in patients with triple-vessel disease and in patients with double-vessel disease with proximal left anterior descending and circumflex artery lesions.

Coronary Artery Surgery Study. This multicenter study performed between 1975 and 1979 randomized patients with mild angina (class I or II) into medical or surgical therapy. Late results demonstrated improved survival with surgery in patients with triple-vessel disease and depressed cardiac function.

Other nonrandomized trials and studies involving the overall Coronary Artery Surgery Study registry (of both randomized and nonrandomized patients) have suggested that surgical intervention might improve survival and event-free intervals in other patients with triple-vessel disease. A study by Jones and colleagues from Duke University evaluated the long-term benefits of bypass surgery and angioplasty vs. medical therapy in 9263 patients with documented CAD treated between 1984 and 1990.¹⁰ Treatment was nonrandomized, with 2449 patients receiving medical therapy, 3890 patients receiving bypass surgery, and 2924 patients receiving angioplasty. Both the surgery and angioplasty treatment groups had better long-term survival than medical therapy for all levels of disease severity, with surgery having the best survival benefit in patients with triple-vessel disease and in patients with double-vessel disease with proximal LAD stenosis.

To summarize, although medical therapy may be appropriate for many patients with chronic stable angina, bypass surgery is indicated for most patients with multivessel disease and CCS class III or IV symptoms. In patients with milder (CCS class I or II) symptoms, surgery results in improved survival in those with left main stenosis and those with triple-vessel disease and depressed LV function or diabetes. Certain other anatomic or physiologic subsets of patients, such as those with multivessel disease and tight proximal left anterior descending stenosis or easily provoked ischemia during stress testing, are also likely to have a survival benefit with surgery.

Unstable Angina

Unstable angina exists when angina is persistent or rapidly progressive despite optimal medical therapy. This occurs from

severe ischemia and represents an unstable clinical situation, usually leading to MI. It commonly represents plaque rupture or hemorrhage, often with local thrombus and spasm, resulting in a sudden decrease in regional blood flow. Patients with unstable angina should be promptly hospitalized for intensive medical therapy and undergo prompt cardiac catheterization. Most patients with unstable angina will require urgent revascularization with either percutaneous coronary intervention (PCI) or CABG.

Acute Myocardial Infarction

CABG generally does not have a primary role in the treatment of uncomplicated acute MI, as PCI or thrombolysis is the preferred method of emergent revascularization in these patients. However, patients with subendocardial MI and underlying left main disease or postinfarction angina and multivessel involvement may require surgery.

The primary indication for surgery after acute transmural MI is in patients who develop mechanical complications, such as postinfarction ventricular septal defect (VSD), papillary muscle rupture with mitral insufficiency, or LV rupture. Postinfarction VSD typically occurs 4 to 5 days after MI, occurring in approximately 1% of patients. These patients usually present with CHF and pulmonary edema, and a new systolic murmur.¹¹ Once recognized, patients with a postinfarction VSD should have an intra-aortic balloon pump (IABP) placed and undergo emergent repair. The operative mortality ranges from 10 to 20%. Another mechanical complication of acute MI is papillary muscle rupture with acute mitral insufficiency. These patients also typically present 4 to 5 days postinfarction with heart failure and a new murmur. Prompt valve repair or replacement offers the only meaningful chance for survival. Operative risk is 10 to 20%. The third mechanical complication of MI is LV free wall rupture. These patients present with cardiogenic shock, often with acute tamponade. Emergent surgery has a success rate of approximately 50%.

PERCUTANEOUS CORONARY INTERVENTION VS. CORONARY ARTERY BYPASS GRAFTING

PCI, or angioplasty, was developed by Gruentzig in 1977 and has significantly changed the treatment of patients with CAD.¹² Over 750,000 PCIs are now performed in the United States each year. The indications for PCI have continually expanded as this technology has advanced. A number of large, randomized studies have compared outcomes of patients with coronary disease treated with PCI and CABG. These studies have attempted to identify the optimal therapy for patients with coronary disease, based on their anatomy and risk stratification. Three large, representative studies are summarized here.

The Bypass Angioplasty Revascularization Investigation Trial. This trial, sponsored by the National Institutes of Health, randomized 1792 patients with multivessel coronary disease to either coronary bypass ($n = 914$) or PCI ($n = 915$).¹³ In-hospital event rates for CABG and PCI were 1.3 and 1.1% for mortality, 4.6 and 2.1% for MI, and 0.8 and 0.2% for stroke. There was no significant difference in 5-year survival—89.3% for CABG and 86.3% for PCI. However, the PCI group required more repeat interventions, with 54% within 5 years vs. only 8% for CABG. In diabetic patients with triple-vessel disease, CABG offered a clear survival advantage at 5 years, 80.6 vs. 65.5% with PCI ($P = .003$).

Arterial Revascularization Therapies Study Group. This large trial compared outcomes in 1205 patients randomly assigned to CABG ($n = 605$) or PCI ($n = 600$).¹⁴ Unlike the *Bypass Angioplasty Revascularization Investigation* trial, PCI patients in this trial received coronary stents. At 1 year, death, stroke, and MI rates were similar, although PCI patients had more recurrent symptoms, 16.8 vs. 3.5% in CABG patients. The 1-year event-free survival rate was 73.8% with PCI compared with 87.8% with CABG.

Most recently, stents coated with pharmacologic agents (such as paclitaxel or sirolimus) aimed at reducing in-stent restenosis

have been introduced.¹⁵ These stents are in wide use presently, however, long-term results remain unknown.¹⁶

New York State Study Group. This patient cohort includes greater than 59,000 patients in New York receiving either coronary stenting or CABG with 3-year follow-up. Propensity analysis was used to adjust for varying clinical cofactors. Long-term patient survival was superior with CABG rather than stenting in patients with two or more diseased coronary arteries.¹⁷

SUMMARY

When comparing CABG to PCI for the treatment of patients with CAD, results demonstrate that with appropriate patient selection both procedures are safe and effective, with little difference in mortality. PCI is associated with less short-term morbidity, decreased cost, and shorter hospital stay, but requires more late reinterventions. CABG provides more complete relief of angina, requires fewer reinterventions, and is more durable. Additionally, CABG appears to offer a survival advantage in diabetic patients with multivessel disease.

OPERATIVE TECHNIQUES AND RESULTS

Conventional Coronary Artery Bypass Grafting

Conventional CABG is performed through a median sternotomy incision (Fig. 21-2), using CPB for extracorporeal perfusion and cardioplegia for intraoperative myocardial protection of the heart.

Fig. 21-2.

In the vast majority of patients the left IMA is used as the primary conduit for bypassing the LAD, which is the most important vessel in the heart (Fig. 21-3). The IMA is harvested from the chest wall and usually is used as an in situ graft, remaining connected proximally to the native left subclavian artery. As such, the IMA remains metabolically active and enlarges over time in response to demand. The IMA is resistant to intrinsic atherosclerotic disease and its patency is rarely compromised by luminal stenosis. After CPB is initiated and the heart is arrested, the IMA to left anterior descending anastomosis is constructed end-to-side with fine sutures.

Coronary artery bypass grafting. **A.** Operative photograph of anastomosis between the left internal mammary artery and the left anterior descending artery. The anastomosis was completed using optical magnification, microvascular technique, and a continuous 8-0 suture. **B.** Fifteen-year follow-up coronary angiogram demonstrating a widely patent left internal mammary artery–left anterior descending artery bypass graft. The *arrow* demonstrates the anastomotic site. The mammary artery is virtually free of graft atherosclerosis.

Loop reported a series of 2306 internal mammary grafts and 3625 vein grafts, demonstrating that use of an IMA graft significantly improved survival at 10 years. Patients who had IMA grafts also had fewer late complications with a decreased risk of MI and reoperation. The left IMA has a 10-year patency rate of approximately 95% when used as an in situ graft to the LAD.

The excellent results obtained with in situ left IMA grafts prompted many other centers to use the right IMA in coronary revascularization. The right IMA may be used to provide a second arterial conduit as either an in situ or a free graft (Fig. 21-4). Dion reported 400 consecutive patients in whom both left and right IMAs were used, and found equivalent patency with the left and the right IMA.¹⁸ Lytle and colleagues showed excellent late results and no increase in perioperative risk in >500 cases in which both IMAs were used.¹⁹ Even when the IMA is used as a "free" graft, patency rates are approximately 70 to 80% at 10 years.

Arterial revascularization. Schematic of arterial conduits used in coronary artery bypass grafting, showing left internal mammary (or thoracic) artery (LITA), right internal mammary (or thoracic) artery (RITA), and composite graft using radial and gastroepiploic arteries (R+GEA).

(Reproduced with permission from Pevni D, Kramer A, Paz Y, et al: Composite arterial grafting with double skeletonized internal thoracic arteries. *Eur J Cardiothorac Surg* 20:299, 2001. Copyright Elsevier.)

Saphenous vein grafts, which were initially the primary conduits used for CABG, continue to be used widely, usually for grafting secondary targets on the lateral and posterior walls of the heart. Once CPB has been established and the heart arrested, a small arteriotomy is performed in the coronary artery, and the distal anastomosis is performed between the saphenous vein and the coronary artery. The proximal anastomosis then connects each vein graft to the ascending aorta. The 10-year patency of saphenous vein grafts is only approximately 65%, however, and patency is limited by the development of progressive intimal hyperplasia and late vein graft atherosclerosis.

In an attempt to achieve better long-term patency than that obtainable with saphenous vein grafts and encouraged by the excellent late patency of internal mammary arterial grafts, surgeons have explored the use of other arterial conduits. The

most widely used has been the radial artery graft. After an Allen test has been performed to assure adequate blood flow to the hand, the radial artery can be harvested and used as a free graft. Reports have demonstrated excellent early and midterm patency rates with radial artery grafts. Other alternative arterial grafts include the right gastroepiploic artery, usually used as an in situ pedicled graft, and the inferior epigastric artery, which is used as a free graft. Reports are mixed regarding late patency rates of the gastroepiploic and inferior epigastric arteries, however. Although the expanded use of arterial grafts is appealing, a significant improvement in patency rates of arterial conduits other than the IMA compared to vein grafts has yet to be verified.

Results

The operative mortality for coronary artery bypass is 1 to 3%, depending on the number of risk factors present. Both the Society of Thoracic Surgeons (STS) and New York state have established large databases to establish risk factors and report outcomes. Variables that have been identified as influencing operative risk according to STS risk modeling include: female gender, age, race, body surface area, NYHA class IV status, low ejection fraction, hypertension, PVD, prior stroke, diabetes, renal failure, chronic obstructive pulmonary disease, immunosuppressive therapy, prior cardiac surgery, recent MI, urgent or emergent presentation, cardiogenic shock, left main coronary disease, and concomitant valvular disease. Perioperative complications include MI, bleeding, stroke, arrhythmias, tamponade, wound infection, aortic dissection, pneumonia, respiratory failure, renal failure, GI complications, and multiorgan failure.

Late results demonstrate that relief of angina is striking after CABG. Angina is completely relieved or markedly decreased in >98% of patients, and recurrent angina is rare in the first 5 to 7 years. Reintervention is required in <10% of patients within 5 years. Symptoms begin to recur more frequently between 8 and 15 years due to progression of disease or late graft occlusion. However, tight control of risk factors can minimize the risk of recurrence. Cessation of smoking and control of hypercholesterolemia are especially important, as late graft occlusion is five to seven times higher in patients who continue to smoke or have persistent hypercholesterolemia. If recurrent angina develops, angiography should be performed promptly, followed by repeat revascularization as indicated.

Exercise capacity generally improves significantly after CABG, with most patients demonstrating a markedly improved functional response to exercise secondary to improved blood flow. This functional improvement lasts up to 10 years, with longer improvement in patients receiving IMA grafts.

Late survival is similarly excellent after CABG, with a 5-year survival of >90% and a 10-year survival of 75 to 90%, depending on the number of comorbidities present. Late survival is influenced by age, diabetes, LV function, NYHA class, CHF, associated valvular insufficiency, completeness of revascularization, and the nonuse of an IMA graft. Intense medical therapy for control of diabetes, hypercholesterolemia, and hypertension, and cessation of smoking significantly improve late survival.

Off-Pump Coronary Artery Bypass

One of the most significant developments in cardiac surgery in the last 15 to 20 years has been the introduction of off-pump coronary artery bypass (OPCAB). This involves performing coronary bypass surgery on a beating heart, without the use of CPB. The main concept in this surgical approach is the elimination of the deleterious consequences of CPB.

The initial experiences with beating heart techniques took place in Argentina under Benetti. This procedure is performed with the assistance of stabilization devices, which allow precise anastomoses while the heart remains beating. During OPCAB surgery, the coronary artery is temporarily snared or occluded to provide a relatively bloodless field for the creation of the

anastomosis. Because this interval of regional ischemia may produce a critical reduction in cardiac function or arrhythmias, several methods such as intracoronary shunts or preischemic conditioning have been developed to minimize the risks of temporary coronary occlusion during construction of the anastomosis.

The temporary displacement of the heart while performing posterior and inferior wall grafts may lead to a reduction in cardiac output and subsequent hemodynamic instability. Many intraoperative maneuvers have been proposed to minimize these effects (Fig. 21-5). These include use of the right lateral decubitus and Trendelenburg ("head down") positions, administration of fluids, opening the right pleural cavity to minimize the compression of the right heart by the pericardium, and the use of pericardial sutures to aid in tilting the heart. Additionally, suction devices are used to position the apex of the heart. These devices limit the compression of the left ventricle and therefore assist in maintaining hemodynamic stability.

Results

The OPCAB technique has been extensively studied and results compared to conventional surgery. Initial attention was given to assessing the accuracy of graft placement with the OPCAB approach, which required grafting onto the beating heart. Puskas and associates assessed 421 grafts in 167 patients and found an overall early graft patency of 98.8%, with 100%

patency of 163 IMA grafts.²⁰ These results were equivalent to those published for conventional CABG. Similarly, when evaluating patients receiving multiple arterial grafts, Kim and colleagues found no difference in the 1-year patency of arterial grafts performed with OPCAB compared with traditional methods.²¹

Sabik and coworkers compared overall results in 406 OPCAB patients with 406 conventional CABG patients.²² The operative mortality and the risks of stroke, MI, and reoperation for bleeding were similar, while OPCAB patients had less risk of encephalopathy, sternal infection, blood transfusion, and renal failure. A prospective randomized comparison between OPCAB and conventional CABG reported by Puskas demonstrated equivalent operative mortality and risk of stroke in each group, but less myocardial injury, fewer blood transfusions, earlier postoperative extubation, and earlier hospital discharge in OPCAB patients.

A study performed by Grossi at New York University in high-risk patients with severe atheromatous aortic arch disease who required CABG compared outcomes in 245 OPCAB patients with outcomes in 245 conventional patients, using propensity case-matching methodology. In this high-risk patient population, OPCAB was associated with a decreased risk of death (6.5 vs. 11.4%), stroke (1.6 vs. 5.7%), and all perioperative complications. Others have similarly shown significant reductions in both mortality and major neurologic events with the OPCAB technique.^{23,24}

Minimally Invasive Direct Coronary Artery Bypass

An even less invasive off-pump approach for CABG, termed *minimally invasive direct coronary artery bypass*, or MIDCAB, uses a small left anterior minithoracotomy incision to perform bypass grafting on the beating heart, without CPB. The technique uses a mechanical stabilizer to isolate the coronary artery and facilitate the anastomosis and an in situ left IMA graft. The technique is mainly useful in performing bypasses to the anterior wall of the heart, primarily to the LAD or to the diagonal branches.

Results

The operative mortality for MIDCAB has been <2%, and the patency rate of the IMA graft has been approximately 98%.²⁵ Because both the use of CPB and the need for sternotomy are eliminated, MIDCAB patients have less pain and blood loss, fewer perioperative complications, and a shorter recovery time than conventional CABG patients. This technique is generally only applicable to patients with single-vessel disease, and therefore, outcomes after MIDCAB are probably best compared with PCI. Diegeler and associates reported a prospective, randomized trial that compared results of MIDCAB and PCI for treatment of isolated, proximal LAD stenosis.²⁶ This study found that the combined perioperative risks of death and MI were equivalent, but the MIDCAB patients had better relief of angina and required fewer subsequent reinterventions. Similarly, a prospective, randomized study reported by Drenth and colleagues compared MIDCAB with PCI and stenting in patients with isolated high-grade LAD stenosis. At 6 months, quantitative coronary angiography showed anastomotic stenosis in 4% after MIDCAB, but restenosis at the intervention site in 29% after PCI ($P < .001$).²⁷ Thus, the late results with MIDCAB for revascularization of the LAD appear to be significantly more durable than those achieved with PCI.

NEW DEVELOPMENTS

Total Endoscopic Coronary Artery Bypass

Minimal access coronary artery bypass performed using endoscopic instrumentation is facilitated with the latest generation of surgical robotic technology. Made possible by advancements in articulation of robotic instruments to more closely approximate the movement of human hands, total endoscopic coronary artery bypass has been reported on both the

arrested and beating heart.²⁸ Robotic instrumentation also has been described to perform IMA harvests as part of the MIDCAB technique. Although early results are promising, larger series with long-term data are necessary before total endoscopic coronary artery bypass moves out of the experimental phase.

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization (TMR) uses a high-powered CO₂ laser or holmium:yttrium-aluminum-garnet laser to drill multiple holes (1 cm²) through the myocardium into the ventricular cavity. The procedure is performed on the beating heart with the laser pulses gated to the R wave on the ECG. The TMR procedure has been used primarily for patients with refractory angina who are unsuitable candidates for standard CABG due to poor distal coronary artery anatomy. The mechanism of benefit of TMR remains uncertain. It has been demonstrated that the transmyocardial laser channels are rapidly occluded and do not allow a direct flow from the ventricle to the myocardium. The most likely possibility is that TMR works by stimulating angiogenesis in the area of injury.

Burkhoff and coworkers reported the results of a large, randomized, multicenter trial with TMR in 182 patients with CCS angina class III or IV, reversible ischemia, and incomplete response to other therapies. They found TMR to be associated with significant increases in exercise tolerance, reduction in angina score, and improvements in quality of life.²⁹ Despite subjective reports of improvement, however, the results of objective cardiac perfusion measurements after TMR have been inconclusive, and multiple randomized trials have failed to demonstrate any survival benefit with the procedure. Thus, the exact role of TMR and its relationship to medical therapeutic angiogenesis remains to be determined.

Biomolecular Therapy and Tissue Engineering

Tissue engineering and biomolecular or gene therapy may be possible in the near future to replace the dysfunctional tissue or to improve organ function with an assembly that contains specific populations of living cells. Significant progress has been made in understanding the cellular and molecular mechanisms of cardiovascular disease, leading to new forms of molecular-genetic therapy. These innovations are currently being tried experimentally for genetically engineered or modified veins and arteries, engineered heart valves, stem cell or progenitor cell cardiomyocyte restoration therapy, and therapeutic angiogenesis. Much of this work has focused on vascular mitogens, on intracellular signaling pathways, and on the underlying genetic functions that control the cellular response.

In the field of CAD, several gene therapy protocols are now under active investigation. These include: (a) genetic engineering of vein grafts that are resistant to atherosclerosis or restenosis; (b) gene therapy for coronary arteries to prevent restenosis after angioplasty or surgical endarterectomy; (c) genetic manipulation of the coronary and peripheral vascular system in an attempt to prevent lipid accumulation and progression of atherosclerosis; (d) the biomolecular delivery of growth factors or genetic material into the coronary system or myocardium to promote therapeutic angiogenesis; and (e) the total bioengineering of blood vessels using cell seeding techniques and a biodegradable scaffold. Although these innovations are currently experimental, biomolecular adjuvant therapy offers great promise for the future.

Anastomotic Devices

Significant technologic progress has led to the development of devices that mechanically construct proximal and distal vascular anastomoses, without the need for sutures or knot tying. The goals for these devices are to provide safe, rapid, and reproducible anastomoses; reduce operative time; limit anastomotic variability between surgeons; and improve graft patency. If perfected, such devices may facilitate newer minimally invasive endoscopic or robotic surgical techniques by

eliminating the difficulties associated with suturing and knot tying in small spaces. Proximal anastomotic devices, some in early clinical trials, are designed to create aortosaphenous anastomoses without the need for aortic cross-clamping. This may have particular significance in patients with severe atherosclerotic aortic disease in whom prevention of aortic manipulation is crucial in preventing embolic complications. Distal anastomotic devices are also in experimental use, and may facilitate off-pump or minimally invasive CABG.

VALVULAR HEART DISEASE

General Principles

The surgical treatment of valve disease has increased significantly in recent years. According to the STS database, valve operations accounted for 14% of all classified procedures performed in 1996. By 2002, that percentage had increased to 20% of all classified procedures. Due to increased PCI and better medical management of coronary disease, CABG volume declined by 15% between 1996 and 1999. However, during this same period, aortic valve replacements increased by 12% and MV operations increased by 58%.

Valvular heart disease can result in a *pressure load* (valvular stenosis), a *volume load* (valvular insufficiency), or both (mixed stenosis and insufficiency). Aortic stenosis increases the afterload of the left ventricle, resulting in LV hypertrophy, while both aortic and mitral insufficiency result in a significant volume overload of the left ventricle, producing cardiac dilatation.

Although the heart can effectively compensate for these hemodynamic changes for some time, progressive deterioration in cardiac function develops, leading to valvular cardiomyopathy. The decision to proceed with surgical intervention is based on the patient's history, symptoms, physical findings, and the results of diagnostic studies, including echocardiography, cardiac catheterization, and radionuclide tests. Demonstration of a decreased ejection fraction at rest (or a rise in the end-systolic volume by echocardiography) or a fall in ejection fraction during exercise are probably the most accurate signs that the systolic function of the heart is beginning to deteriorate and that surgery should be performed promptly. As surgeons have gained experience and as new technologies have been advanced, surgical risk has been reduced and long-term results have improved. Therefore, surgical therapy is now recommended at a much earlier stage of the disease process in an attempt to maintain normal cardiac function long after valve surgery. Studies have proven earlier intervention in mitral disease has clearly shown long-term benefit.³⁰ Survival after cardiac valve replacement is strongly influenced by the myocardial function at the time of operation. For example, Chaliki and associates reported that the operative risk for aortic valve replacement for aortic insufficiency in patients with a low ejection fraction was 14%, compared to 3.7% in patients with preserved LV function.³¹ At 10 years, only $41 \pm 9\%$ of those patients with reduced ejection fraction had survived, compared with $70 \pm 3\%$ of those with normal ventricular function. Postoperative cardiac function generally returns to normal if the operation is performed at an early phase of ventricular dysfunction. Even with impaired LV function, NYHA class IV disability, and pulmonary hypertension, patients with valvular heart disease are rarely inoperable. After the hemodynamic burden on the ventricle has been removed with corrective surgery, the patient is treated with an aggressive medical heart failure regimen (digitalis, diuretics, afterload reduction, and beta blockers when indicated), usually with significant improvement. Additionally, aortic valve replacement in high risk, elderly patients can be performed with excellent results.³² Except in the rare case of advanced cardiomyopathy combined with other systemic disease, surgery should not be denied to most elderly or high-risk patients. The typical valve-related complications from valvular surgery include thromboembolic events, anticoagulant-related hemorrhage, prosthetic valve failure, endocarditis, prosthetic paravalvular leakage, and failure of valve repair.

Surgical Options

Valve replacement can be performed with either mechanical or tissue valves. Current mechanical valves include tilting disk and older ball-in-cage designs. Tissue for valve replacement can be xenograft (porcine valves, bovine or equine pericardium), homograft (human cadaver donor), or autograft (translocation of pulmonic valve). Valve repair is increasingly an option, as opposed to valve replacement, especially for patients with mitral or TV insufficiency. The recommendations for valve repair or replacement, type of prosthesis, and operative approach are based on multiple factors, such as the patient's age, lifestyle, associated medical conditions, access to follow-up health care, desire for future pregnancy, and experience of the surgeon. The risks, benefits, and options should be discussed in detail with the patient before arriving at a joint decision. General considerations regarding these choices are discussed in the following paragraphs.

Mechanical prostheses are highly durable but require permanent anticoagulation therapy to minimize the risk of valve thrombosis and thromboembolic complications. Such lifelong anticoagulation therapy carries the risk of hemorrhagic complications and may dictate lifestyle changes. For some patients, the typical mechanical valve closing sound adversely affects quality of life. Mechanical prostheses are usually preferable in patients with a long life expectancy who want to minimize the risk of reoperation and are suitable candidates for anticoagulation.³³

Tissue valves are naturally less thrombogenic, and generally do not require anticoagulation therapy. Consequently, tissue valves have lower risks of thromboembolic and anticoagulant-related complications, with the total yearly risk of all valve-related complications being considerably less than with mechanical valves. Unfortunately, tissue valves are more prone to structural failure due to late calcification of the xenograft tissue. However, because of improved methods of valve preservation and chemical impregnation to slow calcification of the tissue, the currently available tissue valves are becoming increasingly durable, and it is anticipated that it may take 15 to 20 years before structural failure will occur in these prostheses.

For aortic valve replacement, a mechanical prosthesis, a newer-generation tissue valve (either stented or nonstented), a homograft, or a pulmonary autograft (Ross procedure) may be recommended, depending on the patient's lifestyle and desire to avoid anticoagulation therapy. Some type of tissue valve is usually recommended for patients >65 years of age because anticoagulation therapy may be hazardous and valve durability is better in older patients. For patients >65 years of age, Jamieson and colleagues demonstrated a risk of tissue valve structural deterioration of <10% at 15 years.³⁴

Valve repair can be performed in the vast majority of patients with mitral insufficiency as discussed later in this chapter. In certain patients, valve replacement may still be indicated, particularly with rheumatic disease and valvular stenosis. When valve replacement is necessary, a tissue valve is an appropriate choice in women planning pregnancy or in patients >60 to 65 years of age. A mechanical prosthesis is recommended for younger patients, especially if the patient is in atrial fibrillation, because anticoagulation therapy is already required in this group.

MECHANICAL VALVES

A common mechanical valve used in the United States is the St. Jude Medical bileaflet prosthesis (Fig. 21-6). Mechanical (disk) valves have excellent flow characteristics, an acceptably low risk of late valve-related complications, and an extremely low risk of mechanical valve failure. With proper anticoagulation and keeping the International Normalized Ratio (INR) at two to three times the normal for mechanical aortic valves and 2.5 to 3.5 times the normal for mechanical MVs, the incidence of thromboembolism is approximately 1 to 2% per patient per year, and the risk of anticoagulant-related hemorrhage is 0.5 to 2% per patient per year. Careful monitoring of the INR reduces the risk of thromboembolic events, minimizes

anticoagulation-related complications, and improves survival.³⁵

TISSUE VALVES

Several types of xenograft tissue valves are available and widely used (Fig. 21-7). The stented valves are most common (either porcine or bovine pericardial), while stentless valves are being increasingly used by some groups. Again, the chief advantage of tissue valves is the low incidence of thromboembolism and the absence of the need for anticoagulation therapy. Stented tissue valves have the drawback of having higher gradients across the valve, particularly in smaller sizes (indexed prosthetic valve area $<0.85 \text{ cm}^2$ valve area per square meter body surface area). Therefore, this group of patients may have less symptomatic improvement and a suboptimal hemodynamic response to exercise.³⁶ However, most patients experience excellent symptomatic improvement and have a normal response to exercise after stented tissue valve replacement.

Nevertheless, the limitations in flow characteristics observed in small sizes of stented tissue valves led to the development of stentless valves in an attempt to maximize the effective valve orifice area by eliminating the profile of the stent, and to take

advantage of the natural dynamic nature of the aortic annulus. Since the first clinical report of a stentless porcine valve in 1990 by David and associates,³⁷ several stentless aortic bioprostheses have been introduced (Fig. 21-8). The technique of implantation varies (subcoronary or miniroot), but the results have been excellent in most series. Patients undergoing stentless valve replacement have been found to have a significant reduction in transvalvular gradient, both at rest and with exercise. Although the long-term durability of stentless valves has not yet been established, these valves offer excellent hemodynamics, and durability is anticipated to be similar to that achieved with stented xenografts.

HOMOGRAFTS

Surgical alternatives to prosthetic valve replacement have been developed in an attempt to use the body's natural tissue and lower the incidence of valve-related complications. In the 1960s, Ross in England and Barrett-Boyes in New Zealand described a procedure for aortic valve replacement using antibiotic-preserved aortic homograft (allograft) valves.^{38,39} Since this time, homografts have been used more frequently for aortic and pulmonary valve replacements. Similarly to patients receiving xenografts, the rate of thromboembolic complications is low, and long-term anticoagulation therapy is not required. In addition, homografts have much lower transvalvular pressure gradients than stented tissue valves. Although homografts are attractive options in many instances, there are some limitations to their widespread use. During the first year of implantation, homograft valves rapidly lose their original cellular components and normal tissue architecture. Newer methods of homograft preservation that result in significant retention of cellular viability are possible using cryopreservation techniques, widening the availability of homografts and potentially improving the long-term results. The main disadvantage

of a homograft valve is its uncertain durability, especially in young patients, as structural degeneration of the valve tissue leads to graft dysfunction and valve failure. The 15-year durability is approximately that of a xenograft.

AUTOGRAFTS

Ross described a potentially durable but more complicated alternative for aortic valve replacement with natural autologous tissue, using the patient's native pulmonary valve as an autograft for aortic valve replacement and replacing the pulmonary valve with a homograft (Fig. 21-9). This operation, referred to as the Ross procedure, has the advantage of placing an autologous valve into the aortic position, which functions physiologically and does not require anticoagulation therapy. Results have shown minimal-to-absent transvalvular gradients, with improvement in LV function both at rest and during exercise. Ross reported late follow-up of 339 autograft patients with a rate of freedom from autograft replacement of 85% at 20 years, and a rate of freedom from all valve-related events of 70% at 20 years. Others have reported less durable results, with a combined failure rate of the autograft or pulmonary homograft of 30 to 40% at 12 to 15 years. The Ross procedure may be indicated for younger patients who require aortic valve replacement and want to avoid the need for anticoagulation.

VALVE REPAIR

Valve repair has become the procedure of choice for most patients with MV insufficiency, while repair of the aortic valve is feasible in certain situations. In the 1960s McGoon, Kay, and Reed each developed separate plication techniques for reconstruction of the MV for mitral insufficiency. However, the primary advance in MV repair resulted from work by Carpentier in the 1970s. Valve repair has subsequently proved to be highly reproducible for correction of mitral insufficiency, with excellent durability and freedom from late valve-related complications. The 15-year freedom from valve repair failure is >90% in patients with degenerative mitral insufficiency. Valve repair offers significant advantages over valve replacement, primarily lower risks of thromboembolic- and anticoagulant-related complications. Survival may also be improved in certain groups of patients after valve repair.

Mitral Valve Disease

In the 1920s the first attempts to surgically correct mitral stenosis via a closed atrial approach demonstrated the feasibility of mitral valve surgery. Now, with good preoperative pathophysiologic evaluation and precise surgical technique, mitral valve surgery has become one of the most successful procedures performed by cardiac surgeons.

MITRAL STENOSIS

Etiology

MV stenosis or mixed mitral stenosis and insufficiency almost always are caused by rheumatic heart disease, although a definite clinical history can be obtained in only 50% of patients. Congenital mitral stenosis is rarely seen in adults. Occasionally, intracardiac tumors such as a left atrial myxoma may obstruct the mitral orifice and cause symptoms that mimic mitral stenosis.

Pathology

Although the rheumatic inflammatory process is associated with some degree of pancarditis involving the endocardium, myocardium, and pericardium, permanent injury results predominantly from the endocarditis, with progressive fibrosis of the valves. Rheumatic valvulitis produces three distinct degrees of pathologic change: fusion of the commissures alone, commissural fusion plus subvalvular shortening of the chordae tendineae, and extensive fixation of the valve and subvalvular apparatus with calcification and scarring of both leaflets and chordae (Fig. 21-10). The degree of pathology present should be determined preoperatively, as this predicts the suitability of balloon valvuloplasty, surgical commissurotomy, or valve replacement.

Mitral replacement. **A.** Operative photograph of rheumatic mitral valve with calcific mitral stenosis, viewed through a left atriotomy incision. Arrow points to "bar" of heavily calcified posterior annulus. **B.** Excised calcified mitral valve with fibrotic, shortened chordae tendineae. **C.** St. Jude mechanical mitral valve visualized through the open left atrium. Pledget reinforced sutures were used to secure the valve into the native annulus.

Pathophysiology

Mitral stenosis usually has a prolonged course after the initial rheumatic infection, and symptoms may not appear for 10 to 20 years. The progression to valvular fibrosis and calcification may be related to repeated episodes of rheumatic fever, or may result from scarring produced by inflammation and turbulent blood flow.

Mitral stenosis leads to a progressive decrease in the MV area, which results in a transvalvular gradient across the stenotic valve during diastole. The normal cross-sectional area of the MV is 4 to 6 cm². Symptoms may progressively develop with moderate stenosis, defined as a cross-sectional area of 1.0 to 1.5 cm². Severe symptomatic stenosis occurs when the MV area is <0.8 to 1.0 cm².

The pathophysiology associated with mitral stenosis results from an elevation in left atrial pressure, producing pulmonary venous congestion and pulmonary hypertension. As the left atrium dilates, atrial fibrillation may develop, exacerbating the patient's symptoms and resulting in an increased likelihood of clot formation and embolization. The LV function usually remains normal because the ventricle is protected by the stenotic valve.

Clinical Manifestations

The main symptoms of mitral stenosis are exertional dyspnea and decreased exercise capacity. Dyspnea occurs when the left atrial pressure becomes elevated due to the stenotic valve, resulting in pulmonary congestion. Orthopnea and paroxysmal

nocturnal dyspnea may also occur, or in advanced cases, hemoptysis. The most serious development is pulmonary edema. When the stenosis is chronic, with pulmonary hypertension, the patient may develop right-sided heart failure, which manifests as jugular venous distention, hepatomegaly, ascites, or ankle edema.

Atrial fibrillation develops in a significant number of patients with chronic mitral stenosis, and in some patients, arterial embolization is the initial presenting symptom. Atrial thrombi result from dilation of the left atrium, with stasis of blood. The left atrial appendage becomes especially susceptible to clot formation. Angina is a rare symptom that may result from coronary embolization.

The characteristic auscultatory findings of mitral stenosis, called the *auscultatory triad*, are an increased first heart sound, an opening snap, and an apical diastolic rumble. A loud pansystolic murmur transmitted to the axilla usually indicates associated mitral insufficiency. A systolic murmur along the left lower sternal border, loudest near the xiphoid process, commonly occurs with associated tricuspid insufficiency.

Diagnostic Studies

The ECG may show atrial fibrillation, left atrial enlargement (P mitrale), and right-axis deviation, or it may be normal. On chest x-ray, enlargement of the left atrium is typically seen on the posteroanterior film as a double contour visible behind the right atrial shadow. The overall cardiac size may be normal, but enlargement of the left atrium and the pulmonary artery (PA) may obliterate the normal concavity between the aorta and the left ventricle, producing a "straight" left border of the heart. Calcifications of the MV also may be seen. In the lung fields, the typical abnormalities consistent with pulmonary congestion may be present.

The Doppler echocardiogram is diagnostic. TEE is a particularly useful test because it provides enhanced resolution and unobstructed visualization of the MV and the posterior cardiac structures, including the left atrium and the atrial appendage. Echocardiography gives a very accurate measurement of the transvalvular gradient and the cross-sectional area of the MV, and allows assessment of the degree of leaflet mobility, calcification, and subvalvular fusion, each of which may be important in predicting the feasibility of valve repair.

Cardiac angiography should be performed in patients in whom concomitant CAD is likely, based on the patient's history or risk factors, and in most patients >55 years of age. Right heart catheterization may be valuable in patients with pulmonary hypertension, although a reliable estimate of the PA pressures can usually be determined from Doppler echocardiography.

Indications for Valvuloplasty or Commissurotomy

Although percutaneous balloon valvuloplasty has become an acceptable alternative for many patients with uncomplicated mitral stenosis, open mitral commissurotomy remains an extremely reproducible and durable option. Commissurotomy has the advantage of allowing the surgeon to address nonpliable or calcified MVs, mobilize fused papillary muscles to correct subvalvular restrictive disease, effectively repair patients with mixed stenosis and insufficiency, and remove left atrial clot. Either balloon valvuloplasty or open surgical commissurotomy is indicated for symptomatic patients with moderate (MV area <1.5 cm²) or severe (MV area <1.0 cm²) mitral stenosis. Similarly, the development of pulmonary hypertension or embolic events in the presence of mitral stenosis is considered a relative indication for treatment. If the need for surgery is uncertain, exercise echocardiography may be useful, with a significant increase in the transvalvular gradient and a rise in PA pressure being indications for intervention.

MITRAL INSUFFICIENCY

Etiology

Degenerative disease is the most common cause of mitral insufficiency in the United States, accounting for 50 to 60% of the patients requiring surgery. Other causes include rheumatic fever (15 to 20%), ischemic disease (15 to 20%), endocarditis, congenital abnormalities, and cardiomyopathy.

Pathology

The major structural components of the MV are the annulus, the leaflets, the chordae tendinae, and the papillary muscles. A defect in any of these components may create mitral insufficiency. A functional classification for mitral insufficiency was proposed by Carpentier,⁴⁰ who characterized three basic types of functionally diseased valves. Type I insufficiency occurs from annular dilatation or leaflet perforation with normal leaflet motion. Type II occurs from leaflet prolapse or ruptured chordae tendinae with increased leaflet motion, typically occurring in patients with degenerative disease. Degenerative causes include myxomatous degeneration and fibroelastic deficiency. With myxomatous degeneration, thickened excessive leaflet tissue is present, with leaflet prolapse occurring from chordal elongation or chordal rupture. The valve usually has a billowing appearance (Barlow's syndrome). By contrast, patients with fibroelastic deficiency have thinned leaflets and chordae, with chordal elongation or rupture. In both types, the mitral annulus is invariably dilated. Type III insufficiency occurs from restricted leaflet motion, with the leaflets not reaching the proper plane of closure during systole. Type III insufficiency typically occurs in rheumatic patients and in patients with chronic ischemic insufficiency.

In patients with rheumatic disease, the chordae tendinae are thickened and foreshortened, producing restrictive leaflet motion. Posterior dilatation of the mitral annulus also usually is present. With ischemic insufficiency, ventricular injury results in tethering of the mitral leaflets, producing restrictive leaflet motion, and central insufficiency, often with secondary annular dilation.

Pathophysiology

The basic physiologic abnormality in patients with mitral insufficiency is regurgitation of a portion of the LV stroke volume into the left atrium. This results in decreased forward blood flow and an elevated left atrial pressure, producing pulmonary congestion and volume overload of the left ventricle.

As mitral insufficiency progresses, there is a corresponding increase in the size of the left atrium, and eventually, atrial fibrillation results. Concurrently, the left ventricle dilates. Initially the LV stroke volume increases by Starling's law, but eventually, this compensatory mechanism fails, and the ejection fraction decreases. However, decreased systolic function of the heart is a relatively late finding, because the ventricle is "unloaded" as a result of the valvular insufficiency. Once LV dysfunction and heart failure develop, the left ventricle usually has been significantly and often irreversibly injured.

Clinical Manifestations

In patients with acute mitral regurgitation (MR), CHF develops suddenly, while in patients with chronic mitral insufficiency, the left atrium and ventricle become compliant, and symptoms do not develop until later in the course of the disease when the ventricle eventually fails, resulting in exertional dyspnea, decreased exercise capacity, and orthopnea. As LV dysfunction progresses, symptoms of pulmonary congestion become more prominent, ultimately resulting in pulmonary hypertension and right-sided heart failure.

On physical examination, the characteristic findings of mitral insufficiency are an apical holosystolic murmur and a forceful

apical impulse. The apical murmur usually is harsh and transmitted to the axilla (in cases of anterior leaflet pathology), or to the left sternal border (typically in cases of posterior leaflet pathology), although this is variable. However, the severity of the insufficiency may not correlate with the intensity of the murmur.

Diagnostic Studies

The severity of mitral insufficiency can be determined accurately with echocardiography, along with the site of valvular prolapse or restriction, and the level of LV function. An important measurement is the size of the cardiac chambers. The size of the left atrium reflects the chronicity and severity of the insufficiency. With severe, chronic mitral insufficiency, dilatation of the left atrium to 5 to 6 cm or greater is common. This is important because the propensity for atrial fibrillation is greatly increased when the left atrial size is >4.5 to 5 cm. The LV diastolic dimensions become enlarged relatively early because of volume overload, but LV systolic function is usually well maintained early in the course of the disease. Once the echocardiogram demonstrates a decrease in LV systolic function, manifested as a rise in the end-systolic dimension of the heart and a drop in the ejection fraction, this is an indication that the left ventricle is beginning to decompensate. If there is uncertainty about the physiologic significance of mitral insufficiency, exercise stress-echocardiography may be used. Normally the ejection fraction rises with exercise, but a fall in ejection fraction with exercise is an early sign of LV systolic dysfunction.

Indications for Operation

Delaying an operation until the patient is severely symptomatic and the heart is markedly dilated often results in a certain degree of irreversible ventricular injury. According to the American College of Cardiology/American Heart Association guidelines, MV repair or replacement is recommended in any symptomatic patient with mitral insufficiency, even with normal LV function (defined as ejection fraction >60% and end-systolic dimension <45 mm).⁴¹ Surgery also is currently recommended in asymptomatic patients with severe mitral insufficiency if there are signs of LV systolic dysfunction (increased end-systolic dimension or decreased ejection fraction). Recent onset of atrial fibrillation, pulmonary hypertension, or an abnormal response to exercise testing are considered relative indications for surgery.

MV surgery should be strongly considered in most patients while they remain asymptomatic, before significant LV dysfunction.⁴² A retrospective study by David and associates compared 289 symptomatic with 199 asymptomatic patients undergoing MV repair for degenerative disease.⁴³ Survival at 15 years was 76% for asymptomatic patients, identical to that for the general population matched for age and sex, compared to a survival of 53% for symptomatic patients.

OPERATIVE TECHNIQUES

The traditional approach for MV surgery is through a median sternotomy incision with CPB and cardioplegic arrest. The MV is exposed through a left atrial incision, made posterior and parallel to the intra-atrial groove. After the left atrial incision is made, self-retaining retractor blades are inserted to expose the MV. In certain patients, exposure through the posterior left atrial approach may not be optimal. This is particularly true in patients with a small left atrium, a deep chest, or an aortic prosthesis in place, and in reoperations in which the tissue is fixed and nonelastic. Alternative incisions for exposing the difficult MV include a right atriotomy with transseptal incision, a superior approach through the dome of the atrium, and a biatrial transseptal approach.

Commissurotomy

Once CPB has been established and the heart has been arrested, the left atrium is opened and the MV is visualized. Initially, the atrial cavity is examined for thrombi, especially within the atrial appendage. The MV is assessed by evaluating leaflet

mobility, commissural fusion, and the degree of fibrosis in the subvalvular apparatus. A right-angle clamp often is placed beneath the commissures, gently applying horizontal tension to evaluate commissural fusion.

Once the commissure has been accurately identified and the chordae noted, a right-angle clamp is introduced beneath the fused commissure, stretching the adjacent chordae and leaflets, after which the commissure is carefully incised. The incision is made 2 to 3 mm at a time, serially confirming that the separated margins of the commissural leaflet remain attached to chordae tendineae. The usual commissurotomy curves slightly anteriorly and does not go directly laterally. The incision should stop 1 to 2 mm from the valve annulus where the leaflet tissue becomes thin, indicating the transition from the fused commissure to the normal commissural leaflet of the MV. Once the commissurotomy is completed, any fused papillary muscle is incised as necessary to minimize restriction and improve mobility of the attached leaflet.

After separation of the commissure and mobilization of the underlying chordae tendineae and papillary muscle, leaflet mobility is assessed visually. The anterior leaflet is grasped with a forceps and moved throughout the entire range of motion, looking for subvalvular restriction or leaflet rigidity. In some patients, restricted motion may be further improved by dividing secondary chordae or by the selective débridement of calcium. Extremely thickened chordae can be mobilized by excision of a triangular portion of the fused cords. If extensive débridement and mobilization of the chordal structures are necessary, valve replacement usually is more appropriate. At least 30% of patients undergoing commissurotomy require more than simple incision of the commissure to produce an adequate mitral orifice and to restore mobility to the valve. Competence of the valve is assessed by injection of cold saline into the ventricle.

If the patient is in atrial fibrillation, the atrial appendage is closed with a continuous suture of 3-0 polypropylene to minimize the subsequent risk of emboli. Recently, intraoperative radiofrequency ablation procedures of the left atrium combined with MV surgery have become widely used in an attempt to convert these patients to sinus rhythm.

Mitral Valve Replacement

MV replacement is necessary when the extent of disease precludes commissurotomy or valve reconstruction. Valve replacement is most likely in patients with long-standing rheumatic disease. Once the valve is exposed and the need for valve replacement is determined, an incision is made in the anterior mitral leaflet, usually starting at the 12 o'clock position, and most of the anterior leaflet is resected. The posterior leaflet is preserved whenever possible, and the chordal attachments to both leaflets are preserved or reattached to the annulus, as this has been shown to improve LV function and lower the risk of posterior LV free wall rupture, a potentially lethal complication of valve replacement. However, chordal preservation is not always possible in patients with extensive rheumatic disease, because of extensive valvular thickening and calcification.

When the MV is excised, an appropriate-sized replacement valve is selected. This valve usually is attached with 12 to 16 mattress sutures. A pledgeted mattress suture technique is recommended because it minimizes the risk of perivalvular leakage. The sutures may be inserted from the atrial to the ventricular side, everting the annulus and seating the valve intra-annularly, or from the ventricular side to the atrial side, resulting in supra-annular positioning of the prosthetic valve. Care is taken to insert the sutures precisely into the annular tissue because excessively deep insertion of sutures may injure critical structures, including the circumflex coronary artery posterolaterally (from the surgeon's perspective, at 7 to 8 o'clock), the AV node anteromedially (at 1 to 2 o'clock), or the aortic valve anterolaterally (at 10 to 12 o'clock). Once the sutures are placed through the mitral annulus, they are placed through the valve sewing ring. The valve is then lowered onto the annulus and the sutures are tied and cut. The atriotomy incision is closed, and after air is removed from the cardiac chambers, the

aortic cross-clamp is removed and the heart is reperfused.

Mitral Valve Reconstruction

The basic techniques of MV reconstruction include resection of the posterior leaflet, chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection for repair of the anterior leaflet disease. An annuloplasty to correct associated annular dilation also is recommended in most cases.

The intraoperative assessment of the valvular pathology is an important step in valve reconstruction. A localized roughened area of atrial endocardium, termed a *jet lesion*, may be present from regurgitant blood striking the endocardium, providing a guide to the location of the insufficiency. Subsequently, the commissures are examined, noting whether these are prolapsed, fused, or malformed. The closing plane of the leaflets in the area supported by commissural chordae is determined next, and the anterior and posterior leaflets are then examined, noting areas of prolapse or restriction. Such abnormalities as perforation, fibrosis, calcification, or leaflet clefts also must be recognized. Finally, the degree of annular enlargement is assessed.

Proper evaluation of the degree of leaflet prolapse is critical. The "billowing" MV originally described by Barlow has excessive leaflet tissue, but may remain competent if the chordae are not elongated. In such cases, the rough free edge of the leaflet closes at the proper level, even though the midportion of the leaflet may contain excessive tissue. The anterolateral commissural chordae are seldom elongated, so elevating the commissural leaflet with a nerve hook provides a valuable reference point from which the degree of elongation of other chordae may be determined. Chordal rupture or total lack of structural support leads to prolapse and a completely flail leaflet.

Posterior Leaflet Procedures

Quadrangular resection of the posterior leaflet has become the mainstay of MV reconstruction (Figs. 21-11 and 21-12). A rectangular excision is performed, cutting directly down to, but not through, the mitral annulus. Diseased tissue in the posterior leaflet is excised with a quadrangular excision, usually removing 1 to 2 cm of tissue. Strong chordae of proper length are identified on each side of the excised leaflet and encircled with retraction sutures.

The *narrow arrow* indicates the posterior leaflet repair, while the *wide arrow* demonstrates the ring annuloplasty. Note the total correction of leaflet prolapse and annular dilation.

Once the quadrangular excision has been performed, the annulus of the excised segment of leaflet is corrected either by simple annular plication, folding plasty, or sliding plasty. The simple annular plication is performed with several interrupted sutures placed about 5 mm apart. These are started centrally and extended to include a few millimeters of annulus adjacent to the remaining leaflets. When these annular sutures are tied, the leaflet margins are automatically brought into apposition without any tension. If there were tension on the leaflet tissues, there would be a serious possibility of dehiscence of the subsequent leaflet repair. Once the annular sutures have been tied, the leaflet margins are approximated with simple or figure-of-eight sutures, usually 4-0 or 5-0 polypropylene, depending on the thickness of the leaflets.

The folding plasty technique, described by the group from New York University (NYU), involves folding down the cut vertical edges of the posterior leaflet to the annulus and closing the ensuing cleft.⁴⁴ With this technique the central height of the posterior leaflet is reduced, the edge of leaflet coaptation is moved posteriorly, and annular plication is either eliminated or reduced. This elimination of annular plication avoids the serious complication of circumflex artery kinking, which may occur in the setting of left dominant coronary artery circulation and a large posterior leaflet resection. The sliding plasty technique reported by Carpentier and associates also is successful in reducing posterior leaflet height and moving the edge of leaflet coaptation posteriorly.

Often, the valve appears quite competent after the leaflet repair has been completed. Gently injecting saline into the

ventricle with a bulb syringe and noting both the mobility of the leaflets and their apposition is an excellent visual guide for assessing competency. If localized insufficiency remains in other areas, additional procedures can be performed.

Anterior Leaflet Procedures

Four primary techniques are used for anterior leaflet reconstruction: chordal shortening, chordal transposition, artificial chordal replacement, and triangular resection of anterior leaflet tissue with primary repair. With chordal shortening, the elongated chord is imbricated either onto the free edge of the leaflet or onto the papillary muscle. In contrast, the chordal transposition technique uses a segment of structurally intact posterior leaflet directly opposite the prolapsed anterior leaflet. A small quadrangular excision of the posterior leaflet with the attached chordae is performed, and the mobilized leaflet and chordae are then transposed onto the anterior leaflet to provide structural support. The defect created in the posterior leaflet is then repaired in the manner described in the Posterior Leaflet Procedures section. Artificial chordae replacement has been used by some groups as an alternative for anterior leaflet repair, using polytetrafluoroethylene sutures that are attached to both the papillary muscle and the free edge of the prolapsing leaflet to re-establish structural support. Finally, triangular resection and primary repair has been increasingly used at NYU for treatment of anterior leaflet prolapse (Fig. 21-13). The adjacent intact chordae are identified, and triangular resection is performed to remove the prolapsing segment of the leaflet and any ruptured chordae. The technique is particularly helpful when a large amount of redundant anterior leaflet tissue is present, as in patients with myxomatous degeneration and Barlow's syndrome. Additionally, Gortex neochordae have shown excellent results for the treatment of prolapsing leaflet segments.⁴⁵

Repair of Leaflet Perforation

Leaflet perforations can be repaired by primary suture closure or by closure with a pericardial patch. Extensive leaflet destruction is best managed with MV replacement.

Annuloplasty

Use of a MV annuloplasty device (ring or partial band) to correct annular dilation during valve repair decreases the risk of late repair failure.⁴⁶ The primary purpose of an annuloplasty device is to correct the associated annular dilation that invariably occurs in patients with chronic mitral insufficiency, regardless of etiology, and results in worsening central insufficiency due to lack of leaflet coaptation. Various types of annuloplasty devices are available, including rigid or semirigid rings that geometrically remodel the annulus, flexible rings or bands that provide no geometric remodeling but restrict annular dilation while maintaining physiologic sphincter motion of the annulus, and semirigid bands that provide both annular remodeling and physiologic annular sphincter motion (Fig. 21-14). The relative advantages of the different types of devices remain under investigation, but it is widely accepted that use of an annuloplasty device to correct annular dilation improves long-term repair durability.

RESULTS

Commissurotomy

The operative risk for open mitral commissurotomy is <1%, and long-term results have been excellent. Choudhary and associates reported a 10-year freedom from MV failure after open commissurotomy of $87 \pm 3.5\%$.⁴⁷ The incidence of thromboembolism was only 0.5% per patient-year. Antunes and colleagues reported favorable long-term results after open commissurotomy in 100 patients with a mean follow-up of 8.5 years.⁴⁸ The 9-year actuarial freedom from reoperation was 98%, and 93% were in NYHA functional class I or II. Open mitral commissurotomy is a well-established procedure, allowing effective correction of mitral stenosis.

Balloon Valvuloplasty

Percutaneous mitral balloon valvuloplasty has recently been developed as an alternative treatment for mitral stenosis. The choice between surgical commissurotomy and balloon valvuloplasty varies widely among centers. The main advantages of commissurotomy over balloon valvuloplasty are that, during surgery, the fused chordae can be surgically divided and mobility restored.

A prospective and randomized study has suggested that percutaneous balloon valvuloplasty and surgical commissurotomy result in comparable clinical improvement in selected patients with mitral stenosis.⁴⁹ MV areas were larger early after surgical commissurotomy, but were similar after 24 months. Patients receiving balloon valvuloplasty require more rigid selection criteria, as the procedure becomes less effective if the patient has significant calcification of the valve or fusion of

the subvalvular apparatus.

Valve Replacement

The operative mortality rate for MV replacement is 2 to 6%, depending on the number of comorbidities present. The major predictors of increased operative risk after MV replacement are age, LV function, emergency operation, NYHA functional status, previous cardiac surgery, associated CAD, and concomitant disease in another valve. Mohty and associates reported late survival rates after MV replacement of $71 \pm 3\%$, $49 \pm 3\%$, and $29 \pm 4\%$ at 5, 10, and 15 years, respectively.⁵⁰ The major factors influencing long-term survival are age, urgency of operation, NYHA functional status, mitral insufficiency (vs. stenosis), ischemic etiology, pulmonary hypertension, and the need for concomitant coronary bypass or procedures on another valve.

Improved engineering of mechanical prostheses has produced valves with lower intrinsic thrombogenicity and better durability, resulting in fewer late valve-related complications. Khan and coworkers compared late results in 513 patients receiving mechanical valves with 402 patients receiving tissue valves.⁵¹ There was no difference in survival or in thromboembolic or anticoagulation-related complications between the groups. However, freedom from reoperation at 15 years was 98% with mechanical valves and 79% with tissue valves. Thus, while mechanical valves and tissue valves result in similar long-term survival, there is an increased risk of late reoperation in patients receiving tissue valves.

Valve Repair

The operative risk for MV repair is <1 to 2%, and late results have demonstrated that, compared to replacement, repair is associated with improved survival and better freedom from valve-related complications. A report on 1195 patients undergoing valve repair and ring annuloplasty demonstrated that the actuarial freedoms from complications at 5 and 10 years, respectively, were as follows: thromboembolic, 92 and 88%; anticoagulant-related complications, 98 and 96%; endocarditis, 97 and 96%; and reoperation, 91 and 84%.⁵² The need for anterior leaflet repair (as compared to posterior leaflet repair or annuloplasty alone) did not compromise the 5-year results in terms of patient survival, risk of reoperation, or freedom from valve-related complications. The freedom from reoperation, however, has been shown to be significantly better in nonrheumatic patients (93% at 5 years, 88% at 10 years) than in rheumatic patients (86% at 5 years, 73% at 10 years; $P < .005$).

Braunberger and associates reported long-term (20-year) results after mitral repair in 162 patients with nonrheumatic MV insufficiency.⁵³ The 20-year Kaplan-Meier survival rate was 48%, which is similar to the normal age-matched population. Freedom from cardiac death was 92 and 81% at 10 and 20 years, respectively. The linearized risk of reoperation rate was 0.4% per patient-year, although the need for anterior leaflet repair did decrease late repair durability. Repair of posterior leaflet prolapse resulted in a 98.5% freedom from reoperation at 10 years, while anterior leaflet repair had an 86.2% freedom from reoperation at 10 years ($P < .03$).

Mohty and associates reported the results of 679 MV repairs and 238 valve replacements performed at the Mayo Clinic between 1980 and 1995.⁵⁰ Survival after valve repair was better than after valve replacement ($68 \pm 2\%$ vs. $49 \pm 3\%$ at 10 years, and $37 \pm 5\%$ vs. $29 \pm 4\%$ at 15 years), with an adjusted odds ratio for death of 0.68 for repair vs. replacement ($P < .002$). The overall late risk of reoperation after valve repair was only 16% at 15 years.

Minimally Invasive Mitral Valve Surgery

Newer techniques that allow MV repair or replacement to be performed with a minimally invasive incision have been

increasingly used over the last decade. Most techniques employ either minithoracotomy or a partial sternotomy incision. At NYU, minimally invasive MV surgery has been performed through a small right anterior thoracotomy incision, entering the chest through the third or fourth intercostal space (Fig. 21-15). Others have used partial upper sternotomy, partial lower sternotomy, or parasternal incisions. The ascending aorta may be directly cannulated for perfusion, or cannulation may be performed through the femoral artery, while venous drainage for CPB may be achieved either directly from the right atrium or percutaneously from the femoral vein. Similar to traditional surgery, the operation is performed with moderate systemic hypothermia [28 to 30°C (82.4 to 86°F)] and cardioplegia is used for myocardial protection. The aorta may be directly occluded with a flexible or special long cross-clamp or occluded internally with a balloon catheter. Long instruments are required, but standard valve techniques are used.

Grossi and associates analyzed the initial NYU minimally invasive MV experience in 714 patients operated on between 1996 and 2001. Hospital mortality was 1.1% for isolated MV repair and 5.8% for isolated valve replacement. The risk of complications was similar to that reported with conventional surgery, although minimally invasive patients needed less blood and had less pain, fewer infections, a shorter hospital stay, and a quicker overall recovery.^{54,55} Galloway and colleagues reported late results after minimally invasive valve repair, demonstrating that repair durability, freedom from valve-related complications, and survival were equivalent to results achieved with the traditional sternotomy approach. Thus, the results after minimally invasive valve surgery are encouraging, and more widespread use of minimally invasive techniques is likely in the future.

NEW DEVELOPMENTS

Edge-to-Edge Repair

In 1995, Alfieri described the "double-orifice" or "edge-to-edge" repair as an alternative technique for repair for mitral insufficiency.⁵⁶ With this technique, the free edge of the anterior leaflet is sutured to the opposing free edge of the posterior leaflet, converting the valve into a double-orifice "bow tie." The edge-to-edge technique has been used for anterior leaflet

pathology, ischemic insufficiency, endocarditis, and dilated cardiomyopathy. This method may be used as a primary repair technique or as an alternative after incomplete correction with other methods. However, the late results after edge-to-edge repair are not well established, and some reports suggest that the edge-to-edge technique may negatively influence late repair durability.⁵⁷

Robotic Mitral Valve Surgery

Recent technologic achievements in optics and computerized telemanipulation have enabled robotically assisted MV operations. Chitwood and associates⁵⁸ and Mohr and associates⁵⁹ have reported encouraging results with robotically and videoscopically assisted MV repair, with femoral perfusion and a transthoracic aortic cross-clamp. The da Vinci robot is currently available for surgical use. It is a master-slave (console-effector) telemanipulation system equipped with a three-dimensional camera. It has been reported that the articulated wrist-like instruments and three-dimensional visualization of the da Vinci surgical system enable precise tissue telemanipulation. These systems still have significant limitations, however, and may not be readily adaptable to performing the multiple complex tasks necessary for valve surgery.⁶⁰ The large nationwide trial of the da Vinci robot for MV repair has reported good results, but a disappointingly high early valve repair failure rate.

Aortic Valve Disease

Effective surgical treatment of aortic valve disease became possible in 1960 with the development of satisfactory prosthetic valves by Starr and Edwards and by Harken and associates.

AORTIC STENOSIS

Etiology

In the adult North American population, the primary causes of aortic stenosis include acquired calcific disease, bicuspid aortic valve, and rheumatic disease. Acquired calcific aortic stenosis typically occurs in the seventh or eighth decade of life, and is the most frequent etiology, accounting for over half of the cases. Acquired calcific stenosis, also termed *degenerative aortic stenosis* or *senile aortic stenosis*, appears to be related to the aging process, with progressive degeneration leading to valve damage and calcification, although a causative role of lipids has been demonstrated recently. Lipid-lowering drugs seem to slow the progression of acquired calcific stenosis.

Bicuspid aortic valve accounts for approximately one third of the cases of aortic stenosis in adults, typically presenting in the fourth or fifth decade of life, after years of turbulent flow through the bicuspid valve result in damage and calcification.

The third major cause of aortic stenosis, rheumatic heart disease, accounts for approximately 10 to 15% of patients in North America, but is more common in underdeveloped countries. With rheumatic disease, the degree of stenosis progresses with time. Concomitant MV disease almost always is present, although not always clinically significant.

Pathophysiology

Generally, the aortic valve must be reduced to one third its normal cross-sectional area before significant hemodynamic changes occur. A normal aortic valve has a cross-sectional area of 2.5 to 3.5 cm². Moderate aortic stenosis is defined as an aortic valve area between 1.0 and 1.5 cm², while severe stenosis is defined as a valve area <1.0 cm².⁴¹ Patients with severe stenosis typically have a mean transvalvular pressure gradient >50 mmHg, although the gradient is dependent on both the valve area and the cardiac output, and therefore, may not be severely elevated if the cardiac output is low. Once the valve

area is $<0.5 \text{ cm}^2$, with a transvalvular gradient of 100 mmHg or greater, the degree of stenosis is considered critical.

Aortic stenosis results in increased myocardial work and progressive concentric LV hypertrophy with little ventricular dilatation. This results in a thick, noncompliant ventricle, leading to early diastolic dysfunction. The significance of diastolic dysfunction has been intensively studied and has been implicated as a major cause of CHF in patients with aortic stenosis. The systolic function of the ventricle usually remains well preserved for many years, but eventually deteriorates due to long-standing increased afterload.

Myocardial ischemia develops in some patients with severe aortic stenosis, usually in response to exercise. The LV mass and LV systolic wall tension are increased, resulting in increased oxygen demand. Simultaneously, the cardiac output often is low and does not increase in response to exercise. The end-diastolic pressure of the ventricle becomes progressively elevated during exercise, resulting in increased demand, but with poor perfusion of the subendocardium.

Clinical Manifestations

The classic symptoms of aortic stenosis include exertional dyspnea, decreased exercise capacity, heart failure, angina, and syncope. Once the patient becomes symptomatic, prompt operation is indicated. If heart failure, angina, or syncope is present, the need for surgery is more urgent, as the risk of death exceeds 30 to 50% over the next 5 years. Sudden death, which accounts for a significant number of fatalities from aortic stenosis, possibly due to arrhythmias, becomes a more likely threat once the patient becomes severely symptomatic.

The most common symptoms are exertional dyspnea and decreased exercise capacity (NYHA class II or III), which are indicative of progressive LV decompensation. The presence of NYHA class IV symptoms, manifest as CHF, orthopnea, pulmonary edema, and right-sided heart dysfunction, is a more ominous finding. Once CHF is present, the mortality approaches 40% over 2 to 3 years.

Angina pectoris, which may develop in patients with advanced disease, is a manifestation of increased LV mass and increased myocardial strain, resulting in subendocardial ischemia. Subclinical ischemic episodes may be associated with silent myocardial necrosis, and patients with little history and few prior symptoms may present with markedly depressed LV function, with large amounts of myocardium replaced by scar tissue.

Syncope may develop in patients with severe aortic stenosis secondary to the severe flow limitations imposed by the tightly stenotic valve and decreased cerebral blood flow. Syncope typically develops in response to exercise but may occur when patients vasodilate from any cause after minimal effort and with little warning. In a small proportion of patients, syncope results from heart block. The average life expectancy once angina or syncope has appeared is 3 to 5 years.

With auscultation, the principal finding is a harsh, diamond-shaped (crescendo-decrescendo) systolic murmur at the base of the heart (right second intercostal space) with radiation to the carotid arteries. The two components of the S_2 may become synchronous, or aortic valve closure may even follow pulmonic valve closure, causing paradoxical splitting of the S_2 . An S_4 gallop at the apex reflects the presence of LV hypertrophy or heart failure. The apical impulse has been described as a "prolonged heave," while the pulse pressure in the peripheral circulation is usually narrow and sustained (pulsus parvus et tardus).

Diagnostic Studies

On x-ray the heart size may be either normal or enlarged due to LV hypertrophy. Calcification of the valve often is visible in older patients. The ECG may demonstrate LV hypertrophy but may also be normal. Conduction abnormalities are common,

apparently from spicules of calcium projecting into the conduction bundle located at the base of the commissure between the right cusp and noncoronary cusp, and some patients may develop complete heart block. Atrial fibrillation generally indicates the presence of advanced disease with a prolonged elevation of intracardiac pressures.

The diagnosis of aortic stenosis is now most frequently made by echocardiography, which provides an accurate estimate of the peak and mean systolic transvalvular gradients, which allows calculation of the aortic valve area. Because the Doppler echocardiogram measures flow velocity, the peak instantaneous pressure gradient may overestimate the true peak gradient, and the mean gradient is usually more accurate. The echocardiogram also can demonstrate the amount of calcium in the leaflets, the degree of leaflet immobility, the left atrial size, the degree of LV hypertrophy, the end-systolic and end-diastolic dimensions of the left ventricle, and the LV function. Finally, the echocardiogram is important for identifying any occult subvalvular stenosis and for differentiating valvular stenosis from idiopathic hypertrophic subaortic stenosis (IHSS).

Cardiac catheterization readily confirms the diagnosis by measuring the aortic transvalvular gradient and permitting calculation of the cross-sectional area of the valve, but is often unnecessary for this purpose in the current era due to the accuracy of echocardiography. However, coronary angiography should be performed in patients >55 years of age and in patients at high risk for CAD. The degree of pulmonary hypertension also should be measured in patients with severe CHF and NYHA class IV symptoms.

Operative Indications

Patients with aortic stenosis typically respond well to aortic valve replacement, which immediately relieves the increased afterload. A special subgroup of patients includes those with critical aortic stenosis and advanced LV systolic dysfunction. These patients have an increased operative risk, but may still have significant improvement after valve replacement as long as the ventricle is not irreversibly damaged.⁶¹ Echocardiographic signs of LV dysfunction must be carefully assessed even in asymptomatic patients, because it is well documented that once ventricular systolic dysfunction occurs, symptoms progressively develop within 1 to 2 years, with CHF and ventricular damage progressing thereafter.

Aortic valve replacement is indicated for virtually all symptomatic patients with aortic stenosis. Even in patients with NYHA class IV symptoms and poor ventricular function, surgery has been found to improve both functional status and survival. In asymptomatic patients with moderate to severe stenosis, periodic echocardiographic studies are performed to assess the transvalvular gradient, valve area, LV size, and LV function. Surgery is indicated with the first sign of LV systolic dysfunction, manifest on echocardiography as either a rise in the LV end-systolic size or a drop in the LVEF. Surgery also may be recommended for asymptomatic patients with aortic stenosis who have a progressive increase in the transvalvular gradient on serial echocardiographic studies, a rapid rise in diastolic dimensions, a valve area $<0.80 \text{ cm}^2$, progressive pulmonary hypertension, or right ventricular dysfunction during exercise testing.

AORTIC INSUFFICIENCY

Etiology and Pathology

A variety of diseases can produce aortic valve insufficiency, including degenerative diseases, inflammatory or infectious diseases (endocarditis, rheumatic fever), congenital diseases, aortoannular ectasia or aneurysm of the aortic root, and aortic dissection. Mixed valvular stenosis and insufficiency can develop in any patient with aortic stenosis, regardless of etiology.

Degenerative valvular disease is a manifestation of fibroelastic deficiency or myxomatous degeneration that produces thin and elongated valvular tissue. The aortic valve leaflets sag into the ventricular lumen, often with no other tissue abnormality,

producing central aortic insufficiency. The gross and histologic appearances suggest that this is a variant of the more common MV prolapse.

Infectious and inflammatory etiologies of aortic insufficiency include bacterial endocarditis and rheumatic fever. Streptococci, staphylococci, or enterococci are the most common bacteria involved, in decreasing order of frequency. Syphilis is increasingly rare. Rheumatic fever often produces mixed stenosis and insufficiency but may produce aortic insufficiency alone. Concomitant MV disease is invariably present.

Patients who have a congenitally bicuspid aortic valve rarely become symptomatic during childhood, but prolonged turbulence may lead to aortic stenosis, mixed stenosis and insufficiency, or pure insufficiency later in life. Congenital causes of aortic insufficiency account for 10 to 15% of the patients operated on for aortic insufficiency as adults. Congenital aortic insufficiency may also occur secondary to subaortic VSD, with valvular insufficiency developing from a Venturi effect that results in prolapse of the aortic valve leaflet into the septal defect.

Aneurysmal dilation of the aortic root is thought to be secondary to idiopathic or known connective tissue disorders, with the idiopathic variety seen with increasing frequency as the average age of the population increases. In the less severe forms of degenerative diseases of the aorta, such as idiopathic cystic medial necrosis, there may be a localized aneurysm in the ascending aorta or aortic root, with or without associated aortic valve insufficiency, depending on the degree of distortion of the sinotubular junction. Aortoannular ectasia with aneurysm of the aortic root occurs in its most extreme form in patients with Marfan syndrome or Ehlers-Danlos syndrome. These connective tissue disorders involve defective genes coding for fibrillin cross-linkage or collagen synthesis, resulting in extensive weakness within the aortic wall with frequent involvement of the aortic root. A common presentation is aneurysmal dilation of the entire aortic root with concomitant aortic valve insufficiency. These patients also have an increased risk of aneurysmal disease elsewhere in the aorta, a high incidence of MV prolapse, and a greatly increased risk of aortic dissection. Typically, the aortic root gradually enlarges, starting in the sinuses of Valsalva and progressing until the entire root is involved. Valvular insufficiency results from dilatation of both the aortic sinotubular junction and the aortic valve annulus. The size and shape of the aneurysm is characteristic, resembling an inverted, truncated cone, with the narrow apex in the mid-to-distal ascending aorta and a large dilated aortic root.

Acute aortic dissection may produce aortic valve insufficiency by detachment of the commissures and prolapse of the valve cusps, usually involving the noncoronary cusp and the commissure between the left and right cusps. In patients with chronic dissection, the sinotubular junction is usually dilated and distorted, producing leaflet prolapse and valvular insufficiency. Both the aortic root and ascending aorta may be aneurysmal secondary to the chronic dissection.

Pathophysiology

With aortic valve insufficiency, blood regurgitates into the left ventricle during diastole, producing LV volume overload (increased preload). The ventricle compensates by the Starling mechanism and increases the LV stroke volume during systole. A widened pulse pressure and low diastolic pressure result in diminished coronary perfusion, while oxygen demand is increased secondary to the large stroke volume and increased cardiac work. Progressive valvular insufficiency results in ventricular dilation and eccentric LV hypertrophy, with the heart initially compensating to maintain a normal ratio of wall thickness to cavity size. Because ventricular compliance is normal, the LV diastolic pressure does not increase initially, and the patient usually remains asymptomatic for a long period of time despite significant diastolic volume overload. As the heart continues to dilate, however, the ventricular muscle can no longer compensate and the ratio of wall thickness to cavity size decreases. The systolic wall tension required for ejection eventually exceeds the ability of the ventricular muscle to contract,

resulting in "afterload mismatch" and progressive systolic dysfunction. Further progression leads to LV failure and pulmonary hypertension. In the advanced stages, fibrosis develops within the myocardium, which further contributes to systolic dysfunction, ultimately resulting in a dilated myopathic ventricle.

Clinical Manifestations

Symptoms develop at variable rates in patients with aortic insufficiency, depending on the acuity and severity of the insufficiency and the compliance and strength of the heart muscle. Frequently, the patient who gradually develops moderate to severe insufficiency remains asymptomatic for many years, often 10 or more. Once symptoms appear, however, ventricular function usually is significantly depressed and rapid clinical deterioration occurs over the next 4 to 5 years. The terminal illness usually is progressive heart failure and arrhythmias.

The most common symptoms are dyspnea on exertion and decreased exercise capacity. These symptoms gradually increase in severity as the ventricle deteriorates. Palpitations are also common, apparently arising from forceful contraction of the dilated left ventricle. NYHA class IV symptoms, angina, and right heart failure occur with advanced disease or with severe incompetence in which the regurgitant flow exceeds 50% of forward flow.

Palpation reveals an enlarged heart and a prominent cardiac impulse described as a *forceful thrust*, with the point of maximal impact displaced inferiorly and leftward. The hallmark of aortic insufficiency is a high-pitched decrescendo diastolic murmur heard best in the left third intercostal space with the patient erect and leaning forward. The length of the murmur may correspond with the severity of the insufficiency, but the intensity does not. If the murmur is loudest to the right of the sternum, aortoannular ectasia is likely. A light systolic ejection murmur due to increased flow across the aortic valve may also be present. An S₃ gallop, if present, is indicative of heart failure. A middiastolic rumble at the apex that simulates mitral stenosis has been described, the Austin Flint murmur. This murmur is produced by the aortic insufficiency impeding the opening of the MV during diastole.

Examination of the peripheral arterial circulation may reveal several abnormalities. The pulse pressure is widened, partly from an increase in systolic pressure, but principally from a decrease in diastolic pressure, which may be in the range of 30 to 40 mmHg. The true diastolic pressure, measured by direct arterial puncture, is never <30 to 35 mmHg, even though, on auscultation, a diastolic pressure of zero may be obtained in some patients. Peripheral pulses usually are forceful, bounding, and quickly collapsing, termed *Corrigan's* or *water-hammer pulses*. "Pistol shot" sounds may be heard with the stethoscope over peripheral arteries. A wide variety of other auscultatory phenomena have been described, some over a century ago, all indicating vasodilatation and a hyperdynamic peripheral circulation.

Diagnostic Studies

The chest x-ray usually shows impressive cardiac enlargement, with the apex displaced downward and to the left and a markedly enlarged cardiac-thoracic ratio. The ECG is normal early in the disease, but with cardiac enlargement, signs of LV hypertrophy become prominent. Sinus rhythm usually is present initially, although atrial fibrillation is common later in the course of the disease.

Echocardiography, which measures the degree of valvular insufficiency, the LV end-diastolic and end-systolic dimensions, the left atrial size, and the LV function, is the primary diagnostic tool. The echocardiogram also is used to assess the degree of mitral or tricuspid insufficiency and estimate the PA pressure.

The classic finding on cardiac catheterization is the reflux of contrast material from the aortic root into the ventricle with

aortic root angiography, graded from 1+ to 4+. However, due to the accuracy of current echocardiography, angiographic studies to diagnose aortic insufficiency are no longer necessary in most cases. Aortic root angiography or MRI studies may be performed if aneurysmal disease is suspected. If surgery is planned, coronary angiography should be performed to rule out CAD in patients with appropriate risk factors. In patients with heart failure the LV end-diastolic pressure may be elevated to 15 to 20 mmHg and sometimes higher, with an associated rise in the PA pressure.

Operative Indications

The development of symptoms is an absolute indication for surgery in patients with aortic insufficiency. It has long been recognized, however, that postponing surgery until the patient becomes severely symptomatic is potentially dangerous, as many patients will have already developed substantial ventricular enlargement and cardiac dysfunction by that time. Therefore, echocardiographic studies are routinely used to determine the appropriate timing for surgical intervention, which should be performed before the development of symptoms and before the ventricular function severely deteriorates. Asymptomatic patients with severe aortic insufficiency should be referred for surgery at the first sign of deteriorating LV systolic function on echocardiography, which manifests as a rise in the end-systolic dimension of the ventricle or by a drop in the ejection fraction. Operative results indicate that cardiac function will return to normal and long-term survival will be improved significantly if an operation is done at this stage.

In the authors' experience, valve replacement should be performed even in patients with low ejection fractions and advanced NYHA class IV symptoms, especially if recruitable ventricular wall motion is present with inotropic stimuli. Most class IV patients will improve significantly after surgery, although the degree of improvement may be uncertain for 6 to 12 months. Intensive postoperative medical therapy with a heart failure regimen that includes afterload reduction, low-dose beta blockers, and diuretics is beneficial in this group of patients to help remodel the left ventricle. Because ventricular arrhythmias are a common cause of death in patients with markedly depressed LV function, evidence supports routine electrophysiologic testing and implantation of an automatic internal cardiac defibrillator (ICD) if inducible arrhythmias are present.

OPERATIVE TECHNIQUES

Aortic Valve Replacement

Aortic valve replacement has traditionally been performed through a median sternotomy incision, and this approach remains the standard in most cardiac centers. CPB with moderate systemic hypothermia is used, the aorta is cross-clamped, and the heart is protected by cardioplegia delivered antegrade into the aortic root directly into the coronary ostia by hand-held cannulas, or retrograde through the coronary sinus. Typically, a LV vent is inserted through the right superior pulmonary vein to keep the field free of blood during the procedure and to aid in deairing after blood flow is re-established to the heart.

After the heart has been arrested, an oblique or hockey-stick-shaped aortotomy incision is made, beginning approximately 1 cm above the right coronary artery and extending medially toward the PA and inferiorly into the noncoronary sinus. The aortic valve is excised totally (Fig. 21-16), removing all leaflets and any fragments of calcium present in the annulus. A gauze pack may be placed in the ventricle before removal of the valve to minimize the risk of calcium spillage and embolization. Serial irrigations of the ventricle are performed after removal of the valve and débridement of calcium.

Operation for calcific aortic stenosis. **A.** Operative photograph of calcific aortic stenosis seen through an oblique aortotomy incision. **B.** Excised aortic valve. The valve leaflets were completely immobile and fixed in the midposition, producing a mixture of aortic stenosis and aortic insufficiency. **C.** After excising the valve, pledget reinforced mattress sutures have been placed into the aortic valve annulus. The sutures will be subsequently placed through the sewing ring of the prosthetic valve. **D.** Porcine valve in the aortic position before closure of the aortotomy incision.

At NYU, pledgeted horizontal mattress sutures are routinely used, as this technique is thought to minimize the risk of paravalvular leakage. Other suturing techniques for placement of the valve include simple interrupted sutures, figure-of-eight sutures, and continuous sutures. Care is taken to avoid damage to the coronary ostia, to the conduction bundle adjacent to the membranous septum between the right and the noncoronary valve cusps, and to the MV posteriorly. The valve may be seated on the annulus in either of two ways. For supra-annular placement (Fig. 21-17), the sutures are placed from below the annulus in an upward direction, through the annulus, and then through the valve sewing ring. For intra-annular placement, the sutures are placed from above the annulus downward and then back up through the sewing ring, which results in the valve resting completely within the annulus.

Aortic valve replacement. Supra-annular placement of a St. Jude Hemodynamic Plus valve in the aortic position.
(Illustration courtesy of St. Jude Medical, Inc., St. Paul, MN. All rights reserved.)

Mechanical valves are widely used in younger patients. Two configurations are available, a single tilting disk and a bileaflet disk. The flow characteristics are extremely good with all current mechanical valves, and even better in newer designs that allow supra-annular valve placement and therefore increase the effective orifice size that can be implanted for a particular sized annulus. The flow characteristics of the valve become important when the aortic annulus is small to minimize the postoperative gradient across the smaller prosthesis. Patients with mechanical valves routinely require lifelong anticoagulation with warfarin to minimize the risk of thromboembolic complications.

Tissue valves are most commonly used in older patients, although they now are increasingly used in younger patients who want to avoid the need for long-term anticoagulation therapy. Tissue valves may be either stented or stentless, with the traditional stented valves being easier to implant, and the stentless valves having better flow characteristics, particularly in smaller valve sizes. Current tissue valves have a projected durability of 15 years or longer and do not require long-term anticoagulation.

However, a small aortic root may be a particularly difficult problem when tissue valves are placed, as the stented tissue valves have relatively poor flow characteristics in smaller sizes. This can potentially result in patient-prosthesis mismatch, which may occur if the implanted prosthesis is equal to or <19 mm and the patient's body surface area is >1.7 m², or when the prosthetic valve area is <0.85 cm²/m². Controversy exists regarding the impact of small prosthetic valves on late survival, although avoiding patient-prosthesis mismatch clearly results in better postoperative LV mass regression. Surgical options to avoid patient-prosthesis mismatch include use of valves that have better flow characteristics in small sizes, such as supra-annular mechanical valves, stentless tissue valves, or homografts. Alternately, a larger size stented tissue valve can be placed using procedures to enlarge the aortic annulus.

Results

The operative risk for aortic valve replacement is 1 to 5% for most patients, but may be considerably higher in elderly patients with multiple comorbidities and in patients with severely depressed LV function. Chaliki and associates³¹ reported that aortic valve replacement in patients with aortic insufficiency and poor LV function (ejection fraction <35%) resulted in increased operative risk, 14% compared to 3.7% in patients with ejection fractions >50%. Ten-year survival was 70% in patients with good ventricular function, but only 42% in patients with ejection fractions <35%.

The STS National Database lists the clinical variables affecting the operative risk associated with valve surgery. The major risk factors are age, body surface area, diabetes, renal failure, hypertension, chronic lung disease, PVD, cerebrovascular accident, infectious endocarditis, prior cardiac operation, MI, cardiogenic shock, NYHA functional status, and elevated PA mean pressure. The overall incidence of perioperative stroke is 2.8 to 4.8%.

The 10-year survival after aortic valve replacement in patients <65 years of age exceeds 80% but may be significantly worse in patients with severely impaired ventricular function. The factors affecting late survival are age, NYHA functional status, ventricular function, concomitant CAD, concomitant disease in another valve and diabetes, previous MI, CHF, and urgent or emergent surgery.

Postoperative Care

Postoperative care is usually uneventful after aortic valve replacement in patients with normal LV function. However, patients with significantly reduced LV function may have a complicated postoperative course. Arrhythmias are relatively common, and continuous ECG monitoring is required for the first 48 hours. Anticoagulation therapy is started 1 day after mechanical valve replacement, targeting an INR of 2.5 to 3 times normal. Antiplatelet therapy with aspirin is used in patients with tissue valves, homografts, or autografts. The postoperative hospital stay is usually approximately 5 days, depending on the patient's age and overall physical condition. Early cardiac rehabilitation is particularly helpful in elderly patients.

Except for patients with severe ventricular dysfunction, most patients become asymptomatic and regain a normal range of physical activity within 1 to 2 months after operation. Periodic medical evaluations should be instituted for all patients because of the problems inherent with use of any prosthetic valve. The patient should have long-term monitoring for proper anticoagulation therapy (with the INR followed in patients on warfarin), and the valve function should be periodically assessed by echocardiography. Thromboembolism, anticoagulant-related hemorrhage, endocarditis, and prosthetic valve failure are the principal late complications. Both thromboembolism and anticoagulant-related hemorrhage occur with incidences of 1 to 2% per year after mechanical valve replacement, despite careful anticoagulation therapy and monitoring. Patients with tissue valves have a risk of thromboembolism of 0.5 to 1% per year, but anticoagulant-related hemorrhage is less common because warfarin is not required. Endocarditis remains an infrequent but serious late hazard after valve replacement, and routine antibiotic prophylaxis is recommended lifelong for any invasive procedure that might produce a transient bacteremia.

Aortic Valve Repair

Aortic valve repair rarely has been used as the primary treatment for aortic insufficiency because of the high risk of late repair failure. Recently, however, David, Yacoub, and Casselman independently described different techniques for valve repair in patients with aortic insufficiency, with encouraging results.^{62–64}

David's approach is based on the principle that aortic insufficiency in patients with aortoannular ectasia is secondary to

annular dilatation and distortion of the sinotubular junction. David's approach involved excising the aneurysmal portion of the aortic root and reimplanting the aortic valve inside a tubular Dacron graft, using a technique similar to homograft implantation, with reimplantation of the coronary arteries. Late results were reported in 230 patients who underwent aortic valve-sparing operations for aortic insufficiency. The 8-year survival was 83% and the 8-year freedom from reoperation was 99%.

Yacoub reported a similar valve-sparing technique for patients with annuloaortic ectasia. With Yacoub's technique the aortic wall and sinuses of Valsalva are excised down to the anatomic annulus. The Dacron graft is sutured to the annulus, the valve is resuspended, and the coronary buttons are reimplanted.

The technique described by Casselman and associates for repair of aortic insufficiency in patients with bicuspid aortic valves involves triangular resection of the redundant segment of the involved valve cusp in an attempt to achieve cusp symmetry, followed by annular plication of one or both commissures. Results were reported after repair in 94 patients. The freedom from reoperation was 95%, 87%, and 84% at 1, 5, and 7 years, respectively.

Ross Procedure

The Ross procedure involves replacement of the aortic valve with an autograft from the patient's native pulmonary valve. The resected pulmonary valve is then replaced with a pulmonary homograft. Variations of the technique of implantation of the autograft for the aortic valve replacement include free-hand replacement with resuspension of the valve commissures, and cylinder root replacement with reimplantation of the coronary artery ostia (see Fig. 21-9).

The cylinder root replacement technique is the most reproducible. With this method, the native aorta is transected 5 mm above the sinotubular ridge. The aortic valve leaflets and the aortic tissue in the sinuses of Valsalva are totally removed, preserving the left main and right coronary arteries on buttons of aortic tissue. The main PA is transected at the bifurcation, and a separate incision is made below the pulmonary valve in the right ventricular outflow tract. The pulmonary valve and artery are enucleated en bloc from the outflow tract bed, with care being taken to avoid injury to the first septal perforator as the valve is removed from the septum medially. The pulmonary autograft annulus is sutured to the aortic annulus with continuous or interrupted sutures, and the coronary arteries are reimplanted into the autograft. The pulmonary valve and right ventricular outflow are reconstructed in standard fashion with a homograft.

The Ross procedure has risks similar to those associated with standard aortic valve replacement, although the risk of bleeding may be slightly higher. The primary benefit is that patients do not require long-term anticoagulation and the risk of thromboembolism is negligible. Midterm durability of both the autograft and the pulmonary homograft has been good at 7 to 12 years postoperatively. Paparella and associates reported results in 155 patients, with an 86% 7-year period of freedom from severe recurrent insufficiency. However, progressive late aortic insufficiency has been described in a number of patients, along with calcification of the pulmonary homograft and pulmonary stenosis.⁶⁵ The risk of late reoperation ranges from 30 to 50% at 15 to 20 years.

Minimally Invasive Aortic Valve Surgery

Minimally invasive approaches for aortic valve surgery have recently become an acceptable alternative to conventional median sternotomy. Both ministernotomy and minithoracotomy approaches have been used with excellent success.^{66,67} Although the proposed benefits of minimally invasive aortic valve replacement remain controversial, several centers have reported results that are at least comparable to standard surgery, but with less need for blood transfusions and shorter

hospital stays. Recent review of the extensive NYU experience demonstrated a survival advantage for this minimally invasive approach for high-risk patients requiring aortic valve surgery over the last decade.³²

At NYU, minimally invasive aortic valve replacement is performed through a right anterior minithoracotomy incision, with central aortic cannulation and vacuum-assisted venous drainage. An external cross-clamp is applied directly to the aorta, and the heart is protected with traditional cardioplegic methods. This approach has now been used in >1000 patients. A report by Grossi and colleagues demonstrated that patients treated with the minimally invasive approach had less need for blood transfusions, fewer infections, and a shorter hospital stay than matched patients receiving traditional surgery.⁵⁴ Sharony and coworkers reported results in elderly patients, demonstrating shorter hospital stay and rehabilitation time.⁶⁷ Thus, minimally invasive approaches for aortic valve replacement appear promising and deserve further investigation.

Idiopathic Hypertrophic Subaortic Stenosis

Patients with hypertrophic cardiomyopathy or IHSS have varying degrees of subaortic LV outflow tract obstruction, usually associated with systolic anterior motion of the MV. Systolic anterior motion of the valve has been explained by the presence of Venturi forces created by the high-velocity flow in the narrowed outflow tract, which pulls the adjacent anterior leaflet of the MV into the outflow tract, worsening outflow obstruction. The subaortic obstruction may have a dynamic component and can usually be provoked with volume depletion, vasodilators, or inotropes. The intracavitary pressure of the left ventricle is usually markedly elevated, and the ventricle is hypercontractile with impaired diastolic relaxation. The degree of LV outflow tract obstruction at rest is a strong predictor of progression to severe symptoms of heart failure and death. However, most patients with hypertrophic cardiomyopathy and subaortic obstruction will respond to medical therapy, and only a minority will require surgical intervention.

OPERATIVE TECHNIQUES

Surgical septal myotomy and myectomy, developed by Morrow, has shown consistent results and remains the primary technique for treatment of IHSS.⁷⁰ This approach requires resection of a trough of muscle from the subaortic outflow tract. Typically, the resection is 1 cm wide and 1 cm deep, and extends the length of the septum to below the lower edge of the anterior leaflet of the MV. The resected trough should remain leftward of the right coronary ostium to avoid heart block but should routinely produce a left bundle-branch block. A modification of the Morrow myectomy, termed *extended myectomy*, involves mobilization and partial excision of the papillary muscles. The extended approach has been suggested to resect the deeper portion of the septal bulge and redirect the flow medially and anteriorly away from the MV, abolishing systolic anterior motion. However, there are few data to suggest that the extended myectomy procedure improves late outcomes.

Tricuspid Stenosis and Insufficiency

Acquired TV disease can be classified as *organic* or *functional*. Organic disease is almost always a result of either rheumatic fever or endocarditis. In patients with rheumatic disease, tricuspid stenosis or insufficiency virtually never occurs as an isolated lesion, but only in association with extensive disease of the MV. With mitral disease, the frequency of associated tricuspid disease is 10 to 15%, although an incidence as high as 30% has been reported. Rarely, blunt trauma produces rupture of a papillary muscle or chordae tendineae with resultant tricuspid insufficiency.

Functional tricuspid regurgitation is much more common than insufficiency from organic disease. Functional tricuspid regurgitation develops from dilatation of the tricuspid annulus and right ventricle as a result of pulmonary hypertension and right ventricular failure. These abnormalities usually result from MV disease or from other conditions that result in LV failure

and pulmonary hypertension.

With tricuspid stenosis, the pathologic changes are similar to those found with the more familiar mitral stenosis, with fusion of the commissures. Because right atrial pressure is normally only 4 to 5 mmHg, significant tricuspid stenosis may be present with a valve orifice considerably larger than that seen with mitral stenosis. With rheumatic disease, mixed tricuspid stenosis and insufficiency or pure insufficiency may result from fibrosis and contraction of the valve leaflets, often in association with shortening and fusion of chordae tendineae. Calcification is rare.

Functional dilatation of the tricuspid annulus results in tricuspid insufficiency. The valve leaflets appear stretched, but otherwise are pliable and seemingly normal, even though serious regurgitation is present. The dilatation and deformity of the annulus are irreversible. Valves with severe functional insufficiency and a markedly dilated annulus usually do not regain competency, even after the MV disease is corrected and PA systolic pressure returns to normal.

PATHOPHYSIOLOGY

With tricuspid stenosis or severe insufficiency, the mean right atrial pressure becomes elevated to 10 to 20 mmHg or higher. The higher pressures are found with a TV orifice $<1.5 \text{ cm}^2$ and a mean diastolic gradient between the atrium and ventricle of 5 to 15 mmHg or in patients with pulmonary hypertension and severe insufficiency. When the mean right atrial pressure remains $>15 \text{ mmHg}$, hepatomegaly, ascites, and leg edema usually appear.

CLINICAL MANIFESTATIONS

The symptoms and signs of TV disease are similar to those of right heart failure resulting from MV disease. They result from chronic elevation of right atrial pressure above the range of 15 to 20 mmHg. Clinical manifestations include jugulovenous distention, hepatomegaly, pedal edema, and ascites. With long-standing severe tricuspid insufficiency, hepatic dysfunction and clotting abnormalities may develop.

The characteristic murmur of tricuspid stenosis is best heard as a diastolic murmur at the lower end of the sternum. It is a low-pitched murmur of medium intensity and can easily be overlooked because it is well localized at the lower end of the sternum. During inspiration, the intensity of the murmur increases as the volume of blood returning to the heart is temporarily raised by an increase in intrathoracic negative pressure. Tricuspid insufficiency produces a prominent systolic murmur heard best at the left lower sternal border. The murmur often is found in association with an enlarged, pulsating liver and prominent and engorged jugular veins. A prominent jugular venous pulsation, especially when the cardiac rhythm is sinus, may be the best clue to unsuspected tricuspid disease. A hepatojugular reflex also may be noted.

DIAGNOSTIC STUDIES

The x-ray shows enlargement of the right atrium and right ventricle. Echocardiography confirms the diagnosis and differentiates stenosis from insufficiency. Cardiac catheterization is no longer necessary in most cases.

INDICATIONS FOR SURGERY

Indications for surgery are based primarily on clinical findings, which are correlated with echocardiographic findings and hemodynamics. Severe insufficiency is indicated by echocardiography when the area of the regurgitant jet occupies a large part of the atrium, the effective regurgitant orifice is $>40 \text{ mm}^2$, or the width of the vena contracta (narrowest flow) is $>6.5 \text{ mm}$.⁷¹ Severe tricuspid regurgitation should clearly be repaired because it has been widely demonstrated that annuloplasty provides excellent late results with little added morbidity. Mild degrees of tricuspid insufficiency are usually left alone,

especially in the absence of pulmonary hypertension, while repair of moderate insufficiency requires further consideration of the clinical findings and symptoms present. However, effective TV repair minimizes the risk of late right-sided heart failure and reoperation.

OPERATIVE TECHNIQUES

In the small minority of patients whose tricuspid stenosis is secondary to pure commissural fusion, a commissurotomy may be performed, usually combined with an annuloplasty. More commonly, valve replacement is necessary when significant tricuspid stenosis is present because the entire valve and subvalvular apparatus are damaged. When a prosthetic valve is inserted, care is required in suture placement along the septal leaflet where the conduction bundle is located, and sutures should be placed more superficially in this area.

In patients with functional tricuspid insufficiency, the annulus is markedly dilated while the leaflets appear entirely normal. Virtually all such patients can be treated by annuloplasty. The suture annuloplasty techniques proposed by Kay and Boyd and the De Vega annuloplasty technique have been highly reliable. Alternatively, a flexible or rigid annuloplasty device may be used.

RESULTS

Data on more than 300 patients from the authors' institution show that the suture annuloplasty repair for functional tricuspid insufficiency is reproducible in the absence of significant intrinsic leaflet disease. Valve repair using a posterior suture annuloplasty technique was 98% durable at 7 years. Similar results have been reported with the De Vega annuloplasty.⁷² Other centers prefer the use of rigid or flexible annuloplasty devices for correction of tricuspid insufficiency, especially if the right heart pressures are expected to remain chronically elevated.

When TV replacement is required, the options include use of either a tissue valve or a mechanical valve. Carrier and associates reported follow-up on 97 patients who underwent TV replacement with either tissue valves ($n = 82$) or mechanical valves ($n = 15$).⁷³ The 5-year freedom from reoperation was 92% in patients with mechanical valves and 97% in patients with tissue valves ($P = .2$). Data suggest that the risk of valve thrombosis is increased in mechanical valves placed in the tricuspid position, as emphasized in a report by Kawano and colleagues that demonstrated a 30% risk of mechanical valve thrombosis in the tricuspid position over 15 years, with a linearized rate of 2.9% per patient-year.⁷⁴ Bioprostheses are therefore preferred for most patients requiring TV replacement.

Multivalve Disease

Disease involving multiple valves is relatively common, particularly in patients with rheumatic disease. Prominent signs in one valve can readily mask disease in others. With aortic valve disease, functional mitral insufficiency can result from a progressive rise in the LV end-diastolic pressure and volume. Similarly, MV disease may result in pulmonary hypertension, right heart failure, and functional tricuspid insufficiency. Often these secondary functional changes resolve without treatment if the primary pathology is corrected in a timely fashion. Certainly, multiple-valve surgery has a higher operative risk than single-valve procedures, in part because the condition often represents more advanced disease and is associated with significant cardiac dysfunction.

In a 1992 report by Galloway and colleagues, 513 patients with multiple-valve disease treated surgically between 1976 and 1985 were studied to assess factors influencing operative risk and long-term survival.⁷⁵ Three groups accounted for the majority of the cases: 58% had aortic valve and MV disease, 29% had MV and TV disease, and 12% had triple-valve disease

(aortic, MV, and TV). Preoperative CHF was present in 91%, 41% were NYHA class III, and 54% were NYHA class IV. The average PA systolic pressure was 60 mmHg. Despite chronic symptoms and severe disease, the overall operative mortality rate was 12.5% and the 5-year survival rate was 67%. The variables predicting decreased survival time were systolic PA pressure, age, triple-valve procedures, concomitant coronary bypass grafting, previous heart surgery, and diabetes. After operation, 80% of the patients improved to NYHA class I or II, demonstrating that most patients will have significant clinical improvement despite advanced symptoms preoperatively. The 5-year freedom from late cardiac-related death or complications was 82%.

AORTIC AND MITRAL VALVE DISEASE

Nine combinations of valvular pathology can produce aortic and MV disease because each valve can be stenotic, insufficient, or both. Stenosis in both valves may lead to underestimation of the degree of aortic stenosis, because return of blood to the left ventricle is limited as a result of mitral stenosis. Aortic insufficiency, which produces the Austin Flint murmur, might overshadow and mask true mitral stenosis. With functional mitral insufficiency resulting from severe aortic disease, aortic valve replacement can lead to resolution of insufficiency in some patients, but patients with more severe mitral insufficiency may require mitral repair or replacement. Patients presenting with aortic valve and MV disease should be examined closely for these and other considerations.

MITRAL AND TRICUSPID VALVE DISEASE

Multiple combinations of valvular pathology are possible with mitral and tricuspid disease, but mitral disease with functional tricuspid insufficiency is the most common scenario, resulting from chronic pulmonary hypertension and right heart failure. The presence of associated tricuspid insufficiency increases the operative risk for patients undergoing MV surgery. The risk for isolated MV and TV disease is approximately 6%.

TRIPLE-VALVE DISEASE

Triple-valve surgery can be challenging because the clinical condition usually is a result of chronic aortic and mitral disease with severe pulmonary hypertension, biventricular failure, and functional tricuspid insufficiency. Occasionally, rheumatic disease affects all three valves. The degree of pulmonary hypertension is the most significant predictor of survival in patients with triple-valve disease. The operative mortality for 61 triple-valve procedures in an NYU report was only 5.6% when the PA systolic pressure was <60 mmHg, but >25% when the PA pressures were above 60 mmHg and the patients were >70 years of age.⁷⁵ This emphasizes the value of an early operation, before the development of irreversible ventricular dysfunction and chronic pulmonary hypertension.

SURGICAL THERAPY FOR THE FAILING HEART

Epidemiology of Congestive Heart Failure

CHF affects 5.2 million people in the United States with >500,000 new cases per year. Patients with NYHA IV CHF from CAD have an extremely poor outlook, with 43% and 18% survival at 1 and 3 years, respectively, and the risk of sudden cardiac death is higher, being 6 to 9 times greater than the general population. In the United States, there were >1 million hospital discharges for CHF in 2005 and >3.4 million outpatient visits. The estimated cost of care in 2008 was \$3.48 billion.

Etiology and Pathophysiology

The causes of heart failure differ widely. It can be broken down to idiopathic or secondary causes. Causes include

hypertension, CAD, structural valve disease, and other miscellaneous causes such as postviral, postpartum, and hypertrophic.

Often, the inciting event is an injury. This can be regional or global. In the case of MI, after a heart attack, the affected region becomes akinetic with the ingrowth of scar tissue. This area no longer contracts. If the area is large enough, the remaining walls have to compensate. This sometimes requires enlargement of the ventricle to maintain adequate cardiac output. An additional effect is the change in the normal elliptical shape of the ventricle. Additional adverse side effects include elevated left atrial pressures, ventricular and atrial dysrhythmias, LV dyssynchrony, and geometric distortion of the MV apparatus. This process is referred to as *remodeling*.

Surgery for Cardiomyopathy and Congestive Heart Failure

Heart transplant remains the gold standard for the surgical treatment of end-stage heart disease. Late- and end-stage heart disease, also known as *cardiomyopathy*, often is accompanied by symptoms of CHF. The increasing incidence of heart failure combined with new surgical modalities, improved safety of conventional surgery, and better understanding of the natural history of heart failure, has pushed surgery for CHF into the mainstream of cardiac surgery. There is an increased demand for patients with late-stage or end-stage heart disease to be considered for surgical therapies.⁷⁶

The goals of surgical therapy include improving survival, improving symptoms or the quality of life, or preventing further ongoing insults. Although ideal, a survival benefit in the short or intermediate term is not always possible, and certainly, by the time CHF has presented, surgical therapy is palliative in most cases.

Dobutamine echocardiography is a valuable diagnostic test in patients with cardiomyopathy. This test provides the usual two-dimensional pictures of regional cardiac function. Improved segmental contractility at low doses (5 mcg/kg per minute) and worsening function higher doses indicate both viability and predict functional recovery after revascularization. Cardiac MRI has become a preferred diagnostic test, providing the surgeon with the three-dimensional shape and function of the heart. Wall thinness and lack of myocardial thickening are good indicators of chronic scarring. Gadolinium hyperenhancement quantifies the amount of scar tissues in the segments of heart and its absence is highly predictive of recovery of function after revascularization. Finally, cardiopulmonary exercise testing is used to measure the degree of cardiac dysfunction as it pertains to a heart's ability to support metabolism. In patients with severe heart failure, it allows interpretation of symptoms and determination of prognosis. It also can be used to determine whether a patient is potentially best suited for cardiac transplantation.

Ischemic Cardiomyopathy

Surgical coronary revascularization is one of the most commonly performed procedures for CHF. Coronary bypass grafting is the primary strategy of treatment for ischemic cardiomyopathy.

Good target vessels are essential to successful revascularization in ischemic cardiomyopathy. Old age and poor quality of distal coronary vessels were the significant risk factors for successful outcome after surgical revascularization, with completely poor distal vessels having a 100% predictive value of hospital death and, thus, should be considered a strong contraindication.⁷⁷

Myocardial viability is the pivotal variable in the assessment of these patients. Ongoing angina is often a sufficient indicator to proceed to surgery. In the patient with ischemic cardiomyopathy and CHF symptoms alone that are not related to acute ischemia, viability testing is used to determine whether surgery will improve outcomes. Patients with viability have significantly improved hospital survival and 2-year outcomes compared to those without, whereas patients with no viability

show no benefit from surgical revascularization. In fact, patients with viable myocardium who did not undergo revascularization had double the mortality rate of all patients without viability and five times the mortality rate of those who underwent revascularization.⁷⁸ This underscores both the importance of viable myocardium as well as the adverse consequences of not offering a patient with viability surgical intervention.

Other risk factors for short and intermediate term outcomes include LV size and LV dyssynchrony. A LV end-systolic dimension $>100 \text{ mL/m}^2$ carries an adverse prognosis. Short-term and long-term survival after CABG were significantly reduced in those patients whose preoperative LV dimensions exceeded this threshold, 85 vs. 53% at 5 years ($P < .05$). Similarly, freedom from recurrent CHF was 85 vs. 31% at 5 years ($P < .01$).⁷⁹ LV dyssynchrony held a much higher predictive value than even viability in moderate to high-risk revascularization. Hospital mortality was 2.9 vs. 27.3% ($P < .001$), with an ongoing effect over the next 2 years.⁸⁰

FUNCTIONAL MITRAL REGURGITATION

Functional mitral regurgitation (FMR) is defined as MR secondary to ventricular dysfunction with structurally normal valve leaflets and subvalvular apparatus. In these cases, there is a failure of the valve leaflets to adequately coapt, causing the valve to leak. Structural problems in the geometry, size, and function of the left ventricle are responsible for the mitral dysfunction. There are several components of LV abnormalities that contribute to the pathology. First is LV dyssynchrony. Poor coordination of the contraction of the septum and lateral walls can cause MR that varies in intensity during the cardiac cycle, and can sometime be severe. The classic Carpentier classification system refers to functional regurgitation as a I/IIIB type of lesion. Annular dilatation (type I) and LV distortion (type IIIB) both play roles. FMR can further be classified. Ischemic functional mitral regurgitation (IMR) is a consequence of myocardial ischemia and almost always infarction. Pure FMR is associated with dilated cardiomyopathies. There are many differences and similarities between these subsets.

As the ventricular geometry and function of the left ventricle deteriorate, there is enlargement of the septal lateral dimension of the mitral annulus, reducing the coaptation length on the edges of the MV. Additionally, and more importantly, as the left ventricle enlarges, the papillary muscles are pulled down away from the mitral annulus and outward. This prevents the leaflets of the MV from coming back to the annular plane and further impairs the coaptation. In dilated (nonischemic) cardiomyopathy, this tends to be a symmetric event. In ischemic MR, the area of LV dysfunction most often correlates with the area of MI and secondary remodeling, usually in the inferior and posterior segments of the left ventricle. This correlated with coronary events in the inferior and terminal circumflex coronary distributions. The result is usually a more heterogeneous pathologic process with annular enlargement in the P3 area, and disproportional displacement of the posterior medial papillary muscle. Usually, there is significant decrease in the overall LVEF. LV remodeling leads to an enlarged ventricle with a less elliptical shape, and more MR. This increased regurgitation leads to increased preload, increased wall tension, and increased LV work load, all of which contribute to further LV dysfunction and to progressive heart failure.

The impact of IMR/FMR on long-term survival is significant. The presence of MR is a marker of the severity of disease. After MI, the presence of any MR reduced the 5-year survival from 61 to 38% ($P < .001$). Patients with moderate or greater MR had only a 29% 5-year survival compared to those with milder MR who had 47% 5-year survival ($P < .0001$).⁸¹ Medical therapy and PCI have not reduced the impact of IMR on late mortality after MI.⁸²

Many patients with IMR come to the operating room with indications for coronary revascularization in the setting of reduced ventricular function. Some patients present with primary CHF and valve indications for surgery. Current recommendations are to surgically address the MV if the MR is severe or if the MR is moderate and symptoms of CHF are present. A growing

number of centers will address moderate MR in those patients who are at otherwise low risk for CABG.

MV repair is the procedure of choice. Currently, the recommendations are to use a complete semirigid or rigid ring and to downsize the mitral annulus by two full ring sizes. This seems to provide the greatest success in a competent MV, and seems to promote reverse remodeling and more effectively guard against recurrence. MV replacement, with sparing of the subvalvar apparatus, is indicated when there are complicated issues such as severe tethering of the leaflets, massive LV dilation, or NYHA class 4 symptoms.

Outcomes from surgery are heterogeneous and correlate to the severity of the case mix. Operative mortality runs from <1 to 9% in contemporary series and is related to the severity of LV dysfunction, acuity of presentation, severity of MR, severity of heart failure, and medical comorbidities. It is currently believed at most large centers that the addition of a MV procedure has little impact on short-term mortality in the majority of patients. Revascularization improves survival of patients with ischemic MR. It is unclear whether the addition of a MV procedure further improves survival.⁸³ Adherence to a strict downsizing strategy of the mitral ring appears to mitigate against recurrence and allow for some reverse remodeling.⁸⁴

In a 2006 FDA trial study, isolated MV repairs in a predominately nonischemic cardiomyopathy population had a surprisingly low surgical mortality of 1.6% with a 2-year survival of 85%.⁸⁵ In addition, there was improvement in NYHA class and quality of life, and echocardiographic evidence of improved cardiac performance.

LEFT VENTRICULAR ANEURYSMORRHAPHY AND SURGICAL VENTRICULAR RECONSTRUCTION

The third clinical component of ischemic cardiomyopathy is the postinfarction ventricular aneurysm or postinfarction areas of akinesia associated with significant LV enlargement. Similar to the previously discussed pathologies of ischemic cardiomyopathy and functional mitral regurgitation, this is a heterogeneous group of patients with differing amounts of coronary disease and viable myocardium.

Approximately 5 to 10% of transmural MIs result in LV aneurysms, which develop 4 to 8 weeks following transmural infarct as necrotic myocardium is replaced by fibrous tissue. Collateral coronary circulation in the area of the infarct and reperfusion of the infarct vessel probably limits aneurysm formation in many patients by maintaining partial myocardial viability.

The classic aneurysm is an avascular thin scar, 4 to 6 mm thick, which bulges outward (paradoxical motion) when the remaining LV muscle contracts in systole (Fig. 21-18). More than 80% of aneurysms are in the anteroapical and apical portions of the left ventricle, resulting from occlusions of the left anterior descending coronary artery. Patients with anteroapical aneurysms usually also have significant aneurysmal dilation of the upper part of the ventricular septum. Posterior ventricular aneurysms are less common (15 to 20%), and lateral wall aneurysms are rare. Mural thrombus can be found attached to the ventricular surface of the aneurysm in more than one half of patients.

Left ventricular aneurysm. **A.** A left ventriculogram demonstrating a large left ventricular aneurysm. *Arrows* point to outline of aneurysm cavity distal to the normal ventricle. Note the contrast to the normal left ventriculogram demonstrated in Fig. 21-1B. **B.** Operative photograph of open left ventricular aneurysm. Aneurysmal involvement of the ventricular septum was present, and significant subendocardial scar is seen. **C.** Aneurysm repair using a Dacron patch and the endoaneurysmorrhaphy technique, which excludes the aneurysm and the aneurysmal septum from the normal part of the left ventricular cavity. **D.** The wall of the aneurysm has been closed over the Dacron patch, completing the endoaneurysmorrhaphy technique.

As the aneurysm enlarges, it is associated with a progressive deterioration of LV function due to the LV remodeling. As stated in the Functional MR section, remodeling consists of increasing LV volume, a more spherical LV shape, and worsening efficiency and energetics of the remaining remote myocardium, all leading to globally decreased LV performance. The LV end-diastolic and end-systolic volumes both increase, and the LV end-diastolic pressure is usually elevated. The combination of elevated intracavitary pressure and radius results in a significant elevation in wall tension, according to Laplace's law, and oxygen requirements are increased. The increased wall tension and oxygen consumption may result in angina, which may be worsened by accompanying coronary disease in noninfarcted areas of the heart. Areas of scar tissue around the edge of the aneurysm frequently serve as foci for ventricular arrhythmias, which are prominent in 15 to 20% of patients with LV aneurysms. Symptoms of LV aneurysms include angina, CHF, ventricular arrhythmias, rare embolic phenomenon, and, almost never, rupture.

DIAGNOSTIC EVALUATION

Diagnostic evaluation is most often for CAD, then to identify those patients who may benefit from surgical ventricular reconstruction. Evidence of a large prior anterior wall MI or a total LAD occlusion should prompt an investigation of the left

ventricle size and shape by right anterior oblique or biplane ventriculogram. Transthoracic echocardiography gives important information regarding LV function, size, and MV function, and also can suggest apical LV dyskinesis or thrombus. It is now accepted that cardiac MRI is now the best diagnostic modality, accurately identifying areas of viability by localizing thinned and scarred areas of the myocardium.

INDICATIONS FOR SURGERY

Many patients come to surgery for standard coronary bypass indications. The rest present during evaluation for CHF or arrhythmias. CHF or advanced NYHA functional class is not a prerequisite for surgery. Although not absolute, the indications for this procedure mandate an enlarged left ventricle, left ventricular end-diastolic volume index $>110 \text{ mL/m}^2$ or left ventricular end-systolic volume index $>80 \text{ mL/m}^2$, and an anterior septal MI with an area of akinetic or dyskinetic wall with thinned myocardium subtending about 30% of the total circumference of the heart. There has to be good basilar heart function and reasonable distal coronary targets for those patients with ischemic myocardium that requires revascularization. Relative contraindications include the absence of thinned myocardium, poor distal coronary artery targets, poor basilar heart function, poor right ventricular function, and severe pulmonary hypertension without significant MR.

SURGERY

Like ischemic MR, the primary therapy for a left ventricular aneurysm is surgical revascularization. Operative principles stress complete revascularization, including the LAD if possible. The classic repair was performed by excision of the aneurysm and linear closure of the ventricle. Disadvantages of this linear closure technique included not addressing the thinned, aneurysmal septum, and the possible undesirable geometry of the remaining left ventricle. Therefore, more physiologic techniques of ventricular reconstruction have evolved in the hands of Jatene, Cooley, and Dor. These intracavitary repair techniques all share the principle of downsizing the left ventricle, and excluding the infarct area high up on the anterior septum to achieve a more physiologic size and shape ventricle.^{86–88}

RESULTS

As a proof of concept, a large international study (RESTORE) investigated outcomes after surgical anterior ventricular endocardial restoration in 439 patients with ischemic cardiomyopathy as a result of anterior infarction. They found an overall hospital mortality of 6.6%, with an increase in ejection fraction from 29.7 to 40% and a 3-year survival rate approaching 90%. These encouraging results suggest the benefit that patients with ischemic cardiomyopathy may gain from ventricular remodeling procedures.⁸⁹

The operative mortality for surgical ventricular restoration is 4.9%. Significant MR increases the operative risk to 13%.⁹⁰ LV performance improved, with the ejection fraction increasing from 33 to 40%, left ventricular end-diastolic volume decreasing from 211 to 142 mL, and left ventricular end-systolic volume from 145 to 88 mL. NYHA class decreased from 2.7 ± 0.9 to 1.6 ± 0.7 late after surgery and 10-year survival was 63%. Risk factors for poor outcomes included MR $>2+$, advanced NYHA class, and diastolic dysfunction. Other benefits included documentation of improved remote regional wall motion, improvements in ventricular synchrony, and improvements in the neurohumoral profile of heart failure patients.

CARDIAC RESTRAINT DEVICES

Another attempt at halting ventricular remodeling and inducing "reverse remodeling" is the use of external restraint devices. The Acorn CorCap Cardiac Restraint Device is an external mesh that is applied to myopathic ventricles either at the time of MV surgery or as a stand-alone procedure. As an adjunct to MV remodeling annuloplasty the cardiac restraint device added a

significant but probably clinically unimportant additional reduction in ventricular size and return to a more elliptical shape. In stand-alone patients, there was improved freedom from adverse cardiac events and improvements in quality of life as well as reduction in LV volumes and sphericity.⁸⁵ The Myocor Coapsys device is another external restraint system that also addresses ventricular shape. This device consists of a set of pads external to the LV connected by an intracavitary suture. The suture is tightened to both reshape the LV and treat FMR.⁹¹ Both of the above devices are under clinical investigation.

Mechanical Circulatory Support

INTRA-AORTIC BALLOON PUMP

The IABP is the first line and most common technique for mechanical circulatory support. It is easily deployable in the catheterization laboratory, operating room, or at the bedside. A balloon catheter is inserted through the femoral artery and advanced into the thoracic aorta. With electronic synchronization, the balloon is inflated during diastole and deflated during systole. Coronary blood flow is increased by improved diastolic perfusion, and afterload is reduced. The cardiac index typically improves after insertion, and the preload decreases. Total myocardial oxygen consumption is diminished by approximately 15%.

The most frequent indications for use of IABP are to provide hemodynamic support during or after cardiac catheterization, cardiogenic shock, weaning from CPB, and for preoperative use in high-risk patients and refractory unstable angina. The use of a preoperative IABP in patients with severe LV dysfunction or unstable angina with critical coronary anatomy has resulted in improved outcomes. Kang reported significantly lower risk-adjusted mortality in high-risk patients requiring CABG if a preoperative IABP was used.⁹²

Generally, the IABP is used for a few days with minimal morbidity. Analysis of 911 patients undergoing CABG who received IABP revealed that the duration of IABP therapy ranged from 20 hours to 21 days (mean 3.8 days). Major complications occurred in 5.9% of the patients, and minor complications in 5.8%. Ischemia of the limb requiring thromboembolectomy developed in 2.7%.⁹³ Limb ischemia on the side of insertion is the most serious complication, and the extremity must be examined frequently for viability.

VENTRICULAR ASSIST DEVICES

Indications for ventricular assist device (VAD) support are anytime the heart can no longer support the oxygen delivery demands of the body. Patients can have pre-existing chronic heart failure or acute heart failure after MI, viral illness, or after unsuccessful surgery or intervention. Indications include cardiac index <2 L/min per square meter, systolic blood pressure <90 mmHg, pulmonary capillary wedge pressure or CVP >18 , SVR >2100 , low urine output, metabolic acidosis, and decreased mental status. Contraindications are relative but include sepsis, severe PVD, as well as end-stage renal disease, malignancy, central nervous system injury or irreversible dysfunction, severe hepatic disease, and severe chronic pulmonary disease. These contraindications need to be weighed individually according to the type and goals of support.

The goals of therapy are the preservation of end-organ perfusion and function. Goals can further be divided into short-term or long-term support. In general, one thinks of VADs as used for support while the heart recovers (bridge to recovery), support while the patient waits for a heart transplant (bridge to transplant), or as the final option in a nonheart transplant candidate with chronic heart failure (destination therapy). Patient selection, including contraindications, as well as device selection, takes into account both the etiology goals of therapy.

CANNULATION STRATEGIES

Support of the left ventricle is accomplished by draining blood away from the left ventricle and pumping it into the aorta. Cannulas can be inserted into the LV apex, or the left atrium for inflow to the pump. Return is through an arterial cannula or graft to the ascending or descending aorta. Right-sided devices most often drain the right ventricle by a cannula in the right atrium. Blood is returned to the patient via a cannula or graft in the PA or right ventricular outflow tract.

Pulsatile VADs almost always work in asynchrony to the native heart. Although they are a parallel circuit, almost all of the cardiac output is derived from the VAD, and often, the aortic valve does not open. Pulsatile devices approved by the Food and Drug Administration (FDA) include the Abiomed BVS5000 and AB5000, HeartMate XVE, Novacor (recently withdrawn from the market by the manufacturer), and the Thoratec PVAD and IVAD devices. Newer, nonpulsatile devices provide assistance to the native left ventricle, often with a dramatic reduction in systemic pulsatile flow. Second generation axial flow pumps include the HeartMate II with imminent FDA approval for bridge to transplant, the DeBakey MicroMed, and the Jarvik 2000. The recent pivotal trial comparing the nonpulsatile HeartMate II to the HeartMate XVE showed a dramatic reduction in complications with the newer generation axial flow device.⁹⁴ The so-called third generation pumps include smaller centrifugal pumps with either fluid film or magnetic levitation impeller support to further reduce blood trauma and improve durability.

RIGHT VENTRICULAR AND BIVENTRICULAR ASSIST DEVICES

The majority of patients with chronic heart failure require left ventricular assist device (LVAD) support. Usually a moderate amount of RV dysfunction can be managed by perioperative inotropes and pulmonary vasodilators such as milrinone and nitric oxide. Some LVAD patients need temporary mechanical RV support that can then be weaned. Isolated right ventricular assist devices are unusual. Biventricular support is used for acute cardiogenic shock after an MI or post-open heart surgery. Chronic biventricular failure in some cases can be managed as a bridge to transplant with an implantable biventricular assist device (BiVAD) with either the Thoratec devices or the CardioWest Total Artificial Heart. Although the patients with a Thoratec BiVAD can be discharged home on support, there is no destination therapy option for biventricular failure.

Bridge to Recovery

The most common scenarios for this type of support is after a MI and after open heart surgery when ventricular performance is inadequate to allow weaning from CPB or to support the individual while the heart recovers. MI is most commonly treated with PCI or thrombolytic therapy. Patients who are in shock and continue to be despite opening the culprit vessel are candidates for mechanical support. The IABP is the standard of care, along with inotropes and vasopressors. For those patients who are still in cardiogenic shock, a quick progression to assist device support can be life saving. Those patients in post-MI shock with either unreconstructable coronary disease or what is predicted to be unsalvageable LV function can be implanted with a long-term device as a bridge to transplant. After open heart surgery, patients who continue to be in cardiogenic shock despite IABP and inotropic support have an extremely high mortality. Samuels reviewed 3400 open heart surgery patients and found patients requiring two and three high-dose inotropes had a hospital mortality of 42 and 80% respectively, thus providing a "rule of thumb" guide for consideration of assist device support.⁹⁵ Using this as a guide for early post-cardiotomy VAD support their group was able to wean 62% and discharge 28% of patients with severe, refractory postcardiac surgery acute heart failure.

Bridge to Transplant

LVAD as a bridge to transplant was first performed at Stanford in 1984. LVAD as a bridge to transplant is indicated in patients on the transplant waiting list with severe refractory heart failure. These patients are candidates for heart transplant, but are not predicted to survive the waiting list period secondary to sequelae of cardiac failure including worsening end-organ

function, rising PA pressures, or those with refractory cardiogenic shock on escalating inotropes, and those with malignant ventricular arrhythmias or sudden death. The incidence of patients on mechanical circulatory support at the time of cardiac transplant has increased to 28%. There is equivalent posttransplant survival in patients coming to transplant on continuous inotropic support or on LVAD support. Survival to transplant is about 70%. Complications include infections of the drive line, pocket, and device itself, device malfunction, sepsis, multisystem organ failure, right heart failure, stroke, bleeding, and pulmonary complications. The most common cause of death is multisystem organ failure, with advanced age >60 and the need for right ventricular assist device support being the biggest operative risk factors.

Destination Therapy

This is a relatively new concept where the assist device is implanted as a permanent solution to end-stage heart disease. Initially, this has been reserved for patients with extremely limited life expectancy who were not candidates for heart transplant.⁹⁶ The REMATCH trial showed a 48% reduction in mortality for the LVAD group as compared to optimal medical management. The survival for the LVAD group was 52 and 23% compared to the optimal medical management, which was 25 and 8% at 1 and 2 years, respectively. Current indications include: (a) NYHA IV symptoms for >60 days, (b) LVEF <25%, (c) peak oxygen consumption <12 mL/kg per minute or inability to wean from inotropic support, and (d) contraindications to heart transplant. Currently, the HeartMate XVE is the only device approved for destination therapy in the United States, though several others are in clinical trials. Limitations include medical comorbidities complicating the insertion, size requirements, and device longevity, morbidity, and limitations on activities. Early post-REMATCH registration data now show a modest improvement to 63% 1-year survival. Patient selection plays an important role in the outcomes of destination therapy.⁹⁴ High-risk patients have an 11 to 28% 1-year survival while those with lower preoperative risk profiles have a 62 to 81% 1-year survival. The most significant indicator of outcomes is the 90-day mortality. Technical improvements and patient selection have tremendous impact. With a fixed number of heart transplants being performed, interest in applications is quickly widening and there are many devices in the development and testing phases. As devices improve in the future, it is expected that the indications for destination therapy and the demand will grow to help meet the growing number of patients with end-stage heart disease.

Total Artificial Heart

A total artificial heart (TAH) will be the conceptual end solution for cardiac replacement of the failing heart. This technology has moved in a vastly different direction than VADs. Assist devices work in parallel to the left ventricle, and are becoming simpler, smaller, and valveless, in contrast to the TAH, which displaces the heart and retains pulsatile flow. The original Jarvik TAH is still in use as the CardioWest BiVAD and is used as a bridge to transplant. More recently, the AbioCor TAH has been implanted as part of an FDA trial and recently obtained FDA Humanitarian Device Exemption approval in 2006. Despite tremendous improvements in design and technology, limitations and complications include mobility, stroke, infection, and space limitations in the recipient chest. Current indications include patients <75 years of age with severe irreversible biventricular failure or end-stage heart disease who are not transplant or LVAD candidates, and cannot be weaned from multiple inotropic support or mechanical biventricular support. Total cardiac replacement with an artificial heart, however, is still in the experimental arena. Long-term risks include thromboembolic complications, the risk of infection, and trauma to blood elements.

SURGERY FOR ARRHYTHMIAS

History

Cardiac surgery for arrhythmias began with the treatment of Wolff-Parkinson-White syndrome (ventricular pre-excitation and tachycardia) by surgical division. Subsequently, the surgical treatment of medically refractory AV node re-entrant tachycardia was performed. Subsequently, the development and efficacy of catheter-based endovascular techniques supplanted these more invasive surgical procedures.

Surgery for Atrial Fibrillation

Starting in the 1980s, a series of surgical procedures were developed to address atrial fibrillation. James Cox first developed an "atrial isolation" procedure, followed by Guiraudon's "corridor procedure." A fuller understanding of the electrophysiologic basis of atrial tachyarrhythmias as well as the goals of intact sinus mechanism, AV synchrony, and atrial transport led to the development of the Cox Maze procedures.⁹⁷ This operation, in its current form, consists of a series of surgical incisions and reconstruction of the atria such that the sinus mechanism is preserved and macro-re-entrant circuits necessary for atrial fibrillation to form are prevented. This procedure has a 98% success rate, an extremely low follow-up neurologic event rate, and is the gold standard for the nonmedical treatment of refractory atrial fibrillation.⁹⁸

In 1998, Haissaguerre demonstrated that paroxysmal atrial fibrillation is initiated by ectopic beats in the pulmonary veins.⁹⁹ This led to successful catheter-based ablation of the pulmonary vein ostia for paroxysmal atrial fibrillation, with satisfactory results. This has led to the successful addition of "pulmonary vein ablation" to such surgical procedures as MV reconstruction. Although these procedures are less successful, they are much less complicated to perform and have been performed with low morbidity. Likewise, recently, a series of "lesser invasive" surgical procedures have been designed to electrically exclude the pulmonary veins as well as create other "lines" of ablation that block conduction to treat atrial tachyarrhythmias. These procedures use various thermal energy sources (radio frequency energy, microwave, high intensity focused ultrasound, cryo energy) to create various lesion sets from outside the atria via a minimally invasive approach. It is known, however, that with chronic atrial fibrillation, there is modification of the atrial substrate such that the tissue permanently fibrillates without the need for an instigating stimulus. The learned adage is that atrial fibrillation begets atrial fibrillation. It is not yet clear if and where these procedures will be most successful and beneficial for which subtypes of atrial fibrillation.

Pacemakers

Pacemakers were first developed in the 1950s. A lead was fixed to the surface of the heart (epicardial lead), the pacemaker was AC powered, and the patient was limited by the tether of the power cord. Soon these devices became miniaturized and battery driven so they could be externally worn. In 1960 the first totally implantable pacemaker was placed in a patient; the battery had a life of about 12 to 18 months. It is sobering to remember that before pacemakers, the mean life expectancy of a patient with symptomatic complete heart block was 6 months.

Currently, pacemakers are implanted with transvenous leads that require only a subcutaneous access procedure and fluoroscopic control. The pacemaker system typically consists of transvenous leads introduced into the subclavian veins and a "generator," which is a small sealed unit that contains both the controlling electronics and the battery. These units typically last 8 to 10 years, after which the leads are disconnected and reconnected to a new generator. External pacing generators are still used when only temporary pacing is needed, as in postcardiac surgical patients.

Pacemakers not only treat bradyarrhythmias, but also synchronize atrial and ventricular contractions. Epicardial lead systems are reserved today for small infants and patients without direct access to the endocardium of the right ventricle (patients

status post-Fontan procedure or TV replacement). Additionally, epicardial leads are used for "dyssynchrony pacing" in patients with heart failure. These patients with impaired ventricular function can benefit from both left- and right-sided pacing if a significant intraventricular conduction defect exists.¹⁰⁰

Defibrillators

In the 1990s, a new class of implantable devices was created—ICDs. Although these devices all had basic bradycardiac pacemaker capability, they also had the capacity to detect and treat ventricular tachyarrhythmias. When a persistent ventricular tachycardia is detected, the ICD battery charges a capacitor for several seconds and treats the arrhythmia by delivering upward of 30 joules of energy (at approximately 750 volts) across the myocardium. While these devices at first required a thoracotomy or sternotomy to implant them, transvenous lead access is now routine. Implantation was first reserved for sudden death survivors (due to ventricular tachycardia) or those high-risk patients with inducible arrhythmias. The high success rates of this therapy lead to the MADIT and SCDHFT trials.¹⁰¹ These studies demonstrated a survival advantage to empiric ICD implantation in patients with both ischemic and nonischemic cardiomyopathy.

SURGERY FOR PERICARDIAL DISEASE

Acute Pericarditis

Acute pericarditis results from acute inflammation of the pericardial space, and may result in substernal chest pain or ECG changes. A pericardial friction rub may be heard on physical examination. The pain often is inspiratory, worsened in the supine position, and relieved by leaning forward. The associated ECG changes commonly include sinus tachycardia with concave upward ST-segment elevation throughout the precordium. The ECG typically progresses to T-wave inversion, followed by the total resolution of all changes. The causes of acute pericarditis are variable, including infection, MI, trauma, neoplasm, radiation, autoimmune diseases, drugs, nonspecific causes, and others. Untreated pericarditis may result in progressive development of a pericardial effusion with subsequent cardiac tamponade. Infectious causes may result in septic complications. Chronic constrictive pericarditis may develop after resolution of the acute process.

DIAGNOSIS

The diagnostic work-up should attempt to determine the underlying cause of the pericarditis. Blood tests should include erythrocyte sedimentation rate, hematocrit level, white blood cell count, bacterial cultures, viral titers, blood urea nitrogen, T₃, T₄, thyroid-stimulating hormone, antinuclear antibody, rheumatoid factor, and myocardial enzyme levels. The ECG may be typical or nonspecific. The chest x-ray may be normal or may demonstrate an enlarged cardiac silhouette or a pleural effusion. An echocardiogram to evaluate the degree of pericardial effusion is essential. A pericardiocentesis or pericardial biopsy may be necessary when the diagnosis or etiology is uncertain.

TREATMENT

The preferred treatment depends on the underlying cause. Purulent pyogenic pericarditis requires drainage and prolonged IV antibiotic therapy. Postpericardiotomy syndrome, post-MI syndrome, viral pericarditis, and idiopathic pericarditis often are self-limiting, but can require a short course of treatment with NSAIDs. If a significant pericardial effusion is present, drainage is indicated if tamponade occurs or if resolution is not prompt with anti-inflammatory agents. A 5- to 7-day course of steroids is occasionally necessary. Follow-up studies should be done to document resolution of pericardial effusion or to assess for late constrictive pericarditis.

Chronic Constrictive Pericarditis

ETIOLOGY

In the majority of patients, the cause of chronic constrictive pericarditis is unknown and probably is the end stage of an undiagnosed viral pericarditis. Tuberculosis is a rarity. Intensive radiation is a significant cause in some series. Constrictive pericarditis may develop after an open-heart operation. Previous cardiac surgery was reported to be the cause in 39% of the patients treated surgically for constrictive pericarditis at the authors' institution.

PATHOLOGY AND PATHOPHYSIOLOGY

The pericardial cavity is obliterated by fusion of the parietal pericardium to the epicardium, forming dense scar tissue that encases and constricts the heart. In chronic cases, areas of calcification develop, adding an additional element of constriction. The ultimate form of this process is "coeur de stein" in which the entire visceral surface of the heart is covered with an armor-like calcification.

The pathophysiology of this disease remains the limitation of diastolic filling of the ventricles. This results in a decrease in cardiac output from a decrease in stroke volume. The right ventricular diastolic pressure is increased, with a corresponding increase in right atrial and central venous pressure ranging from 10 to 30 mmHg. This venous hypertension may produce hepatomegaly, ascites, peripheral edema, and a generalized increase in blood volume. The disease is slowly progressive with increasing ascites and edema. Fatigability and dyspnea on exertion are common, but dyspnea at rest is unusual. The ascites often is severe, and the diagnosis is easily confused with cirrhosis. Hepatomegaly and ascites often are the most prominent physical abnormalities. Peripheral edema is moderate in some patients, but severe in others. These findings are manifestations of advanced congestive failure from any form of heart disease. With constrictive pericarditis, however, the usual cardiac findings are a heart of normal size without murmurs or abnormal sounds. Atrial fibrillation is present in about one third of the patients, and a pleural effusion is common in more severe cases. A paradoxical pulse is found in a small proportion of patients.

LABORATORY FINDINGS

Venous pressure is elevated, often to 15 to 20 mmHg or higher. The ECG, though not diagnostic, usually is abnormal with a low voltage and inverted T waves. The chest x-ray usually shows a heart of normal size, but pericardial calcification may be seen in a significant proportion of cases and often is the first clue to the diagnosis. Echocardiogram, MRI, or CT scan may demonstrate a thickened pericardium.

Findings on cardiac catheterization are highly characteristic. There is elevation of the right ventricular diastolic pressure with a change in contour, showing an early filling with a subsequent plateau, called the *square root sign*. There also is "equalization" of pressures in the different cardiac chambers, because right atrial pressure, right ventricular diastolic pressure, PA diastolic pressure, pulmonary wedge pressure, and left atrial pressure are similar. The one condition that cannot be excluded without myocardial biopsy is a restrictive cardiomyopathy, and this disease process is often misdiagnosed as "constrictive" pericarditis. Echocardiographic features have been used in an attempt to distinguish between these two processes.

TREATMENT

A pericardiectomy should be done promptly in symptomatic patients. An operation can be done through a sternotomy incision

or a long left anterolateral thoracotomy. The constricting pericardium should be removed from all surfaces of the ventricle, mobilizing the heart so it can be held freely upward in the hand. Removal of the pericardium over the atria and the venae cavae is considered optional, although this usually is done as well. CPB is not usually necessary, but may be needed in the event of significant hemorrhage. The pericardium is removed anteriorly from the pulmonary veins on the right to the pulmonary veins on the left. Both phrenic nerves are identified, mobilized, and protected. Particular care is taken to remove pericardial tissue over the PA, where residual constriction can seriously impair the operative results.

As the constricting scar develops from organization of an exudate between the pericardium and the epicardium, the plane of dissection may be external to the epicardium, which will greatly decrease operative hemorrhage. If the epicardium is thickened, it must be removed from the underlying myocardium, although this is tedious and results in diffuse bleeding.

Intracardiac pressures may be measured before and after pericardiectomy. Often with a complete pericardiectomy the characteristic pressure abnormalities are eliminated or greatly improved. If significant abnormalities remain, the operative field should be carefully checked for any residual sites of constriction. In the past, slow recovery over many months probably was a result of inadequate pericardiectomy, not underlying ventricular atrophy.

RESULTS

After a radical pericardiectomy that corrects the hemodynamic abnormalities, patients improve promptly with a massive diuresis. If a prompt diuresis does not occur, the original diagnosis should be questioned. The risk of an operation varies with the age of the patient and the severity of the disease; the mortality rate usually is <5%. A good result can be anticipated for >95% of the patients. The authors have previously reported surgical treatment for chronic constrictive pericarditis with total pericardiectomy, with an operative mortality rate of 3%. After the operation hemodynamic abnormalities were promptly corrected, ascites and peripheral edema resolved, and functional status improved dramatically.

CARDIAC NEOPLASMS

Overview

Primary cardiac neoplasms are rare, reported to occur with incidences ranging from 0.001 to 0.3% in autopsy series. Benign tumors account for 75% of primary neoplasms and malignant tumors account for 25%. The most frequent primary cardiac neoplasm is myxoma, comprising 30 to 50%. Other benign neoplasms, in decreasing order of occurrence, include lipoma, papillary fibroelastoma, rhabdomyoma, fibroma, hemangioma, teratoma, lymphangioma, and others. Most primary malignant neoplasms are sarcomas (angiosarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, and liposarcoma), with malignant lymphomas accounting for 1 to 2%.

Metastatic cardiac neoplasms are more common than primary neoplasms, occurring in 4 to 12% of patients dying of cancer. Symptoms include dyspnea, fever, malaise, weight loss, arthralgias, and dizziness. Clinical findings may include murmurs of mitral stenosis or insufficiency, heart failure, pulmonary hypertension, and systemic embolization. Usually, the diagnosis is readily established by two-dimensional echocardiography. TEE may be useful when transthoracic findings are equivocal or confusing. MRI has been of value in diagnosis, providing excellent cardiac definition. Cardiac catheterization is not necessary in the majority of cases, but may be necessary when other cardiac disease is suspected or if other diagnostic studies are equivocal.

Excision is the treatment of choice for most benign tumors. Care is taken to avoid deformity or destruction of adjacent cardiac structures, and reconstruction of the involved cardiac chamber is sometimes necessary. Total excision of metastatic

or primary malignant neoplasms is less frequently possible but should be attempted. Otherwise incisional diagnostic biopsy is performed. Multimodality therapy with excision, chemotherapy, and radiotherapy is indicated for most malignant cardiac neoplasms.

Myxomas

Sixty to 75% of cardiac myxomas develop in the left atrium, almost always from the atrial septum near the fossa ovalis. Most other myxomas develop in the right atrium; <20 have been reported in the right or left ventricle. The predilection for a myxoma to develop from the rim of the fossa ovalis in the left atrium has been studied, but no satisfactory explanation has been found.

Myxomas are true neoplasms, although their similarity to an organized atrial thrombus has led to considerable debate. The occurrence of myxomas in the absence of other organic heart disease, histochemical studies of myxomas demonstrating mucopolysaccharide and glycoprotein, and a distinct histologic appearance indicate that myxomas are true neoplasms. Although they can recur locally, they do not invade or metastasize and are considered benign.

PATHOLOGY

The tumors usually are polypoid, projecting into the atrial cavity from a 1- to 2-cm stalk attached to the atrial septum. The size ranges from 0.5 to >10 cm. Only the superficial layer of the septum is involved; invasion of the septum does not occur. Some myxomas grow slowly; a few patients have symptoms for many years. There is no tendency to invade other areas of the heart, and distant metastases are rarely reported. The friable consistency of a myxoma is of particular significance because frequently, the first presentation is that of an embolic event.

Histologically, a myxoma is covered with endothelium and composed of a myxomatous stroma with large stellate cells mixed with fusiform or multinucleated cells. Mitoses are infrequent. Lymphocytes and plasmacytes are regularly found. Hemosiderin, a result of hemorrhage into the tumor, is commonly present. Myxoma cells usually express interleukin-6, and some tumors have abnormal cellular DNA content.

Sporadic myxomas usually present in the fifth or sixth decade of life but have been described in younger and older patients. Familial myxomas (autosomal dominant) can occur, usually presenting at <30 years of age. The familial myxoma syndrome includes myxomas, freckles, pigmented nevi, nodular adrenal cortical disease, and mammary myomatous fibroadenomas. Testicular tumors and pituitary adenomas with two or more components are required for diagnosis.

PATHOPHYSIOLOGY

A myxoma may be completely asymptomatic until it grows large enough to obstruct the MV or TV or fragments to produce emboli. Embolization has been estimated to occur in 40 to 50% of patients. A pedunculated myxoma may be quite mobile, moving through the cardiac chamber with each contraction. Intermittent acute obstruction of the mitral orifice has been reported to produce syncope and even sudden death (Fig. 21-19). In a series of 49 patients, it has been reported that most myxomas originated from the left atrium (87.7%), but also much less frequently from the MV (6.1%), from the right atrium (4.1%), and from the left and right atria (2%). These myxomas prolapsed into the left ventricle in 40.8% of the patients, creating mitral stenosis in 10.2%, and even LV outflow tract obstruction in 2%.¹⁰² Some myxomas produce generalized symptoms resembling an autoimmune disorder, including fever, weight loss, digital clubbing, myalgia, and arthralgia. These patients may have an immune reaction to the neoplasm, as elevated levels of interleukin-6 and elevated levels of antimyocardial antibodies have been described.

Massive left atrial myxoma. **A.** Intraoperative echocardiogram of a large left atrial mass, diagnosed preoperatively as a left atrial myxoma. The mass can be seen prolapsing through the mitral valve orifice causing intermittent symptoms of mitral stenosis. **B.** The resected specimen. The neck of the mass that was obstructing the mitral orifice is clearly delineated.

CLINICAL MANIFESTATIONS

Symptoms may include those of MV obstruction that resemble mitral stenosis; peripheral embolization; or generalized autoimmune symptoms. The diagnosis often is made after an embolic episode from histologic examination of the surgically removed embolus, or as a result of subsequent diagnostic studies to determine the reason for embolism. The precision and reliability of two-dimensional echocardiography has greatly simplified diagnosis. Angiography is optional unless additional disease is suspected. CT scan has been reported to be helpful with small tumors, but MRI is more definitive.

TREATMENT

Surgery should be performed as soon as possible after the diagnosis has been established due to the inherent risk of a disabling or fatal cerebral embolus. Either a sternotomy or a minimally invasive approach can be used. Once extracorporeal circulation has been established, the aorta is clamped to avoid embolism. Palpation is avoided. The right atrium is opened, and the fossa ovalis incised to expose the stalk of the myxoma. The left atrium is then opened in the interatrial groove. With the tumor visualized, the segment of atrial septum from which the tumor arises is excised, after which the tumor is removed through the left atrium. The defect in the atrial septum is closed primarily or with a small patch. This technique is simple and allows exploration of atria and ventricles.

A few cases of recurrent myxoma have been reported, some of which have been re-excised successfully. Although thought to result from inadequate excision of the site of origin, some have recurred at more remote sites in the atrium, indicating the multipotential source of these unusual neoplasms. Periodic echocardiography should be routinely performed for several years after an operation.

Keeling and associates described their experience with a series of 49 patients with cardiac myxomas over 20 years. Cardiac myxomas represented 86% of all surgically treated cardiac tumors. The early mortality rate was 2%, while the rate of reoperation was 2% after 24 years.¹⁰²

Metastatic Neoplasms

Cardiac metastases have been found in 4 to 12% of autopsies performed for neoplastic disease. Although they have occurred from primary neoplasms developing in almost every known site of the body, the most common have been carcinoma of the lung or breast, melanoma, and lymphoma. Cardiac metastases involving only the heart are very unusual. Similarly, a solitary cardiac metastasis is rare; usually there are multiple areas of involvement. Cardiac involvement is common with leukemia or lymphoma, developing in 25 to 40% of patients.¹⁰³ All areas of the heart are involved with equal frequency except the cardiac valves, perhaps because lymphatics are absent in valvular tissue.

The diagnosis of a primary cardiac malignant tumor may be suspected in a patient in whom an unexplained hemorrhagic pericardial effusion develops, especially in association with a bizarre cardiac shadow on the radiograph. Echocardiography should confirm the presence of an abnormal cardiac mass. Thoracotomy or sternotomy usually is required to establish the diagnosis. Combined chemotherapy and radiation is indicated, but only rarely is effective therapy possible.

Miscellaneous Neoplasms

Unusual benign lesions of the heart include fibromas, lipomas, angiomas, teratomas, and cysts. Fewer than 50 of each of these types of lesion have been reported. Fibromas have been found most frequently in the left ventricle, often as 2- to 5-cm nodules within the muscle. Sudden death, probably from a cardiac arrhythmia, has been reported with these tumors.

Lipomas are rare asymptomatic tumors found projecting from the epicardial or endocardial surface of the heart in older

patients. Angiomas are small, focal, vascular malformations of no clinical significance, although they may be associated with heart block. Pericardial teratomas and bronchogenic cysts are rare lesions that can cause symptoms from compression of the right atrium with obstruction of venous return. Most of these occur in children and can be up to 10 cm in diameter. Myxomas are by far the most common benign tumor in adults; they are seldom found in children except as part of the familial syndrome described in the Pathology section.

Renal cell carcinoma, Wilms' tumor, uterine tumors, and adrenal tumors may have direct intracardiac extension. Excision of these infradiaphragmatic tumors by radical surgery associated with cavoatrial thrombectomy has been suggested, and extracorporeal circulation and deep circulatory arrest provide an optimal technique for removing the tumor thrombus, even in the presence of metastatic disease, and have good early and long-term results.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 22. Thoracic Aneurysms and Aortic Dissection >

KEY POINTS

1. Assessing urgency of repair for an aortic aneurysm is essential to developing an appropriate management plan. Although emergent repair carries greater operative risk than does elective repair, any inappropriate delay of repair risks death.
2. Surgical repair of an aortic aneurysm requires the development of a patient-tailored plan based on careful preoperative medical evaluation. When possible, optimization of a patient's health status to mitigate existing comorbidities is essential before surgical intervention.
3. Ascending aortic aneurysms that are symptomatic or >5.5 cm should be repaired.
4. Ascending aortic dissection is a life-threatening condition, and immediate operative repair is indicated.
5. The natural progression of an aortic aneurysm is continued expansion and eventual rupture. Hence, regular noninvasive imaging studies, as part of a lifelong surveillance plan, are necessary to ensure long-term patient health. Even small asymptomatic aneurysms are routinely imaged to assess overall growth and yearly rate of expansion.
6. Although endovascular devices are approved for use in repairing simple descending thoracic aortic aneurysms, the long-term durability of this type of aortic repair has yet to be clearly established.
7. The development and use of surgical adjuncts like antegrade selective cerebral perfusion and cerebrospinal fluid drainage have significantly reduced morbidity rates associated with complex aortic repair.

ANATOMY OF THE AORTA

The aorta consists of two major segments—the proximal aorta and the distal aorta—whose anatomic characteristics affect both the clinical manifestations of disease in these segments and the selection of treatment strategies for such disease (Fig. 22-1). The proximal aortic segment includes the ascending aorta and the transverse aortic arch. The ascending aorta begins at the aortic valve and ends at the origin of the innominate artery. The first portion of the ascending aorta is the aortic root, which includes the aortic valve annulus and the three sinuses of Valsalva; the coronary arteries originate from two of these sinuses. The aortic root joins the tubular portion of the ascending aorta at the sinotubular ridge. The transverse aortic arch is the area from which the brachiocephalic branches arise. The distal aortic segment includes the descending thoracic aorta and the abdominal aorta. The descending thoracic aorta begins distal to the origin of the left subclavian artery and extends to the diaphragmatic hiatus, where it joins the abdominal aorta. The descending thoracic aorta gives rise to multiple bronchial and esophageal branches, as well as to the segmental intercostal arteries, which provide circulation to the spinal cord.

Fig. 22-1.

Illustration of normal thoracic aortic anatomy. The brachiocephalic vessels arise from the transverse aortic arch and are used as anatomic landmarks to define the aortic regions. The ascending aorta is proximal to the innominate artery, whereas the descending aorta is distal to the left subclavian artery.

The volume of blood that flows through the thoracic aorta at high pressure is far greater than that found in any other vascular structure. For this reason, any condition that disrupts the integrity of the thoracic aorta, such as aortic dissection, aneurysm rupture, or traumatic injury, can have catastrophic consequences.

Historically, open surgical repair of such conditions has been an intimidating undertaking associated with significant morbidity and mortality. Strategies for protecting the brain and spinal cord during such repairs have become critical in preventing devastating complications. In recent years, endovascular therapy for thoracic aortic disease in selected patients has become accepted practice, producing fewer adverse outcomes than traditional approaches do.

THORACIC AORTIC ANEURYSMS

Aortic aneurysm is defined as a permanent, localized dilatation of the aorta to a diameter that is at least 50% greater than is normal at that anatomic level.¹ The annual incidence of thoracic aortic aneurysms is estimated to be 5.9 per 100,000 persons.² The clinical manifestations, methods of treatment, and treatment results in patients with aortic aneurysms vary according to the cause and the aortic segment involved. Causes of thoracic aortic aneurysms include degenerative disease of the aortic wall, aortic dissection, aortitis, infection, and trauma. Aneurysms can be localized to a single aortic segment, or they can involve multiple segments. Thoracoabdominal aortic aneurysms, for example, involve both the descending thoracic aorta and the abdominal aorta. In the most extreme cases, the

entire aorta is aneurysmal; this condition is often called *mega-aorta*.

Aortic aneurysms can be either "true" or "false." True aneurysms can take two forms: fusiform and saccular. Fusiform aneurysms are more common and can be described as symmetrical dilatations of the aorta. Saccular aneurysms are localized outpouchings of the aorta. False aneurysms, also called *pseudoaneurysms*, are leaks in the aortic wall that cause blood to collect in pouches of scar tissue on the exterior of the aorta.

Aneurysms of the thoracic aorta consistently increase in size and eventually progress to cause serious complications. These include rupture, which is usually a fatal event. Therefore, aggressive treatment is indicated in all but the poorest surgical candidates. Small, asymptomatic thoracic aortic aneurysms can be followed, especially in high-surgical-risk patients, and can be treated surgically later if symptoms or complications develop, or if progressive enlargement occurs. Meticulous control of hypertension is the primary medical treatment for patients with small, asymptomatic aneurysms.

Elective resection with graft replacement is indicated in asymptomatic patients with an aortic diameter of at least twice normal in the involved segment (5 to 6 cm in most thoracic segments). Elective repair is contraindicated by extreme operative risk due to severe coexisting cardiac or pulmonary disease and by other conditions that limit life expectancy, such as malignancy. An emergency operation is performed for any patient in whom a ruptured aneurysm is suspected.

Patients with thoracic aortic aneurysm often have coexisting aneurysms of other aortic segments. A common cause of death after repair of a thoracic aortic aneurysm is rupture of a different aortic aneurysm. Therefore, staged repair of multiple aortic segments often is necessary. As with any major operation, careful preoperative evaluation for coexisting disease and subsequent medical optimization are essential for successful surgical treatment.

An alternative to traditional open repair of a descending thoracic aortic aneurysm is endovascular stent grafting. Certain anatomic criteria must be satisfied for this treatment option to be considered, including the presence of at least a 2-cm landing zone of healthy aortic tissue proximally and distally to the aneurysm to be excluded. Although data on long-term outcomes are still lacking, endovascular repair of descending thoracic aortic aneurysm has become an accepted practice that produces excellent midterm results.

Etiology and Pathogenesis

GENERAL CONSIDERATIONS

The normal aorta derives its elasticity and tensile strength from the medial layer, which contains approximately 45 to 55 lamellae of elastin, collagen, smooth muscle cells, and ground substance. Elastin content is highest within the ascending aorta, as would be expected because of its compliant nature, and decreases distally into the descending and abdominal aorta. Maintenance of the aortic matrix involves complex interactions among smooth muscle cells, macrophages, proteases, and protease inhibitors. Any alteration in this delicate balance can lead to aortic disease.

Thoracic aortic aneurysms have a variety of causes (Table 22-1). Although these disparate pathologic processes differ in biochemical and histologic terms, they share the final common pathway of progressive aortic expansion and eventual rupture.

Table 22-1 Causes of Thoracic Aortic Aneurysms
Nonspecific medial degeneration
Aortic dissection
Genetic disorders
Marfan syndrome
Loeys-Dietz syndrome
Ehlers-Danlos syndrome
Familial aortic aneurysms

Congenital bicuspid aortic valve
Poststenotic dilatation
Infection
Aortitis
Takayasu's arteritis
Giant cell arteritis
Rheumatoid aortitis
Trauma

Hemodynamic factors clearly contribute to the process of aortic dilatation. The vicious cycle of increasing diameter and increasing wall tension, as characterized by Laplace's law (tension = pressure x radius), is well established. Turbulent blood flow is also recognized as a factor. Poststenotic aortic dilatation, for example, occurs in some patients with aortic valve stenosis or coarctation of the descending thoracic aorta. Hemodynamic derangements, however, are only one piece of a complex puzzle.

Atherosclerosis is commonly cited as a cause of thoracic aortic aneurysms. However, although atherosclerotic disease often is found in conjunction with aortic aneurysms, the notion that atherosclerosis is a distinct cause of aneurysm formation has been challenged. In thoracic aortic aneurysms, atherosclerosis appears to be a coexisting process, rather than the underlying cause.

Research into the pathogenesis of abdominal aortic aneurysms has focused on the molecular mechanisms of aortic wall degeneration and dilatation. For example, imbalances between proteolytic enzymes (e.g., matrix metalloproteinases) and their inhibitors contribute to abdominal aortic aneurysm formation. Building on these advances, current investigations are attempting to determine whether similar inflammatory and proteolytic mechanisms are involved in thoracic aortic disease, in hope of identifying potential molecular targets for pharmacologic therapy.

NONSPECIFIC MEDIAL DEGENERATION

Nonspecific medial degeneration is the most common cause of thoracic aortic disease. Histologic findings of mild medial degeneration, including fragmentation of elastic fibers and loss of smooth muscle cells, are expected in the aging aorta. However, an advanced, accelerated form of medial degeneration leads to progressive weakening of the aortic wall, aneurysm formation, and eventual dissection, rupture, or both. The underlying causes of medial degenerative disease remain unknown.

AORTIC DISSECTION

An aortic dissection usually begins as a tear in the inner aortic wall, which initiates a progressive separation of the medial layers and creates two channels within the aorta. This event profoundly weakens the outer wall. As the most common catastrophe involving the aorta, dissection represents a major, distinct cause of thoracic aortic aneurysms and is discussed in detail in the second half of this chapter.

GENETIC DISORDERS

Marfan Syndrome

Marfan syndrome is an autosomal dominant genetic disorder characterized by a specific connective tissue defect that leads to aneurysm formation. The phenotype of patients with Marfan syndrome typically includes a tall stature, high palate, joint hypermobility, eye lens disorders, mitral valve prolapse, and aortic aneurysms. The aortic wall is weakened by fragmentation of elastic fibers and deposition of extensive amounts of mucopolysaccharides (a process previously called *cystic medial degeneration*). Patients with Marfan syndrome have a mutation in the fibrillin gene located on the long arm of chromosome 15. The traditionally held view is that abnormal fibrillin in the extracellular matrix decreases connective tissue strength in the aortic wall and produces abnormal elasticity, which predisposes the aorta to dilatation from wall tension caused by left ventricular ejection impulses.³ More recent evidence, however, shows that the abnormal fibrillin causes degeneration of the aortic wall matrix by increasing the activity of transforming growth factor beta (TGF-β).⁴

Between 75 and 85% of patients with Marfan syndrome have dilatation of the ascending aorta and annuloaortic ectasia (dilatation of the aortic sinuses and annulus).⁵ Such aortic abnormalities are the most common cause of death among patients with Marfan syndrome.⁶ Marfan syndrome also is frequently associated with aortic dissection.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome includes a spectrum of inherited connective tissue disorders of collagen synthesis. The subtypes represent differing defective steps of collagen production. Vascular type Ehlers-Danlos syndrome is characterized by an autosomal dominant defect in type III collagen synthesis, which can have life-threatening cardiovascular manifestations. Spontaneous arterial rupture, usually involving the mesenteric vessels, is the most common cause of death in these patients. Thoracic aortic aneurysms and dissections are less commonly associated with Ehlers-Danlos syndrome, but when they do occur, they pose a particularly challenging surgical problem because of the reduced integrity of the aortic tissue in patients with Ehlers-Danlos syndrome.

Loeys-Dietz Syndrome

Recently described, Loeys-Dietz syndrome is phenotypically distinct from Marfan syndrome. It is characterized as an aneurysmal syndrome with widespread systemic involvement. Loeys-Dietz syndrome is an aggressive, autosomal dominant condition that is distinguished by the triad of arterial tortuosity and aneurysms, hypertelorism (widely spaced eyes), and bifid uvula or cleft palate. It is caused by heterozygous mutations in the genes encoding TGF- β receptors, rather than fibrillin 1.^{7,8}

Familial Aortic Aneurysms

Families without the heritable connective tissue disorders described earlier also can be affected by genetic conditions that cause thoracic aortic aneurysms. In fact, it is estimated that at least 20% of patients with thoracic aortic aneurysms and dissections have a genetic predisposition to them. The involved mutations are characterized by autosomal dominant inheritance with decreased penetrance and variable expression. Thus far, mutations involving the genes for TGF- β receptor 2 (*TGF β R2*), β -myosin heavy chain (*MYH11*), and α -smooth muscle cell actin (*ACTA2*) have been identified as causes of familial thoracic aortic aneurysms and dissection. Two other loci—on chromosomes 5 and 11—also have been associated with this condition, but the responsible genes have not yet been clearly identified.⁹

Congenital Bicuspid Aortic Valve

Bicuspid aortic valve is the most common congenital malformation of the heart or great vessels, affecting up to 2% of Americans.¹⁰ Compared to patients with normal, trileaflet aortic valves, patients with bicuspid aortic valves have an increased incidence of ascending aortic aneurysm formation and, often, a more rapid rate of aortic enlargement.¹¹ Fifty percent to 70% of adults with bicuspid aortic valve, but without significant valve dysfunction, have echocardiographically detectable aortic dilatation.^{12,13} This dilatation usually is limited to the ascending aorta and root.¹⁴ Dilatation occasionally is found in the arch and only rarely in the descending or abdominal aorta. In addition, aortic dissection occurs 10 times more often in patients with bicuspid valves than in the general population.¹⁵ Recent findings suggest that aneurysms associated with bicuspid aortic valves have a fundamentally different pathobiologic cause than aneurysms that occur in patients with trileaflet valves.¹⁶

The exact mechanism responsible for aneurysm formation in patients with bicuspid aortic valves remains controversial. The two most popular theories posit that the dilatation is caused by (a) a congenital defect involving the aortic wall matrix that results in progressive degeneration, or (b) ongoing hemodynamic stress caused by turbulent flow through the diseased valve. It is likely that both proposed mechanisms are involved: patients with bicuspid aortic valves may have a congenital connective tissue abnormality that predisposes the aorta to aneurysm formation, especially in the presence of chronic turbulent flow through a deformed valve.

In support of the theory that aneurysms result from vascular matrix remodeling that causes structural weakness of the aortic wall, evidence suggests that fibrillin 1 content is significantly lower and matrix metalloproteinase activity is significantly higher in the aortic media in patients with bicuspid aortic valves than in persons with normal tricuspid aortic valves.^{16–18} In recent years, clinical studies

have increasingly supported the theory that aortic wall fragility, not turbulent flow, is the main mechanism of dilatation in these patients. For example, one study showed that the aorta progressively dilates when the bicuspid valve is replaced with a prosthesis, despite the elimination of the hemodynamic lesion.¹⁹ In addition, several studies have found evidence of a genetic predisposition to this condition.^{20–22}

INFECTION

Primary infection of the aortic wall resulting in aneurysm formation is rare. Although these lesions are termed *mycotic aneurysms*, the responsible pathogens usually are bacteria rather than fungi. Bacterial invasion of the aortic wall may result from bacterial endocarditis, endothelial trauma caused by an aortic jet lesion, or extension from an infected laminar clot within a pre-existing aneurysm. The most common causative organisms are *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Salmonella*, and *Streptococcus*.^{23,24} Unlike most other causes of thoracic aortic aneurysms, which generally produce fusiform aneurysms, infection often produces saccular aneurysms located in areas of aortic tissue destroyed by the infectious process.

Although syphilis was once the most common cause of ascending aortic aneurysms, the advent of effective antibiotic therapy has made syphilitic aneurysms a rarity in developed nations. In other parts of the world, however, syphilitic aneurysms remain a major cause of morbidity and mortality. The spirochete *Treponema pallidum* causes an obliterative endarteritis of the vasa vasorum that results in medial ischemia and loss of the elastic and muscular elements of the aortic wall. The ascending aorta and arch are the most commonly involved areas. The emergence of HIV infection in the 1980s was associated with a substantial increase in the incidence of syphilis in both HIV-positive and HIV-negative patients. Because syphilitic aortitis often presents 10 to 30 years after the primary infection, the incidence of associated aneurysms may increase in the near future.

AORTITIS

In patients with pre-existing degenerative thoracic aortic aneurysms, localized transmural inflammation and subsequent fibrosis can develop. The dense aortic infiltrate responsible for the fibrosis consists of lymphocytes, plasma cells, and giant cells. The cause of the intense inflammatory reaction is unknown. Although the severe inflammation is a superimposed problem rather than a primary cause, its onset within an aneurysm can further weaken the aortic wall and precipitate expansion.

Systemic autoimmune disorders also cause thoracic aortitis. Aortic Takayasu's arteritis generally produces obstructive lesions related to severe intimal thickening, but associated medial necrosis can lead to aneurysm formation. In patients with giant cell arteritis (temporal arteritis), granulomatous inflammation may develop that involves the entire thickness of the aortic wall, causing intimal thickening and medial destruction. Rheumatoid aortitis is an uncommon systemic disease that is associated with rheumatoid arthritis and ankylosing spondylitis. The resulting medial inflammation and fibrosis can affect the aortic root, causing annular dilatation, aortic valve regurgitation, and ascending aortic aneurysm formation.

PSEUDOANEURYSMS

Pseudoaneurysms of the thoracic aorta usually represent chronic leaks that are contained by surrounding tissue and fibrosis. By definition, the wall of a pseudoaneurysm is not formed by intact aortic tissue; rather, the wall develops from organized thrombus and associated fibrosis. Pseudoaneurysms can arise from primary defects in the aortic wall (e.g., after trauma or contained aneurysm rupture) or from anastomotic leaks that occur after cardiovascular surgery. Anastomotic pseudoaneurysms can be caused by technical problems or by deterioration of the native aortic tissue, graft material, or suture. Tissue deterioration usually is related to either progressive degenerative disease or infection. Improvements in sutures, graft materials, and surgical techniques have decreased the incidence of thoracic aortic pseudoaneurysms.

Natural History

Treatment decisions in cases of thoracic aortic aneurysm are guided by our current understanding of the natural history of these aneurysms, which classically is characterized as progressive aortic dilatation and eventual dissection, rupture, or both. An analysis by

Eleftheriades of data from 1600 patients with thoracic aortic disease has helped quantify these well-recognized risks.²⁵ Average expansion rates were 0.07 cm/y in ascending aortic aneurysms and 0.19 cm/y in descending thoracic aortic aneurysms. As expected, aortic diameter was a strong predictor of rupture, dissection, and mortality. For thoracic aortic aneurysms >6 cm in diameter, annual rates of catastrophic complications were 3.6% for rupture, 3.7% for dissection, and 10.8% for death. Critical diameters, at which the incidence of expected complications significantly increased, were 6.0 cm for aneurysms of the ascending aorta and 7.0 cm for aneurysms of the descending thoracic aorta; the corresponding risks of rupture after reaching these diameters were 31 and 43%, respectively.²⁶

Certain types of aneurysms have an increased propensity for expansion and rupture. For example, aneurysms in patients with Marfan syndrome dilate at an accelerated rate and rupture or dissect at smaller diameters than non-Marfan-related aneurysms. Before the era of surgical treatment for aortic aneurysms, this aggressive form of aortic disease resulted in an average life expectancy of 32 years for Marfan patients; aortic root complications caused the majority of deaths.²⁷ Saccular aneurysms, which commonly are associated with aortic infection and typically affect only a discrete small section of the aorta, tend to grow more rapidly than fusiform aneurysms, which are associated with more widespread degenerative changes and generally affect a larger section of the aorta.

One common clinical scenario deserves special attention. A moderately dilated ascending aorta (i.e., 4 to 5 cm) often is encountered during aortic valve replacement or coronary artery bypass operations. The natural history of these ectatic ascending aortas has been defined by several studies. Michel and colleagues²⁸ studied patients whose ascending aortic diameters were >4 cm at the time of aortic valve replacement; 25% of these patients required reoperation for ascending aortic replacement. Prenger and colleagues²⁹ reported that aortic dissection occurred in 27% of patients who had aortic diameters of >5 cm at the time of aortic valve replacement.

Clinical Manifestations

In many patients with thoracic aortic aneurysms, the aneurysm is discovered incidentally when imaging studies are performed for unrelated reasons. Therefore, patients often are asymptomatic at the time of diagnosis. However, thoracic aortic aneurysms that initially go undetected eventually create symptoms and signs that correspond with the segment of aorta that is involved. These aneurysms have a wide variety of manifestations, including compression or erosion of adjacent structures, aortic valve regurgitation, distal embolism, and rupture.

LOCAL COMPRESSION AND EROSION

Initially, aneurysmal expansion and impingement on adjacent structures causes mild, chronic pain. The most common symptom in patients with ascending aortic aneurysms is anterior chest discomfort; the pain is frequently precordial in location but may radiate to the neck and jaw, mimicking angina. Aneurysms of the ascending aorta and transverse aortic arch can cause symptoms related to compression of the superior vena cava, the pulmonary artery, the airway, or the sternum. Rarely, these aneurysms erode into the superior vena cava or right atrium, causing acute high-output failure. Expansion of the distal aortic arch can stretch the recurrent laryngeal nerve, which results in left vocal cord paralysis and hoarseness. Descending thoracic and thoracoabdominal aneurysms frequently cause back pain localized between the scapulae. When the aneurysm is largest in the region of the aortic hiatus, it may cause middle back and epigastric pain. Thoracic or lumbar vertebral body erosion typically causes severe, chronic back pain; extreme cases can present with spinal instability and neurologic deficits from spinal cord compression. Although mycotic aneurysms have a peculiar propensity to destroy vertebral bodies, spinal erosion also occurs with degenerative aneurysms. Descending thoracic aortic aneurysms may cause varying degrees of airway obstruction, manifesting as cough, wheezing, stridor, or pneumonitis. Pulmonary or airway erosion presents as hemoptysis. Compression and erosion of the esophagus cause dysphagia and hematemesis, respectively. Thoracoabdominal aortic aneurysms can cause duodenal obstruction or, if they erode through the bowel wall, GI bleeding. Jaundice due to compression of the liver or porta hepatis is uncommon. Erosion into the inferior vena cava or iliac vein presents with an abdominal bruit, widened pulse pressure, edema, and heart failure.

AORTIC VALVE REGURGITATION

Ascending aortic aneurysms can cause displacement of the aortic valve commissures and annular dilatation. The resulting deformation of the aortic valve leads to progressively worsening aortic valve regurgitation. In response to the volume overload, the heart remodels and becomes increasingly dilated. Patients with this condition may present with progressive heart failure, a widened pulse pressure, and a diastolic murmur.

DISTAL EMBOLIZATION

Thoracic aortic aneurysms—particularly those involving the descending and thoracoabdominal aorta—are commonly lined with friable, atheromatous plaque and mural thrombus. This debris may embolize distally, causing occlusion and thrombosis of the visceral, renal, or lower-extremity branches.

RUPTURE

Patients with ruptured thoracic aortic aneurysms often experience sudden, severe pain in the anterior chest (ascending aorta), upper back or left chest (descending thoracic aorta), or left flank or abdomen (thoracoabdominal aorta). When ascending aortic aneurysms rupture, they usually bleed into the pericardial space, producing acute cardiac tamponade and death. Descending thoracic aortic aneurysms rupture into the pleural cavity, producing a combination of severe hemorrhagic shock and respiratory compromise. External rupture is extremely rare; saccular syphilitic aneurysms have been observed to rupture externally after eroding through the sternum.

Diagnostic Evaluation

Although certain constellations of symptoms and signs are highly suggestive of thoracic aortic aneurysm, diagnosing and characterizing these aneurysms requires imaging studies. In addition to establishing the diagnosis, imaging studies provide critical information that guides the selection of treatment options. Optimal imaging techniques for the thoracic and thoracoabdominal aorta are somewhat institution-specific, varying with the availability of imaging equipment and expertise.

PLAIN RADIOGRAPHY

Plain radiographs of the chest, abdomen, or spine often provide enough information to support the initial diagnosis of thoracic aortic aneurysm. Ascending aortic aneurysms produce a convex shadow to the right of the cardiac silhouette. The anterior projection of an ascending aneurysm results in the loss of the retrosternal space in the lateral view. An aneurysm may be indistinguishable from elongation and tortuosity.³⁰ It is important to recognize that chest radiographs (CXRs) often appear normal in patients with thoracic aortic disease and thus cannot exclude the diagnosis of aortic aneurysm. Aortic root aneurysms, for example, often are hidden within the cardiac silhouette. Plain CXRs may reveal convexity in the right superior mediastinum, loss of the retrosternal space, or widening of the descending thoracic aortic shadow, which may be highlighted by a rim of calcification outlining the dilated aneurysmal aortic wall. Aortic calcification also may be seen in the upper abdomen on a standard radiograph made in the anteroposterior or lateral projection (Fig. 22-2). Once a thoracic aortic aneurysm is detected on plain radiographs, additional studies are required to define the extent of aortic involvement.

ULTRASONOGRAPHY

Although useful in evaluating infrarenal abdominal aortic aneurysms, standard transabdominal ultrasonography does not allow visualization of the thoracic aorta. During ultrasound evaluation of a suspected infrarenal abdominal aortic aneurysm, if a definitive neck cannot be identified at the level of the renal arteries, the possibility of thoracoabdominal aortic involvement should be suspected and investigated by using other imaging modalities.

ECHOCARDIOGRAPHY

Ascending aortic aneurysms are commonly discovered during echocardiography in patients presenting with symptoms or signs of aortic valve regurgitation. Both transthoracic and transesophageal echocardiography provide excellent visualization of the ascending aorta, including the aortic root.³¹ Transesophageal echocardiography (TEE) also allows visualization of the descending thoracic aorta but is not ideal for evaluating the transverse aortic arch (which is obscured by air in the tracheobronchial tree) or the upper abdominal aorta. Effective echocardiography requires considerable technical skill, both in obtaining adequate images and in interpreting them. This imaging modality has the added benefit of assessing cardiac function and revealing any other abnormalities that may be present.

COMPUTED TOMOGRAPHY

Computed tomographic (CT) scanning is widely available and provides visualization of the entire thoracic and abdominal aorta. Consequently, CT is the most common—and arguably the most useful—imaging modality for evaluating thoracic aortic aneurysms.³² Systems capable of constructing multiplanar images and performing three-dimensional aortic reconstructions are widely available. In addition to establishing the diagnosis, CT provides information about an aneurysm's location, extent, anatomic anomalies, and relationship to major branch vessels. CT is particularly useful in determining the absolute diameter of the aorta, especially in the presence of laminated clot. Contrast-enhanced CT provides information about the aortic lumen and can detect mural thrombus, aortic dissection, inflammatory periaortic fibrosis, and mediastinal or retroperitoneal hematoma due to contained aortic rupture. The major disadvantage of contrast-enhanced CT scanning is the possibility of contrast-induced acute renal failure in patients who are at risk (e.g., patients with pre-existing renal disease or diabetes).³³ If possible, surgery is performed ≥ 1 day after contrast administration to allow time to observe renal function and to permit diuresis of the contrast agent. If renal insufficiency occurs or is worsened, elective surgery is postponed until renal function returns to normal or stabilizes.

MAGNETIC RESONANCE ANGIOGRAPHY

Magnetic resonance angiography (MRA) is becoming widely available and has the ability to facilitate visualization of the entire aorta. This modality produces aortic images comparable to those produced by contrast-enhanced CT but does not necessitate exposure to ionizing radiation. In addition, MRA offers excellent visualization of branch vessel details, and it is useful in detecting branch vessel stenosis.³⁴ Current limitations of MRA include high expense and a susceptibility to artifacts created by ferromagnetic materials. Also, a few recent studies have suggested that gadolinium—the contrast agent for MRA—may be linked to nephrogenic systemic fibrosis and acute renal failure in patients with advanced renal insufficiency.³⁵ Furthermore, the MRA environment is not appropriate for many critically ill patients.

AORTOGRAPHY AND CARDIAC CATHETERIZATION

Although diagnostic aortography was, until recently, considered the gold standard for evaluating thoracic aortic disease, CT and MRA have largely replaced this modality. Technologic improvements have enabled CT and MRA to provide excellent aortic imaging while causing less morbidity than catheter-based studies do, so CT and MRA should now be considered the gold standard. Therefore, the role of diagnostic angiography in patients with thoracic aortic disease is currently limited. However, the advent of endovascular therapies has given catheter-based angiography a new role, because intraprocedural angiography is an essential component of endovascular procedures.

In selected cases, aortography is used to gain important information when other types of studies are contraindicated or have not provided satisfactory results. For example, information about obstructive lesions of the brachiocephalic, visceral, renal, or iliac arteries is useful when surgical treatment is being planned; if other imaging studies have not provided adequate detail, aortograms can be obtained in patients with suspected branch vessel occlusive disease.

Unlike standard aortography, cardiac catheterization continues to play a major role in diagnosis and preoperative planning, especially in patients with ascending aortic involvement. Proximal aortography can reveal not only the status of the coronary arteries and left ventricular function but also the degree of aortic valve regurgitation, the extent of aortic root involvement, coronary ostial displacement, and the relationship of the aneurysm to the arch vessels.

The value of the information one can obtain from catheter-based diagnostic studies should be weighed against the established limitations and potential complications of such studies. A key limitation of aortography is that it images only the lumen and may therefore underrepresent the size of large aneurysms that contain laminated thrombus. Manipulation of intraluminal catheters can result in embolization of laminated thrombus or atheromatous debris. Proximal aortography carries a 0.6 to 1.2% risk of stroke. Other risks include allergic reaction to contrast agent, iatrogenic aortic dissection, and bleeding at the arterial access site. In addition, the volumes of contrast agent required to adequately fill large aneurysms can cause significant renal toxicity. To minimize the risk of contrast nephropathy, patients receive periprocedural IV fluids for hydration, mannitol for diuresis, and acetylcysteine.^{36,37} As with contrast-enhanced CT, surgery is performed ≥ 1 day after angiography whenever possible to ensure that renal function has stabilized or returned to baseline.

Treatment

DETERMINATION OF THE APPROPRIATE TREATMENT

Once a thoracic aortic aneurysm is detected, management begins with patient education, particularly if the patient is asymptomatic. A detailed medical history is collected, a physical examination is performed, and a systematic review of medical records is carried out to clearly assess the presence or absence of pertinent symptoms and signs, despite any initial denial of symptoms by the patient. Signs of genetic diseases such as Marfan syndrome are thoroughly reviewed. If clinical criteria are met for such a genetic condition, confirmatory laboratory tests are conducted. Patients with such genetic diseases are best treated in a dedicated aortic clinic where they can be appropriately followed. Surveillance CT scans and aggressive blood pressure control are the mainstays of initial management for asymptomatic patients. When patients become symptomatic or their aneurysms grow to meet certain size criteria, the patients become surgical candidates.

Since the last edition of this textbook was published, endovascular therapy has become an accepted treatment for thoracic aortic aneurysms. Although its role in treating proximal aortic disease and thoracoabdominal aortic aneurysms remains experimental, endoluminal stenting is approved by the Food and Drug Administration for the treatment of isolated descending thoracic aortic aneurysms. For aneurysms with proximal aortic involvement and for thoracoabdominal aortic aneurysms, open procedures remain the gold standard and preferred approach.

DETERMINATION OF THE EXTENT AND SEVERITY OF DISEASE

Serial CT scans are critical when one is evaluating a thoracic aneurysm, determining treatment strategy, and planning necessary procedures. Note that, commonly, patients with a thoracic aortic aneurysm also have a remote aneurysm.² In such cases, the more threatening lesion usually is addressed first. In many patients, staged operative procedures are necessary for complete repair of extensive aneurysms involving the ascending aorta, transverse arch, and descending thoracic or thoracoabdominal aorta.³⁸ When the descending segment is not disproportionately large (compared with the proximal aorta) and is not causing symptoms, the proximal aortic repair is carried out first. An important benefit of this approach is that it allows treatment of valvular and coronary artery occlusive disease at the first operation.

Proximal aneurysms (proximal to the left subclavian artery) usually are addressed via a sternotomy approach. Left thoracotomy incisions are used for open repairs of aneurysms involving the descending thoracic aorta, unless the aneurysm fulfills certain endovascular criteria. A CT scan can reveal detailed information about aortic calcification and luminal thrombus. These details are important in preventing embolization during surgical manipulation.

Indications for Operation

Thoracic aortic aneurysms are repaired to prevent fatal rupture. Therefore, on the basis of the natural history studies discussed earlier, elective operation is recommended when the diameter of an ascending aortic aneurysm is >5.5 cm, when the diameter of a descending thoracic aortic aneurysm is >6.5 cm, or when the rate of dilatation is >1 cm/y.^{25,39} In patients with connective tissue disorders, such as Marfan and Loeys-Dietz syndromes, the threshold for operation is lower with regard to both absolute size (5.0 cm for the ascending aorta and 6.0 cm for the descending thoracic aorta) and rate of growth. Smaller ascending aortic aneurysms (4.0 to 5.5 cm) also are considered for repair when they are associated with significant aortic valve regurgitation.

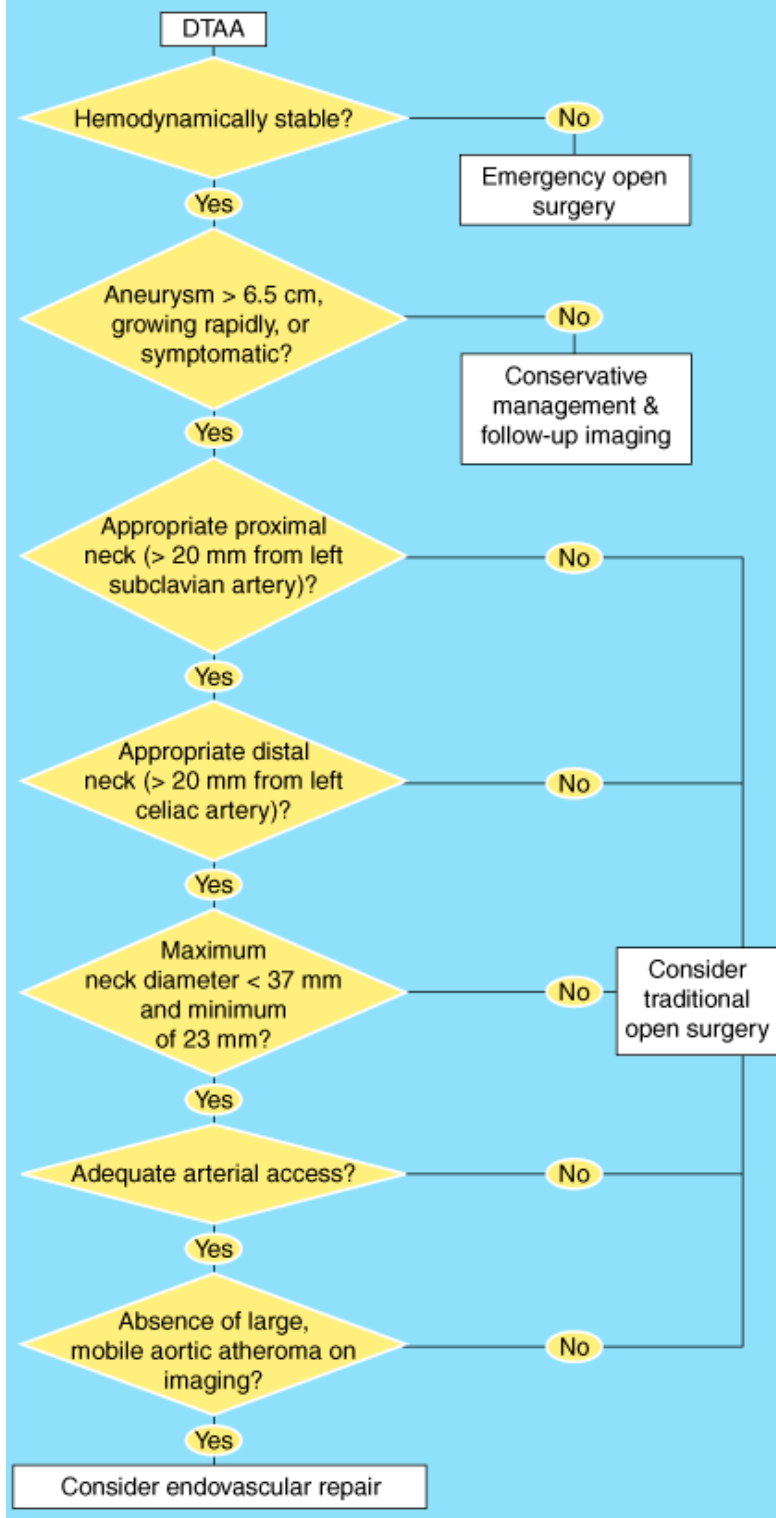

The acuity of presentation is a major factor in decisions about the timing of surgical intervention. Many patients are asymptomatic at the time of presentation, so there is time for thorough preoperative evaluation and improvement of their current health status, such as through smoking cessation and other optimization programs. In contrast, patients who present with symptoms may need urgent operation. Symptomatic patients are at increased risk of rupture and warrant expeditious evaluation. The onset of new pain in patients with known aneurysms is especially concerning, because it may herald significant expansion, leakage, or impending rupture. Because emergent interventions produce worse outcomes than elective procedures do, emergent intervention is reserved for patients who present with rupture or superimposed acute dissection.⁴⁰

Open Repair vs. Endovascular Repair

As noted earlier, endovascular repair of thoracic aortic aneurysms has become an accepted treatment option in selected patients, particularly patients with isolated degenerative descending thoracic aortic aneurysms. For endovascular repairs to produce optimal outcomes, several anatomic criteria must be met. For one, the proximal and distal neck diameters should fall within a range that will allow proper sealing. Also, the proximal and distal necks should be at least 20 mm long so that an appropriate landing-zone seal can be made. Note that the limiting structures proximally and distally are the brachiocephalic vessels and celiac axis, respectively. Another anatomic limitation for this therapy relates to vascular access: The femoral and iliac arteries have to be wide enough to accommodate the large sheaths necessary to deploy the stent grafts. Occasionally, a "side graft" must be anastomosed to the iliac artery through a retroperitoneal incision because of poor distal access. When any of these anatomic criteria is not met, an open approach is preferable to an endovascular approach. Of note, attempts have been made to extend the use of endovascular therapy to aortic arch aneurysms and thoracoabdominal aortic aneurysms. Reports of these types of purely endovascular repair are limited. Still experimental, hybrid approaches involve debranching the aortic arch or the visceral vessels of the abdominal aorta followed by endovascular exclusion of the aneurysm. Figure 22-3 provides an algorithm for the management of descending thoracic aortic aneurysm.

Management of descending thoracic aortic aneurysm (DTAA)

Algorithm for the management of descending thoracic aortic aneurysm as used to facilitate decisions regarding treatment.

The patients who benefit more from an endovascular approach than from traditional open techniques are those who are of advanced age or have significant comorbidities. The open repair of a descending thoracic aortic aneurysm can result in significant pulmonary morbidity. Therefore, patients with borderline pulmonary reserve may be best suited for an endovascular or hybrid procedure. In

contrast, patients with significant intraluminal atheroma are best served by an open approach because of the risk of embolization and stroke posed by catheter manipulations. Similarly, patients with connective tissue disease should undergo an open procedure and generally are not considered candidates for endovascular repair. Endovascular repair in the setting of connective tissue disorders has been met with poor results, which are mainly due to progressive dilatation, stent graft migration, and endoleak.

PREOPERATIVE ASSESSMENT AND PREPARATION

Given the impact of comorbid conditions on perioperative complications, a careful preoperative assessment of physiologic reserve is critical in assessing operative risk. Therefore, most patients undergo a thorough evaluation—with emphasis on cardiac, pulmonary, and renal function—before undergoing elective surgery.^{41,42}

Cardiac Evaluation

Coronary artery disease is common in patients with thoracic aortic aneurysms and is responsible for a substantial proportion of early and late postoperative deaths in such patients. Similarly, valvular disease and myocardial dysfunction have important implications when one is planning anesthetic management and surgical approaches for aortic repair. Transthoracic echocardiography is a satisfactory noninvasive method for evaluating both valvular and biventricular function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that have reversible ischemia, and this test is more practical than exercise testing in older patients with concomitant lower-extremity peripheral vascular disease. Cardiac catheterization and coronary arteriography are performed in patients who have evidence of coronary disease—as indicated by either the patient's history or the results of noninvasive studies—or who have a left ventricular ejection fraction of $\leq 30\%$. If significant valvular or coronary artery disease is identified before a proximal aortic operation, the disease can be addressed directly during the procedure. Patients who have asymptomatic distal aortic aneurysms and severe coronary occlusive disease undergo percutaneous transluminal angioplasty or surgical revascularization before the aneurysmal aortic segment is replaced.

Pulmonary Evaluation

Pulmonary function screening with arterial blood gas measurement and spirometry is routinely performed before thoracic aortic operations. Patients with a forced expiratory volume in 1 second of >1.0 L and a partial pressure of carbon dioxide of <45 mmHg are considered surgical candidates. In suitable patients, borderline pulmonary function can be improved by implementing a regimen that includes smoking cessation, weight loss, exercise, and treatment of bronchitis for a period of 1 to 3 months before surgery. Although surgery is not withheld from patients with symptomatic aortic aneurysms and poor pulmonary function, adjustments in operative technique should be made to maximize these patients' chances of recovery. In such patients, preserving the left recurrent laryngeal nerve, the phrenic nerves, and diaphragmatic function is particularly important.

Renal Evaluation

Renal function is assessed preoperatively by measuring serum electrolyte, blood urea nitrogen, and creatinine levels. Information about kidney size and perfusion can be obtained from the CT scan or aortogram used to evaluate the aorta.

Accurate information about baseline renal function has important therapeutic and prognostic implications. For example, perfusion strategies and perioperative medications are adjusted according to renal function. Patients with severely impaired renal function frequently require at least temporary hemodialysis after surgery. These patients also have a mortality rate that is significantly higher than normal. Patients with thoracoabdominal aortic aneurysms and poor renal function secondary to severe proximal renal occlusive disease undergo renal artery endarterectomy, stenting, or bypass grafting during the aortic repair.

OPERATIVE REPAIR

Proximal Thoracic Aortic Aneurysms

Open Repair

Operations to repair proximal aortic aneurysms—which involve the ascending aorta, transverse aortic arch, or both—are performed through a midsternal incision and require cardiopulmonary bypass. The best choice of aortic replacement technique varies depending on the extent of the aneurysm and the condition of the aortic valve. The spectrum of operations ranges from simple graft replacement of the tubular portion of the ascending aorta (Fig. 22-4) to graft replacement of the entire proximal aorta, including the aortic root, and reattachment of the coronary arteries and brachiocephalic branches. The options for treating aortic valve disease, repairing aortic aneurysms, and maintaining perfusion during repair procedures each deserve detailed consideration (Table 22-2).

Illustration of an ascending aortic repair. The tubular portion of the ascending aorta has been replaced by a graft, and the native aortic root and arch are left intact.

Table 22-2 Options for Open Surgical Repair of Proximal Aortic Aneurysms
<i>Options for treating aortic valve disease</i>
Aortic valve annuloplasty (annular plication)
Aortic valve replacement with mechanical or biologic prosthesis
Aortic root replacement
Composite valve graft
Aortic homograft

Stentless porcine root
Pulmonary autograft (Ross procedure)
Valve-sparing techniques
<i>Options for graft repair of the aortic aneurysm</i>
Patch aortoplasty
Ascending replacement only
Beveled hemiarch replacement
Total arch replacement with reattachment of brachiocephalic branches
Total arch replacement with bypass grafts to the brachiocephalic branches
Elephant trunk technique
<i>Perfusion options</i>
Standard cardiopulmonary bypass
Hypothermic circulatory arrest without adjuncts
Hypothermic circulatory arrest with adjuncts
Retrograde cerebral perfusion
Selective antegrade cerebral perfusion
Balloon perfusion catheters
Right axillary artery cannulation
Combined antegrade and retrograde cerebral perfusion

Aortic Valve Disease and Root Aneurysms

Many patients undergoing proximal aortic operations have aortic valve disease that requires concomitant surgical correction. When such disease is present and the sinus segment is normal, separate repair or replacement of the aortic valve and graft replacement of the tubular segment of the ascending aorta are carried out. Mild to moderate valve regurgitation with annular dilatation in this setting can be addressed by plicating the annulus with mattress sutures placed below each commissure. The valve is replaced with a stented biologic or mechanical prosthesis in patients with more severe valvular regurgitation or with valvular stenosis. Separate replacement of the aortic valve and ascending aorta is not performed in patients with Marfan syndrome, because progressive dilatation of the remaining sinus segment eventually leads to complications that necessitate reoperation. Therefore, patients with Marfan syndrome or annuloaortic ectasia require some form of aortic root replacement.⁴³

In most cases, the aortic root is replaced with a mechanical or biologic graft that has both a valve and an aortic conduit. Currently, three graft options are commercially available: composite valve grafts, which consist of a bileaflet mechanical valve attached to a polyester tube graft; aortic root homografts, which are harvested from cadavers and cryopreserved; and stentless porcine aortic root grafts.^{44,45}

Another option for selected patients is the Ross procedure, in which the patient's pulmonary artery root is excised and placed in the aortic position. The right ventricular outflow tract is reconstructed by using a cryopreserved pulmonary homograft. This option is rarely used, largely because of its technical demands and because of concerns about the potential for autograft dilatation in patients with connective tissue disorders.⁴⁶ An additional option is valve-sparing aortic root replacement, which has evolved substantially during the past decade.⁴⁷ The valve-sparing technique that is currently favored is called *aortic root reimplantation* and involves excising the aortic sinuses, attaching a prosthetic graft to the patient's annulus, and resuspending the native aortic valve inside the graft. The superior hemodynamics of the native valve and the avoidance of anticoagulation are major advantages of the valve-sparing approach. Long-term results in carefully selected patients have been excellent.⁴⁸ The durability of this procedure in patients with either Marfan syndrome or bicuspid aortic valves has been the subject of controversy. Recently, in appropriately experienced centers, this technique has shown encouraging long-term durability for patients with Marfan syndrome.^{49,50} Also, there is evidence that valve-sparing

techniques can produce acceptable outcomes in patients with bicuspid aortic valves.⁵¹

Regardless of the type of conduit used, aortic root replacement requires reattaching the coronary arteries to openings in the graft. In the original procedure described by Bentall and De Bono,⁵² this was accomplished by suturing the intact aortic wall surrounding each coronary artery to the openings in the graft. The aortic wall was then wrapped around the graft to establish hemostasis. However, this technique frequently produced leaks at the coronary reattachment sites that eventually led to pseudoaneurysm formation. Cabrol's modification, in which a separate, small tube graft is sutured to the coronary ostia and the main aortic graft, achieves tension-free coronary anastomoses and reduces the risk of pseudoaneurysm formation.⁵³ Kouchoukos's button modification of the Bentall procedure is currently the most widely used technique.⁵⁴ The aneurysmal aorta is excised, and buttons of aortic wall are left surrounding both coronary arteries, which are then mobilized and sutured to the aortic graft (Fig. 22-5). The coronary suture lines may be reinforced with polytetrafluoroethylene felt or pericardium to enhance hemostasis. When the coronary arteries cannot be mobilized adequately because of extremely large aneurysms or scarring from previous surgery, the Cabrol technique can be used. Another option, originally described by Zubieta and Kay,⁵⁵ is the construction of bypass grafts by using interposition saphenous vein or synthetic grafts.

Fig. 22-5.

Illustration of the modified Bentall procedure for replacing the aortic root and ascending aorta. The aortic valve and entire ascending aorta, including the sinuses of Valsalva, have been replaced by a mechanical composite valve graft. The coronary arteries with buttons of surrounding aortic tissue have been mobilized and are being reattached to openings in the aortic graft.

Aortic Arch Aneurysms

Several options are also available for handling aneurysms that extend into the transverse aortic arch. The surgical approach depends on the extent of involvement and the need for cardiac and cerebral protection. Saccular aneurysms that arise from the lesser curvature of the distal transverse arch and that encompass <50% of the aortic circumference are treated by patch graft aortoplasty. For fusiform aneurysms, when the distal portion of the arch is a reasonable size, a single, beveled replacement of the lower curvature (hemiarch) is performed. More extensive arch aneurysms require total replacement involving a distal anastomosis to the proximal descending thoracic aorta and separate reattachment of the brachiocephalic branches. The brachiocephalic vessels are reattached to one or more openings made in the graft, or if these vessels are aneurysmal, they are replaced with separate, smaller grafts. In the most extreme cases, the aneurysm involves the entire arch and extends into the descending thoracic aorta. Such aneurysms are approached by using Borst's elephant trunk technique of staged total arch replacement (Fig. 22-6).⁵⁷ The distal anastomosis is constructed so that a portion of the graft is left suspended within the proximal descending thoracic aorta. During a subsequent operation, this "trunk" is used to facilitate repair of the descending thoracic aorta through a thoracotomy incision. This technique permits access to the distal portion of the graft at the second operation without the need for dissection around the distal transverse aortic arch; this reduces the risk of injuring the left recurrent laryngeal nerve, esophagus, and pulmonary artery if an open approach is used at the second stage. As described in the section on hybrid repair of arch aneurysms (see later), the elephant trunk can be completed by using a hybrid endovascular approach in certain settings.

Cardiopulmonary Bypass Perfusion Strategies

Like the operations themselves, perfusion strategies used during proximal aortic surgery depend on the extent of the repair. Aneurysms that are isolated to the ascending segment can be replaced by using standard cardiopulmonary bypass and distal ascending aortic clamping. This provides constant perfusion of the brain and other vital organs during the repair. Aneurysms involving the transverse aortic arch, however, cannot be clamped during the repair, which necessitates the temporary withdrawal of cardiopulmonary bypass support; this is called *circulatory arrest*. To protect the brain and other vital organs during the circulatory arrest period, profound cooling must be initiated before pump flow is stopped. An electroencephalogram is monitored during cooling. Once electrocerebral

silence is achieved—indicating cessation of brain activity and minimization of metabolic requirements—the pump flow is stopped, and the arch is repaired. Electrocerebral silence usually occurs when the patient's nasopharyngeal temperature falls below 18°C (64.4°F). Although brief periods of circulatory arrest generally are well tolerated, this technique does have substantial limitations. The well-recognized risks of brain injury and death increase dramatically as the duration of circulatory arrest increases. Techniques for monitoring the brain during circulatory arrest have proven benefits in pediatric patients.⁵⁸ Whether transcranial Doppler ultrasonography and near-infrared spectroscopy are of any benefit in adult patients remains to be determined.
