Approximately 80% of patients with PHPT have some degree of renal dysfunction or symptoms. Kidney stones were previously reported in up to 80% of patients but now occur in about 20 to 25%. The calculi are typically composed of calcium phosphate or oxalate. In contrast, PHPT is found to be the underlying disorder in only 3% of patients presenting with nephrolithiasis. *Nephrocalcinosis*, which refers to renal parenchymal calcification, is found in <5% of patients and is more likely to lead to renal dysfunction. Chronic hypercalcemia also can impair concentrating ability, thereby resulting in polyuria, polydipsia, and nocturia. The incidence of hypertension is variable but has been reported to occur in up to 50% of patients with PHPT. Hypertension appears to be more common in older patients and correlates with the magnitude of renal dysfunction and, in contrast to other symptoms, is least likely to improve after parathyroidectomy.

Bone Disease

Bone disease, including osteopenia, osteoporosis, and osteitis fibrosa cystica, is found in about 15% of patients with PHPT. Increased bone turnover, as found in patients with osteitis fibrosa cystica, can be determined by documenting an elevated blood alkaline phosphatase level. Advanced PHPT with osteitis fibrosa cystica now occurs in <5% of patients. It has pathognomonic radiologic findings, which are best seen on x-rays of the hands and are characterized by subperiosteal resorption (most apparent on the radial aspect of the middle phalanx of the second and third fingers), bone cysts, and tufting of the distal phalanges (Fig. 38-29). The skull also may be affected and appears mottled with a loss of definition of the inner and outer cortices. Brown or osteoclastic tumors and bone cysts also may be present. Severe bone disease, resulting in bone pain and tenderness and/or pathologic fractures, is rarely observed nowadays. However, reductions of bone mineral density (BMD) with osteopenia and osteoporosis are more common. Patients with normal serum alkaline phosphatase levels almost never have clinically apparent osteitis fibrosa cystica. HPT typically results in a loss of bone mass at sites of cortical bone such as the radius and relative preservation of cancellous bone such as that located at the vertebral bodies. Patients with PHPT, however, also may have osteoporosis of the lumbar spine that improves dramatically following parathyroidectomy. Fractures also occur more frequently in patients with PHPT, and the incidence of fractures also decreases after parathyroidectomy. Bone disease correlates with serum PTH and vitamin D levels.

X-ray of the hand showing subperiosteal bone resorption most apparent along the radial aspect of the middle phalanx, characteristic of osteitis fibrosa cystica.

Gastrointestinal Complications

PHPT has been associated with peptic ulcer disease. In experimental animals, hypergastrinemia has been shown to result from PTH infusion into blood vessels supplying the stomach, independent of its effects on serum calcium. An increased incidence of pancreatitis also has been reported in patients with PHPT, although this appears to occur only in patients with profound hypercalcemia ($\text{Ca}^{2+} \geq 12.5 \text{ mg/dL}$). Patients with PHPT also have an increased incidence of cholelithiasis, presumably due to an increase in biliary calcium, which leads to the formation of calcium bilirubinate stones.

Neuropsychiatric Complications

Severe hypercalcemia may lead to various neuropsychiatric manifestations such as florid psychosis, obtundation, or coma. Other findings such as depression, anxiety, and fatigue are more commonly observed in patients with only mild hypercalcemia. The etiology of these symptoms is not known. Studies demonstrate that levels of certain neurotransmitters (monoamine metabolites 5-hydroxyindoleacetic acid and homovanillic acid) are reduced in the cerebrospinal fluid of patients with PHPT when compared to controls. Electroencephalogram abnormalities also occur in patients with primary and secondary HPT and normalize following parathyroidectomy.

Other Features

PHPT also can lead to fatigue and muscle weakness, which is prominent in the proximal muscle groups. Although the exact etiology of this finding is not known, muscle biopsy studies show that weakness results from a neuropathy, rather than a primary myopathic abnormality. Patients with HPT also have an increased incidence of chondrocalcinosis, gout, and pseudogout, with deposition of uric

acid calcium pyrophosphate crystals in the joints. Calcification at ectopic sites such as blood vessels, cardiac valves, and skin also has been reported, as has hypertrophy of the left ventricle independent of the presence of hypertension. Several large studies from Europe also suggest that PHPT is associated with increased death rates from cardiovascular disease and cancer even in patients with mild HPT,^{64,65} although this finding was not substantiated in North American studies.⁶⁶

Physical Findings

Parathyroid tumors are seldom palpable, except in patients with profound hypercalcemia. A palpable neck mass in a patient with PHPT is more likely to be thyroid in origin or a parathyroid cancer. Patients also may demonstrate evidence of band keratopathy, a deposition of calcium in Bowman's membrane just inside the iris of the eye. This nonspecific condition generally is caused by chronic eye diseases such as uveitis, glaucoma, and trauma but also may occur in the presence of conditions associated with high calcium or phosphate levels. Fibro-osseous jaw tumors, and or the presence of familial disease in patients with PHPT and jaw tumors, if present, should alert the physician to the possibility of parathyroid carcinoma.

Differential Diagnosis

Hypercalcemia may be caused by a multitude of conditions, as listed in Table 38-9. PHPT and malignancy account for >90% of all cases of hypercalcemia. PHPT is more common in the outpatient setting, whereas malignancy is the leading cause of hypercalcemia in hospitalized patients. PHPT can virtually always be distinguished from other diseases causing hypercalcemia by a combination of history, physical examination, and appropriate laboratory investigations.

Table 38-9 Differential Diagnosis of Hypercalcemia
Hyperparathyroidism
Malignancy—hematologic (multiple myeloma), solid tumors (due to PTHrP)
Endocrine diseases—hyperthyroidism, addisonian crisis, VIPoma
Granulomatous diseases—sarcoidosis, tuberculosis, berylliosis, histoplasmosis
Milk-alkali syndrome
Drugs—thiazide diuretics, lithium, vitamin A or D intoxication
Familial hypocalciuric hypercalcemia
Paget's disease
Immobilization

PTHrP = parathyroid hormone-related protein; VIP = vasoactive intestinal peptide.

Hypercalcemia associated with malignancy includes three distinct syndromes. Although bone metastases may cause hypercalcemia, patients with solid tumors of the lung, breast, kidney, head and neck, and ovary often have humoral hypercalcemia of malignancy, without any associated bony metastases. In addition, hypercalcemia also may be associated with hematologic malignancies such as multiple myeloma. Humoral hypercalcemia of malignancy is known to be mediated primarily by PTH-related peptide (PTHrP), which also plays a role in the hypercalcemia associated with bone metastases and multiple myeloma.

Thiazide diuretics cause hypercalcemia by decreasing renal clearance of calcium. This corrects in normal patients within days to weeks after discontinuing the diuretic, but patients with PHPT continue to be hypercalcemic. Thiazide diuretics can, therefore, exacerbate underlying PHPT and can be used to unmask PHPT in patients with borderline hypercalcemia. Familial hypocalciuric hypercalcemia (FHH) is a rare autosomal dominant condition with nearly 100% penetrance and results from inherited heterozygous mutations in the CASR gene located on chromosome 3.⁵⁷ Homozygous germline mutations at this locus result in neonatal hypercalcemia, a condition that can rapidly prove fatal. Patients with FHH have lifelong hypercalcemia, which is not corrected by parathyroidectomy. Hypercalcemia also is found in approximately 10% of patients with sarcoidosis secondary to increased 25-

hydroxy vitamin D 1-hydroxylase activity in lymphoid tissue and pulmonary macrophages, which is not subject to inhibitory feedback control by serum calcium. Thyroid hormone also has bone-resorption properties, thus causing hypercalcemia in thyrotoxic states, especially in immobilized patients. Hemoconcentration appears to be an important factor in the hypercalcemia associated with adrenal insufficiency and pheochromocytoma, although the latter patients may have associated parathyroid tumors (MEN2A), and some pheochromocytomas are known to secrete PTHrP. Other endocrine lesions such as vasoactive intestinal peptide-secreting tumors may be associated with hypercalcemia due to increased secretion of PTHrP. Milk-alkali syndrome requires the ingestion of large quantities of calcium with an absorbable alkali such as that used in the treatment of peptic ulcer disease with antacids. Ingestion of large quantities of vitamin D and A are infrequent causes of hypercalcemia, as is immobilization.

Diagnostic Investigations

Biochemical Studies

The presence of an elevated serum calcium and intact PTH or two-site PTH levels, without hypocalciuria establishes the diagnosis of PHPT with virtual certainty. These sensitive PTH assays use immunoradiometric or immunochemiluminescent techniques and can reliably distinguish PHPT from other causes of hypercalcemia. Furthermore, they do not cross-react with PTHrP (Fig. 38-30). In patients with metastatic cancer and hypercalcemia, intact PTH levels help to determine whether the patient also has concurrent PHPT. Although extremely rare, a patient with hypercalcemia may have a tumor that secretes PTH. FNAB of such a tumor for PTH levels or selective venous catheterization of the veins draining such tumors can help clarify the diagnosis.

Patients with PHPT also typically have decreased serum phosphate (~50%) and elevated 24-hour urinary calcium concentrations (~60%). A mild hyperchloremic metabolic acidosis also is present (80%), thereby leading to an elevated chloride to phosphate ratio (>33). Urinary calcium levels need not be measured routinely, except in patients who have not had previously documented normocalcemia or have a family history of hypercalcemia to rule out FHH. In patients with FHH, 24-hour urinary calcium excretion is characteristically low (<100 mg/d). Furthermore, the serum calcium to creatinine clearance ratio usually is <0.01 in patients with FHH, whereas it is typically >0.02 in patients with PHPT. Other biochemical features of PHPT are listed in Table 38-10. Elevated levels of alkaline phosphatase may be found in approximately 10% of patients with PHPT and are indicative of high turnover bone disease. These patients are prone to developing postoperative hypocalcemia due to bone hunger. Serum and urine protein electrophoresis may be necessary to exclude multiple myeloma.

Table 38-10 Biochemical Features of Primary Hyperparathyroidism	
Serum Tests	Alteration
Calcium	Increased, except in normocalcemic primary hyperparathyroidism
Intact PTH	Increased or inappropriately high
Chloride	Increased or high normal
Phosphate	Decreased or low normal
Chloride:phosphate ratio	Increased (usually >33)
Magnesium	Unchanged or decreased (in patients with osteitis fibrosa cystica)
Uric acid	Normal or increased
Alkaline phosphatase	Normal or increased (in the presence of high turnover bone disease)
Acid-base status	Mild hyperchloremic metabolic acidosis
Calcium:creatinine ratio	>0.02 (vs. <0.01 in BFHH)
1,25-dihydroxy vitamin D	Normal or increased
Urine tests	
24-h urinary calcium	Normal or increased

BFHH = benign familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

Occasionally, patients present with normocalcemic PHPT due to vitamin D deficiency, a low serum albumin, excessive hydration, a high phosphate diet, or a low normal blood calcium set point. These patients have increased total PTH levels with or without increased blood ionized calcium levels and must be distinguished from patients with renal leak hypercalciuria who also have increased PTH levels due to excessive calcium loss in the urine. This can be accomplished by administering thiazide diuretics. In patients with idiopathic hypercalciuria, the urinary calcium level falls, and the secondary increase in the blood PTH level also decreases to normal whereas patients with normocalcemic HPT continue to have elevated urine calcium and blood PTH levels, and may, in fact, become hypercalcemic.

Radiologic Tests

In patients with profound hypercalcemia or PHPT associated with vitamin D deficiency, hand and skull x-rays may demonstrate osteitis fibrosa cystica. BMD studies using dual energy absorptiometry are being increasingly used to assess the effects of PHPT on bone. Abdominal ultrasound examination is used selectively to document renal stones. Parathyroid localization studies are not used to confirm the diagnosis of PHPT, but rather to aid in identifying the location of the offending gland(s), as discussed below in

Treatment

Indications for Parathyroidectomy and Role of Medical Management

Most authorities agree that patients who have developed complications and have "classic" symptoms of PHPT or are younger than 50 years old should undergo parathyroidectomy. However, the treatment of patients with asymptomatic PHPT has been the subject of controversy, due, in part, to the fact that there is little agreement on what constitutes an asymptomatic patient. At the National Institutes of Health consensus conference in 1990, "asymptomatic" PHPT was defined as "the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal, or neuromuscular disorders." The panel advocated nonoperative management of these patients with mild PHPT based on observational studies, which suggested relative stability of biochemical parameters over time.⁶⁷ This was further substantiated by more recent work, including the study by Silverberg and colleagues.⁶⁸ In their cohort of 52 patients with asymptomatic HPT followed without surgery, levels of serum and urinary calcium, PTH, alkaline phosphatase, and vitamin D metabolites remained relatively stable over a 10-year period in most patients. However, the consensus panel considered certain patients to be candidates for surgery.⁶⁹ These guidelines were recently reassessed at a second workshop on asymptomatic PHPT held at the National Institutes of Health in 2002 as shown in Table 38-11.⁷⁰ The guidelines are essentially unchanged except for those relating to parathyroidectomy. It now is recommended for patients with smaller elevations in serum calcium levels (>1 mg/dL above the upper limit of normal) and if BMD measured at any of three sites (radius, spine, or hip) is greater than 2.5 standard deviations below those of gender- and race-matched, not age-matched, controls (i.e., peak bone density or T score (rather than Z score) <-2.5). The panel still recommends exercising caution in using neuropsychologic abnormalities, cardiovascular disease, GI symptoms, menopause, and elevated serum or urine indices of increased bone turnover as sole indications for parathyroidectomy.

Table 38-11 Indications for Parathyroidectomy in Patients with Asymptomatic Primary HPT (2002 NIH Consensus Conference Guidelines)
• Serum calcium >1 mg/dL above the upper limits of normal
• Life-threatening hypercalcemic episode
• Creatine clearance reduced by 30%
• Kidney stones on abdominal x-rays
• Markedly elevated 24-h urinary calcium excretion (≥400 mg/d)
• Substantially decreased bone mineral density at the lumbar spine, hip, or distal radius (>2.5 SD below peak bone mass, T score <-2.5
• Age <50 y
• Long-term medical surveillance not desired or possible

HPT = hyperparathyroidism; NIH = National Institutes of Health; SD = standard deviation.

To determine the best course of action for these patients, it is important to consider the natural history of untreated PHPT and the outcomes of treatment options, both medical and surgical. With respect to the former, it is important to note that, in the cohort studies mentioned in this section, a significant proportion of patients were either lost to follow-up or experienced progression of disease requiring surgery. Silverberg and associates reported development of a new indication for surgery in 14 of 52 (27%) of their asymptomatic patients and, because approximately 50% of their patients were initially treated surgically, overall, about 75% of patients were treated surgically.⁶⁸ Similarly, Scholz and Purnell⁶⁷ also reported that 23% of 147 patients in their series from the Mayo Clinic developed a new indication for parathyroidectomy during a 10-year follow-up period. Uncontrolled PHPT also leads to worsening bone, renal, and other effects, in addition to a possible effect on overall survival.

Successful parathyroidectomy results in resolution of osteitis fibrosa cystica, improved BMD (6 to 8% in the first year and up to 12 to 15% at 15 years),⁶⁸ decreased formation of new renal stones, increased muscle strength, and decreased left ventricular hypertrophy. In addition, it also improves peptic ulcer disease and a number of the nonspecific manifestations of PHPT such as fatigue, polydipsia, polyuria and nocturia, bone and joint pain, constipation, nausea, and depression in most, but not all, patients. This also has been demonstrated using symptom questionnaires and various standardized general quality-of-life assessments such as SF-36⁷¹ and a specific parathyroidectomy assessment of symptoms scale.⁶³ The results were similar in a randomized controlled trial of patients with mild PHPT.⁶² The increased death rate in patients with PHPT appears to be reversible by successful parathyroidectomy. Lastly, parathyroidectomy can be accomplished with >95% success rates with minimal morbidity, even in elderly patients and is the only curative treatment option for PHPT.

A number of medical therapies such as selective estrogen receptor modifiers and bisphosphonates have been used to successfully lower serum calcium and increase BMD in patients with PHPT. More recently, calcimimetics (modifiers of the sensitivity of the CASR) have been used in randomized, multicenter controlled trials and have been shown to decrease both serum calcium and PTH levels in both symptomatic and asymptomatic PHPT patients.⁷² Although these therapies show promise, long-term outcome data are lacking, and their routine use is not advocated at this time. Previous investigations also have documented that parathyroidectomy is more cost-effective than medical management or follow-up. Therefore, it is recommended that parathyroidectomy should be offered to virtually all patients except those in whom the operative risks are prohibitive.

Unfortunately, to date, there are no definitive criteria to indicate which patients with mild PHPT will have progressive disease. Therefore, patients who do not undergo surgery should undergo routine follow-up consisting of biannual calcium measurements and annual measurements of BMD and serum creatinine.⁷⁰

Preoperative Localization Tests

It is important to emphasize that the diagnosis of PHPT is a metabolic one and that localization studies should not be used to make or confirm it. Localization studies may be classified into noninvasive or invasive modalities. These studies have variable performance characteristics, which, in turn, vary with experience and institutional experience, as outlined in Table 38-12.

Table 38-12 Commonly Used Parathyroid Localization Studies		
Study	Advantages	Disadvantages
Preoperative, noninvasive		
Sestamibi- ^{99m} technetium scan	Allows planar and SPECT imaging	False-positive tests due to thyroid neoplasms, lymphadenopathy
		False-negative study more common with multiple abnormal parathyroids
Ultrasound	Identification of juxta- and intrathyroidal tumors	False-positive results due to thyroid nodules, cysts, lymph nodes, esophageal lesions
	Relatively inexpensive	
		False-negatives result from substernal, ectopic, and undescended tumors
CT scan	Localization of ectopic (mediastinal) glands	Not useful for juxta- or intrathyroidal glands
		False positives from lymph nodes
		Relatively high cost
		Radiation exposure
		Requires IV contrast
		Interference from shoulders and metallic clips

MRI scan	Localization of ectopic tumors	Expensive
	No radiation exposure	False positives from lymph nodes and thyroid nodules
	No IV contrast	Cannot be used in claustrophobic patients
	No metal clip artifact	
Preoperative, invasive		
FNAB	Can distinguish parathyroid tumor from lymphadenopathy using PTH assay	Experienced cytologist needed
Angiogram	Provides a road map for selective venous sampling	Expensive
	Treatment of mediastinal tumors by embolization	Experienced radiologist needed
		Neurologic complications
Venous sampling	Useful to lateralize tumor in equivocal cases or negative localization studies	Expensive, experienced radiologist needed
Intraoperative		
PTH assay	Immediate confirmation of tumor removal	Expensive
		Increased operative time, decreased accuracy in multiple gland disease

CT = computed tomography; FNAB = fine-needle aspiration biopsy; MRI = magnetic resonance imaging; PTH = parathyroid hormone; SPECT = single-photon emission computed tomography.

Most endocrine surgeons agree that localization studies are mandatory and invaluable before any neck redo-parathyroid surgery, but their use before initial neck exploration continues to be controversial. Localization studies have permitted surgeons to perform more limited operations, some of them under local anesthesia. These "minimally invasive" procedures include unilateral and focused neck exploration, radio-guided parathyroidectomy, and several endoscopic or video-assisted approaches. The use of localization studies has been shown in some studies to be associated with lower morbidity rates (hypoparathyroidism and RLN injury) and decreased operative times, reduced duration of hospital stay and improved cosmetic outcomes; while maintaining success rates similar to those obtained with traditional bilateral neck explorations. Some studies also show that use of localization studies may be more cost effective.

There also is little consensus on which localization studies should be used. ^{99m}Tc -labeled sestamibi (Fig. 37-31A) is the most widely used and accurate modality with a sensitivity >80% for detection of parathyroid adenomas.⁷³ Sestamibi (Cardiolite) initially was introduced for cardiac imaging and is concentrated in mitochondria-rich tissue. It was subsequently noted to be useful for parathyroid localization due to the delayed washout of the radionuclide from hypercellular parathyroid tissue compared to thyroid tissue. Sestamibi scans generally are complemented by neck ultrasound (Fig. 38-31B), which can identify adenomas with >75% sensitivity in experienced centers,⁷³ and is most useful in identifying intrathyroidal parathyroids. Single-photon emission computed tomography, particularly when used with CT, has been shown to be superior to other nuclear medicine-based imaging.⁷⁴ Specifically, single-photon emission computed tomography can indicate whether an adenoma is located in the anterior or posterior mediastinum (aortopulmonary window), thus enabling the surgeon to modify the operative approach accordingly.⁷⁵ CT and MRI scans are less sensitive than sestamibi scans, but are helpful in localizing large paraesophageal and mediastinal glands. IOPTH was initially introduced in 1993 and is used to determine the adequacy of parathyroid resection (Fig. 38-32).⁷⁶ According to one commonly used criterion, when the PTH falls by 50% or greater 10 minutes after removal of a parathyroid tumor, as compared to the highest preremoval value, the test is considered positive, and the operation is terminated. IOPTH measurements, like localization studies, are less reliable in multiglandular disease.

Although preoperative localization studies and IOPTH have become widely used since their inception, the literature is lacking in studies directly comparing procedures performed with and without these studies. Furthermore, localization studies, including intraoperative PTH, are less sensitive and accurate when they are most necessary, such as in the presence of multiple gland parathyroid disease. Long-term outcome data and cost-effectiveness studies are needed before routine use of localization studies can be recommended; however, they should be used if a focused approach or reoperation is planned.⁷⁰

Operative Approaches

Unilateral parathyroid exploration was first carried out using intraoperative staining of a biopsy from the normal parathyroid gland with Sudan black dye to rule out a double adenoma. Initially, the choice of side to be explored was random, but the introduction of preoperative localization studies has enabled a more directed approach. In contrast, the focused approach identifies only the enlarged parathyroid gland, and no attempts are made to locate other normal parathyroid glands. Unilateral neck explorations have several advantages over bilateral neck exploration, including reduced operative times and complications, such as injury to the RLN and hypoparathyroidism. However, most existing studies comparing the two approaches are retrospective and do not analyze the results on an intention-to-treat basis. Another argument against a unilateral exploration is the risk of missing another adenoma on the opposite side of the neck. The incidence of double adenomas has been reported to range from 0 to 10%, with an increased incidence in elderly patients. The risk of missing a second adenoma is higher in populations with a higher incidence of multiple adenomas, such as those with familial HPT, MEN syndromes, and the elderly. Another difficulty inherent with unilateral exploration is the inability to discern whether the combination of an abnormal gland and a normal gland on the initial side constitute a single adenoma or asymmetric hyperplasia. A recently published update on the 5-year results of a randomized trial comparing unilateral vs. bilateral neck exploration did not note any difference in the rates of recurrent or persistent disease in the two groups of patients.⁷⁷ These issues will only be resolved by a large, prospective, multicenter study or improved molecular analytic techniques.

Radio-guided parathyroidectomy takes advantage of the ability of parathyroid tumors to retain ^{99m}Tc -sestamibi. One to two mCi of the isotope is injected before surgery and a hand-held gamma probe is used to guide the identification of the enlarged gland, taking care to ensure the equilibration of radioactivity counts in all quadrants. Reported advantages include easier localization, particularly in reoperative cases, and the ability to perform the procedure under local anesthetic or sedation using smaller incisions. Many studies demonstrated the feasibility of this technique; however, it is rarely used now, largely because it offers little advantage over preoperative sestamibi scans and is associated with increased operative times. Like preoperative scanning, it also has reduced accuracy in the presence of multiglandular disease.

Endoscopic approaches include both video-assisted and total endoscopic techniques. Total endoscopic parathyroidectomy was first described by Gagner in 1996⁷⁸ and several other investigators have since reported on this technique. Although port placements are variable, as is the case with endoscopic thyroidectomy, they all involve creation of a working space in the neck using CO_2 insufflation, with the reported advantages being superior cosmesis and excellent visualization. Although feasible, these techniques also have been associated with increased operating times, more personnel, and greater expense, and have, in general, not been useful for patients with multiglandular disease, a large thyroid mass, or previous neck surgery and irradiation. Their greatest use has been in patients with tumors at ectopic sites such as the mediastinum where thoracoscopic parathyroidectomy is an excellent alternative to sternotomy.

Studies have shown that if both sestamibi scan and neck ultrasound studies independently identify the same, enlarged parathyroid gland, and no other gland, it is indeed the abnormal gland in approximately 95% of cases. These patients with sporadic PHPT are candidates for a focused neck exploration, an approach that is most commonly referred to as *minimally invasive parathyroidectomy* and has been reported to be the method of choice for members of the International Association of Endocrine Surgeons preferring a minimal-access approach.⁷² A standard bilateral neck exploration is planned if parathyroid localization studies or IOPTH are not available; if the localizing studies fail to identify any abnormal parathyroid gland or identify multiple abnormal glands, in patients with a family history of PHPT, MEN1, or MEN2A; or a concomitant thyroid disorder requires bilateral exploration. In addition, finding a minimally abnormal parathyroid gland on the side indicated by localization studies during focal exploration should prompt a bilateral exploration or at least the identification of a normal parathyroid gland on the same side. In patients with MEN1, HPT should be corrected before treatment of gastrinomas because gastrin levels decline after parathyroidectomy.

Conduct of Parathyroidectomy (Standard Bilateral Exploration)

An experienced parathyroid surgeon with a thorough knowledge of parathyroid anatomy and embryology and meticulous technique is crucial for the best surgical results. The procedure usually is performed under general anesthesia. The patient is positioned supine on the operating table with the neck extended. For a bilateral exploration, the neck is explored via a 3- to 4-cm incision just caudal to the cricoid cartilage. The initial dissection and exposure is similar to that used for thyroidectomy. After the strap muscles are separated in the midline, one side of the neck is chosen for exploration. In contrast to a thyroidectomy, the dissection during a parathyroidectomy is maintained lateral to the thyroid, making it easier to identify the parathyroid glands and not disturb their blood supply.

Identification of Parathyroids

A bloodless field is important to allow identification of parathyroid glands. The middle thyroid veins are ligated and divided, thus enabling medial and anterior retraction of the thyroid lobe, with the aid of a peanut sponge or placement of 2 to 0 silk sutures into the thyroid. The space between the carotid sheath and thyroid is then opened by gentle sharp and blunt dissection, from the cricoid cartilage superiorly to the thymus inferiorly and the RLN is identified. Approximately 85% of the parathyroid glands are found within 1 cm of the junction of the inferior thyroid artery and RLNs. The upper parathyroid glands usually are superior to this junction and dorsal (posterior) to the nerve, whereas the lower glands are located inferior to the junction and ventral (anterior) to the recurrent

nerve. Because parathyroid glands are partly surrounded by fat, any fat lobule at typical parathyroid locations should be explored because the normal or abnormal parathyroid gland may be concealed in the fatty tissue. The thin fascia overlying a "suspicious" fat lobule should be incised using a sharp curved hemostat and scalpel. This maneuver often causes the parathyroid gland to "pop" out. Alternatively, gentle, blunt peanut sponge dissection between the carotid sheath and the thyroid gland often reveals a "float" sign, suggesting the site of the abnormal parathyroid gland. Normal parathyroids are light beige and only slightly darker or brown compared to adjacent fat.

Parathyroid tissue needs to be distinguished from normal or brown fat tissue, thyroid nodules, lymph nodes, and ectopic thymus. Lymph nodes generally are light beige to whitish gray in color, glassy, and multiple in number, whereas thyroid nodules generally are more vascular, firm, dark or reddish brown in color, and have a more variegated appearance. Intraoperatively, a suspicious nodule may be aspirated using a fine needle attached to a syringe containing 1 cc of saline. Very high PTH levels in the aspirate have been shown to be diagnostic in the intraoperative identification of parathyroid glands. Several characteristics such as size (>7 mm), weight, and color are used to distinguish normal from hypercellular parathyroid glands. Hypercellular glands generally are darker, more firm, and more vascular than normocellular glands. No single method is 100% reliable, and, therefore, the parathyroid surgeon must rely on experience and, at times, advice from a pathologist to help distinguish normal from hypercellular glands. Although several molecular studies have shown use in distinguishing parathyroid adenomas from hyperplasia, this determination also must be made by the surgeon intraoperatively by documenting the presence of a normal parathyroid gland.

Location of Parathyroid Glands

The majority of lower parathyroid glands are found in proximity to the lower thyroid pole (Fig. 38-33A). If not found at this location, the thyrothymic ligament and thymus should be mobilized. The upper end of the cervical thymus is gently grasped with a right angle clamp, and the distal portion is bluntly dissected from perithymic fat with a peanut sponge. One can then "walk down" the thymus with successive right-angle clamps (Fig. 38-33B). Applying light tension along with a "twisting" motion helps to free the upper thymus. The carotid sheath also should be opened from the bifurcation to the base of the neck if the parathyroid tumor cannot be found. If these maneuvers are unsuccessful, an intrathyroidal gland should be sought by using intraoperative ultrasound, incising the thyroid capsule on its posterolateral surface or by performing an ipsilateral thyroid lobectomy and "bread-loafing" the thyroid lobe. Preoperative or intraoperative ultrasonography can be useful for identifying intrathyroidal parathyroid glands. Rarely, the third branchial pouch may maldescend and be found high in the neck (undescended parathymus), anterior to the carotid bulb, along with the missing parathyroid gland. Upper parathyroid glands are more consistent in position and usually are found near the junction of the upper and middle thirds of the gland, at the level of the cricoid cartilage (Fig. 38-33C). Ectopic upper glands may be found in carotid sheath, tracheoesophageal groove, retroesophageal, or in the posterior mediastinum. The locations of ectopic upper and lower parathyroid glands are shown in Fig. 38-34. Every attempt must be made to identify all four glands. Treatment depends upon the number of abnormal glands.

1. A single adenoma is presumed to be the cause of a patient's PHPT if only one parathyroid tumor is identified and the other parathyroid glands are normal, a situation present in about 80% of patients with PHPT. Adenomas typically have an atrophic rim of normal parathyroid tissue but this characteristic may be absent. The adenoma is dissected free of surrounding tissue, taking care to stay immediately adjacent to the tumor, without fracturing it. The vascular pedicle is clamped, divided, and ligated. Care should be taken to not rupture the parathyroid gland to decrease the risk of parathyromatosis. If there is any question about the presumed normal glands, one of them should be biopsied and examined by frozen section.
2. If two abnormal and two normal glands are identified, the patient has double adenomas. Triple adenomas are present if three glands are abnormal and one is normal. Multiple adenomas are more common in older patients with an incidence of up to 10% in patients >60 years old. The abnormal glands should be excised, provided the remaining glands are confirmed as such, thus excluding asymmetric hyperplasia after biopsy and frozen section.
3. If all parathyroid glands are enlarged or hypercellular, patients have parathyroid hyperplasia that has been shown to occur in about 15% of patients in various series. These glands are often lobulated, usually lack the rim of normal parathyroid gland seen in adenomas, and may be variable in size. It often is difficult to distinguish multiple adenomas from hyperplasia

with variable gland size. Hyperplasia may be of the chief cell (more common), mixed, or clear-cell type. Patients with hyperplasia may be treated by subtotal parathyroidectomy or by total parathyroidectomy and autotransplantation, with the choice of procedure being determined by rates of recurrence, postoperative hypocalcemia, and failure rates of autotransplanted tissue. Initial studies demonstrated equivalent cure rates and postoperative hypocalcemia for the two techniques, with the latter having the added advantage of avoiding recurrence in the neck. However, autotransplanted tissue may fail to function in about 5% of cases.

Location of ectopic upper and lower parathyroid glands.

(Reproduced with permission from Akerström G, et al: Surgical anatomy of human parathyroid glands. *Surgery* 95:15, 1984.

All four parathyroid glands are identified and carefully mobilized. For patients with hyperplasia, a titanium clip is placed across the most normal gland, leaving a 50-mg remnant and taking care to avoid disturbing the vascular pedicle and that the gland is resected with a sharp scalpel. If possible, it is preferable to subtotally resect an inferior gland, which is more easily accessible in case of recurrence due to its anterior location with respect to the RLN. The resected parathyroid tissue is confirmed by frozen section or PTH assay. If the remnant appears to be viable, the remaining glands are resected. If there is any question as to the viability of the initially subtotally resected gland, another gland is chosen for subtotal resection and the initial remnant is removed. Whenever multiple parathyroids are resected, it is preferable to cryopreserve tissue, so that it may be autotransplanted should the patient become hypoparathyroid. Parathyroid tissue usually is transplanted into the nondominant forearm. A horizontal skin incision is made overlying the brachioradialis muscle a few centimeters below the antecubital fossa. Pockets are made in the belly of the muscle and one to two pieces of parathyroid tissue measuring 1 mm each are placed into each pocket. A total of 12 to 14 pieces are transplanted. Autotransplanted tissue also has been reported to function when transplanted into fat.

Indications for Sternotomy

A sternotomy is usually not recommended at the initial operation, unless the calcium level is >13 mg/dL. Rather, it is preferred to biopsy the normal glands and subsequently close the patient's neck and obtain localizing studies, if they were not obtained previously. Intraoperative PTH assay during the operation from large veins may be helpful. Using highly selective venous catheterization postoperatively also may be needed when noninvasive localization studies are negative, equivocal, or conflicting. Lower parathyroid glands tend to migrate into the anterior mediastinum in the thymus or perithymic fat and usually can be approached via a cervical incision. A sternotomy is needed to deliver these tumors in approximately 5% of cases. Generally, the gland can be approached by a partial sternotomy to the third intercostal space. The midline sternotomy can be extended to the left or right side as required. Upper glands tend to migrate to the posterior mediastinum in the tracheoesophageal groove. Mediastinal glands also may be found in the aortopulmonary window or pericardium, or attached to the ascending aorta, aortic arch, or its branches.

Special Situations

Parathyroid Carcinoma

Parathyroid cancer accounts for approximately 1% of PHPT cases. It may be suspected preoperatively by the presence of severe symptoms, serum calcium levels >14 mg/dL, significantly elevated PTH levels (5 x normal), and a palpable parathyroid gland. Local invasion is most common; approximately 15% of patients have lymph node metastases and 33% have distant metastases at presentation. Intraoperatively, parathyroid cancer is suggested by the presence of a large, gray-white to gray-brown parathyroid tumor that is adherent to or invasive into surrounding tissues like muscle, thyroid, RLN, trachea, or esophagus. Enlarged lymph nodes also may be present. Accurate diagnosis necessitates histologic examination that reveals local tissue invasion, vascular or capsular invasion, trabecular or fibrous stroma, and frequent mitoses.

Treatment of parathyroid cancer consists of bilateral neck exploration, with en bloc excision of the tumor and the ipsilateral thyroid lobe. Modified radical neck dissection is recommended in the presence of lymph node metastases. Prophylactic neck dissection is not advised because it is associated with an increased risk of complications and does not appear to have a significant impact on survival. If the diagnosis is made postoperatively, a decision must be made regarding the adequacy of initial surgery based on a review of operative notes, pathology reports, localization studies, and calcium and PTH levels. If any question exists, histologic review by another experienced pathologist can be helpful. Additional procedures can then be performed accordingly. Reoperation is indicated for locally recurrent or metastatic disease to control hypercalcemia. Radiation and chemotherapy may be considered in patients with unresectable disease. Bisphosphonates have shown some effectiveness in treating hypercalcemia associated with parathyroid

carcinoma. Cinacalcet hydrochloride, a calcimimetic, can reduce PTH levels by directly binding to the CASR cells on the parathyroid gland and has been shown to be useful in controlling hypercalcemia in patients with refractory parathyroid carcinoma.⁷⁹

Familial Hyperparathyroidism

PHPT may occur as a component of various inherited syndromes such as MEN1 and MEN2A. Inherited PHPT also can occur as isolated familial HPT (non-MEN), or familial HPT with jaw tumors. The diagnosis of familial HPT is known or suspected in approximately 85% of patients preoperatively. Furthermore, patients with hereditary HPT generally have a higher incidence of multiglandular disease, supernumerary glands, and recurrent or persistent disease. Therefore, these patients warrant a more aggressive approach and are not candidates for various focused surgical approaches.

Although not absolutely necessary, preoperative sestamibi scan and ultrasound can be obtained in patients with inherited HPT to identify potential ectopic glands. A standard bilateral neck exploration is performed, along with a bilateral cervical thymectomy, regardless of the results of localization studies. Both subtotal parathyroidectomy and total parathyroidectomy with autotransplantation are appropriate and parathyroid tissue also should be cryopreserved. If an adenoma is found in patients with familial HPT, the adenoma and the ipsilateral normal parathyroid glands are resected. The normal-appearing glands on the contralateral side are biopsied and marked, so that only one side of the neck will need to be explored in the event of recurrence. Patients with MEN2A require total thyroidectomy and central neck dissection for prevention/treatment of MTC, a procedure that places the parathyroids at risk. Moreover, HPT is less aggressive in these patients. Hence, only abnormal parathyroid glands need to be resected at neck exploration. The other normal parathyroid glands should be marked with a clip.

Neonatal Hyperparathyroidism

Infants with neonatal HPT present with severe hypercalcemia, lethargy, hypotonia, and mental retardation. This disorder is associated with homozygous mutations in the CASR gene. Urgent total parathyroidectomy (with autotransplantation and cryopreservation) and thymectomy is indicated. Subtotal resection is associated with high recurrence rates.

Parathyromatosis

Parathyromatosis is a rare condition characterized by the finding of multiple nodules of hyper-functioning parathyroid tissue throughout the neck and mediastinum, usually following a previous parathyroidectomy. The true etiology of parathyromatosis is not known. It is postulated to arise either from overgrowth of congenital parathyroid rests (ontogenous parathyromatosis) or seeding at surgery from rupture of parathyroid tumors or subtotal resection of hyperplastic glands. Parathyromatosis represents a rare cause of persistent or recurrent HPT⁸⁰ and can be identified intraoperatively. Aggressive local resection of these deposits can result in normocalcemia but is rarely curative. Some studies suggest that these patients have low-grade carcinoma because of invasion into muscle and other structures distant from the resected parathyroid tumor.

Postoperative Care and Follow-Up

Patients who have undergone parathyroidectomy are advised to undergo calcium level checks 2 weeks postoperatively, at 6 months, and then annually. Recurrence rates are rare (<1%), except in patients with familial HPT. Recurrence rates of 15% at 2 years and 67% at 8 years have been reported for MEN1 patients.

PERSISTENT AND RECURRENT HYPERPARATHYROIDISM

Persistence is defined as hypercalcemia that fails to resolve after parathyroidectomy and is more common than recurrence, which refers to HPT occurring after an intervening period of at least 6 months of biochemically documented normocalcemia.⁸¹ The most common causes for both these states include ectopic parathyroids, unrecognized hyperplasia, or supernumerary glands. More rare causes include parathyroid carcinoma, missed adenoma in a normal position, incomplete resection of an abnormal gland, parathyromatosis, or an inexperienced surgeon. The most common sites of ectopic parathyroid glands in patients with persistent or

recurrent HPT are paraesophageal (28%), mediastinal (26%), intrathyroid (24%), intrathyroidal (11%), carotid sheath (9%), and high cervical or undescended (2%) (Fig. 38-35).

Fig. 38-35.

Anatomic location of ectopic parathyroid glands. Numbers represent number of glands found in each location, with a total of 54.
(Reproduced with permission from Shen W, et al: Re-operation for persistent or recurrent primary hyperparathyroidism. *Arch Surg* 131:864, 1996. Copyright © 1996 American Medical Association. All rights reserved.)

Once the diagnosis of persistent or recurrent HPT is suspected, it should be confirmed by the necessary biochemical tests. In particular, a 24-hour urine collection should be performed to rule out FHH. In redo-parathyroid surgery, the glands are more likely to be in ectopic locations and postoperative scarring tends to make the procedure more technically demanding. Cure rates are generally lower (80 to 90% compared with 95 to 99% for initial operation) and risk of injury to RLNs and permanent hypocalcemia are higher. Therefore, an evaluation of severity of HPT and the patient's anesthetic risk (using the American Society of Anesthesiology classification of physical status or the Goldman cardiac index) is important. High-risk patients whose tumors cannot be identified by localization studies may benefit from nonoperative management such as calcimimetic drugs or angiographic embolization. The latter approach has been associated with significant complications and has not gained widespread acceptance;

however, it may be helpful for poor-risk patients with ectopic glands in the mediastinum.

Preoperative localization studies are routinely performed. Noninvasive studies such as a sestamibi scan, ultrasound, and MRI (with gadolinium contrast) are recommended and have reported a combined accuracy of about 85% for these studies in cases of persistent or recurrent HPT. If these studies are negative or equivocal, highly selective venous catheterization for PTH levels is performed, which increases the accuracy to 95%. Previous operative notes and pathology reports should be carefully reviewed and reconciled with the information obtained from localization studies before any neck re-exploration. An algorithm for the treatment of patients with recurrent and persistent HPT is shown in Fig. 38-36.

Fig. 38-36.

Management of recurrent and persistent hyperparathyroidism (HPT). FHH = familial hypocalciuric hypercalcemia; PTH = parathyroid hormone.

Generally, these patients are approached with a focused exploration. The lateral approach usually is used to identify the RLN more easily. Parathyroid tissue is cryopreserved routinely.

HYPERCALCEMIC CRISIS

Patients with PHPT may occasionally present acutely with nausea, vomiting, fatigue, muscle weakness, confusion, and a decreased level of consciousness; a complex referred to as *hypercalcemic crisis*. These symptoms result from severe hypercalcemia from

uncontrolled PTH secretion, worsened by polyuria, dehydration, and reduced kidney function and may occur with other conditions causing hypercalcemia. Calcium levels are markedly elevated and may be as high as 16 to 20 mg/dL. Parathyroid glands tend to be large or multiple, and the tumor may be palpable. Patients with parathyroid cancer or familial HPT are more likely to present with hypercalcemic crisis.

Treatment consists of therapies to lower serum calcium levels followed by surgery to correct HPT. The mainstay of therapy involves rehydration with a 0.9% saline solution to keep urine output >100 cc/h. Once urine output is established, diuresis with furosemide (which increases renal calcium clearance) is begun. If these methods are unsuccessful, other drugs may be used to lower serum calcium levels as outlined in Table 38-13. Occasionally, in life-threatening cases, hemodialysis may be of benefit.

Table 38-13 Medications Commonly Used to Treat Hypercalcemia			
Medication	Dosage and Administration	Mechanism Onset of Action and Duration	Side Effects
Bisphosphonates (pamidronate)	60–90 mg IV over 4–24 h	Inhibits osteoclastic bone resorption; rapid onset, 2–3 d	May cause local pain and swelling, low-grade fever, lymphopenia, electrolyte abnormalities
Calcitonin	4 IU/kg SC/IM	Inhibits osteoclast function, augments renal calcium excretion; onset of action in hours; but short lived, therefore not useful as sole therapy	Transient nausea and vomiting, abdominal cramps, flushing, and local skin reaction
Mithramycin (plicamycin)	25 µg/kg per day IV for 3–4 d	Inhibits osteoclasts RNA secretion; rapid onset of action (12 h); peaks at 48–72 h and lasts days to several weeks	May cause renal, hepatic, and hematologic complications, nausea and vomiting
Gallium nitrate	200 mg/m ² BSA/d IV for 5 d	Reduces urinary calcium excretion; onset of action delayed (5–7 d)	Nephrotoxicity, nausea, vomiting, hypotension, anemia, hypophosphatemia
Glucocorticoids	Hydrocortisone 100 mg IV q8h	Delayed onset of action (7–10 d); useful for hematologic malignancies, sarcoidosis, vitamin D intoxication, hyperthyroidism	Hypertension, hyperglycemia

BSA = body surface area.

SECONDARY HYPERPARATHYROIDISM

Secondary HPT commonly occurs in patients with chronic renal failure but also may occur in those with hypocalcemia secondary to inadequate calcium or vitamin D intake, or malabsorption. The pathophysiology of HPT in chronic renal failure is complex and appears to be related to hyperphosphatemia (and resultant hypocalcemia), deficiency of 1,25-dihydroxy vitamin D due to loss of renal tissue, low calcium intake, decreased calcium absorption, and abnormal parathyroid cell response to extracellular calcium or vitamin D in vitro and in vivo. Patients generally are hypocalcemic or normocalcemic. Aluminum hydroxide, which often was used as a phosphate binder, has been shown to contribute to the osteomalacia observed in this disease. These patients generally are treated medically with a low-phosphate diet, phosphate binders, adequate intake of calcium and 1,25-dihydroxy vitamin D and a high calcium, low-aluminum dialysis bath. Calcimimetics have been shown to control parathyroid hyperplasia and osteitis fibrosa cystica associated with secondary HPT in animal studies and to decrease plasma PTH and total and ionized calcium levels in humans.

Surgical treatment was traditionally recommended for patients with bone pain, pruritus, and (a) a calcium-phosphate product ≥ 70 , (b) calcium >11 mg/dL with markedly elevated PTH, (c) calciphylaxis, (d) progressive renal osteodystrophy, and (e) soft tissue calcification and tumoral calcinosis, despite maximal medical therapy. The role of parathyroidectomy in the era of calcimetics will require long-term studies; however, parathyroidectomy should be considered if PTH levels remain high despite optimal therapy.⁸² Calciphylaxis is a rare, limb- and life-threatening complication of secondary HPT characterized by painful (sometimes throbbing),

violaceous, and mottled lesions usually on the extremities, which often become necrotic and progress to nonhealing ulcers, gangrene, sepsis, and death. These are critically ill, high-risk patients, but successful parathyroidectomy sometimes relieves symptoms.

Patients should undergo routine dialysis the day before surgery to correct electrolyte abnormalities. Localization studies are not necessary but can identify ectopic parathyroid glands. A bilateral neck exploration is indicated. The parathyroid glands in secondary HPT are characterized by asymmetric enlargement and nodular hyperplasia. These patients may be treated by subtotal resection, leaving about 50 mg of the most normal parathyroid gland or total parathyroidectomy and autotransplantation of parathyroid tissue into the brachioradialis muscle of the nondominant forearm. Upper thymectomy usually is performed because 15 to 20% of patients have one or more parathyroid glands situated in the thymus or perithymic fat. Bone and joint pain improve in approximately 75% of patients who undergo parathyroidectomy. Pruritus and malaise also improve in most, but not all, patients. Parathyroidectomy also has been shown to improve BMD, sexual function, muscle strength, and survival in patients with secondary HPT.

TERTIARY HYPERPARATHYROIDISM

Generally, renal transplantation is an excellent method of treating secondary HPT, but some patients develop autonomous parathyroid gland function and tertiary HPT. Tertiary HPT can cause problems similar to PHPT, such as pathologic fractures, bone pain, renal stones, peptic ulcer disease, pancreatitis, and mental status changes. The transplanted kidney is also at risk. Operative intervention is indicated for symptomatic disease or if autonomous PTH secretion persists for >1 year after a successful transplant. All parathyroid glands should be identified. The traditional surgical management of these patients consisted of subtotal or total parathyroidectomy with autotransplantation and an upper thymectomy. Some authors suggest that these patients derive similar benefit from excision of only obviously enlarged glands, while avoiding the higher risks of hypocalcemia associated with the former approach. Others recommend that all parathyroid glands be identified and subtotal parathyroidectomy be performed as long-term follow-up studies show that limited excisions in these patients are associated with an up to fivefold increased risk of recurrent or persistent disease.⁸³

COMPLICATIONS OF PARATHYROID SURGERY

Parathyroidectomy can be accomplished successfully in >95% of patients with minimal mortality and morbidity, provided the procedure is performed by a surgeon experienced in parathyroid surgery. Specific complications include transient and permanent vocal cord palsy and hypoparathyroidism. The latter is more likely to occur in patients who undergo four-gland exploration with biopsies, subtotal resection with an inadequate remnant, or total parathyroidectomy with a failure of autotransplanted tissue. Furthermore, hypocalcemia is more likely to occur in patients with high turnover bone disease as evidenced by elevated preoperative alkaline phosphatase levels. Vocal cord paralysis and hypoparathyroidism are considered permanent if they persist for >6 months. Fortunately, these complications are rare, occurring in approximately 1% of patients undergoing surgery by experienced parathyroid surgeons.

Patients with symptomatic hypocalcemia or those with calcium levels <8 mg/dL are treated with oral calcium supplementation (up to 1 to 2 g every 4 hours). 1,25-dihydroxy vitamin D [calcitriol (Rocaltrol) 0.25 to 0.5 µg bid] may also be required, particularly in patients with severe hypercalcemia and elevated serum alkaline phosphatase levels preoperatively and with osteitis fibrosa cystica. Intravenous calcium supplementation rarely is needed, except in cases of severe, symptomatic hypocalcemia.

Hypoparathyroidism

Hypocalcemia can be the result of a multitude of conditions, which are listed in Table 38-14. The parathyroid glands may be congenitally absent in DiGeorge syndrome, which also is characterized by lack of thymic development and, therefore, a thymus-dependent lymphoid system. By far, the most common cause of hypoparathyroidism is thyroid surgery, particularly total thyroidectomy with a concomitant central neck dissection. Patients often develop transient hypocalcemia due to ischemia of the

parathyroid glands; permanent hypoparathyroidism is rare. Hypoparathyroidism also may occur after parathyroid surgery, which is more likely if patients undergo a subtotal resection or total parathyroidectomy with parathyroid autotransplantation.

Table 38-14 Conditions Causing Hypocalcemia
Hypoparathyroidism
• Surgical
• Neonatal
• Familial
• Heavy metal deposition
• Magnesium depletion
Resistance to the action of parathyroid hormone
• Pseudohypoparathyroidism
• Renal failure
• Medications—calcitonin, bisphosphonates, mithramycin
Failure of normal 1,25-dihydroxy vitamin D production
Resistance to the action of 1,25-dihydroxy vitamin D
Acute complex formation or deposition of calcium
• Acute hyperphosphatemia
• Acute pancreatitis
• Massive blood transfusion (citrate overload)
• "Hungry bones"

Acute hypocalcemia results in decreased ionized calcium and increased neuromuscular excitability. Patients initially develop circumoral and fingertip numbness and tingling. Mental symptoms include anxiety, confusion, and depression. Physical examination reveals positive Chvostek's sign (contraction of facial muscles elicited by tapping on the facial nerve anterior to the ear) and Trousseau's sign (carpopedal spasm which is elicited by occluding blood flow to the forearm with a blood pressure cuff for 2 to 3 minutes). Tetany, which is characterized by tonic-clonic seizures, carpopedal spasm, and laryngeal stridor, may prove fatal and should be avoided. Most patients with postoperative hypocalcemia can be treated with oral calcium and vitamin D supplements; IV calcium infusion is rarely required except in patients with preoperative osteitis fibrosa cystica.

ADRENAL

Historical Background

Eustachius provided the first accurate anatomic account of the adrenals in 1563. The anatomic division of the adrenals into the cortex and medulla was described much later, by Cuvier in 1805. Subsequently, Thomas Addison in 1855 described the features of adrenal insufficiency, which still bear his name. DeCreccio provided the first description of congenital adrenal hyperplasia (CAH) occurring in a female pseudohermaphrodite in 1865. Pheochromocytomas were first identified by Frankel in 1885, but were not named as such until 1912 by Pick, who noted the characteristic chromaffin reaction of the tumor cells. Adrenaline was identified as an agent from the adrenal medulla that elevated blood pressure in dogs and was subsequently named epinephrine in 1897. The first successful adrenalectomies for pheochromocytoma were performed by Roux in Switzerland, and Charles Mayo in the United States.

In 1932, Harvey Cushing described 11 patients who had moon facies, truncal obesity, hypertension, and other features of the syndrome that now bears his name. Although several individuals prepared adrenocortical extracts to treat adrenalectomized animals, cortisone was first synthesized by Kendall. Aldosterone was identified in 1952, and the syndrome resulting from excessive secretion

of this mineralocorticoid was first described in 1955 by Conn.

Embryology

The adrenal or suprarenal glands are two endocrine organs in one; an outer cortex and an inner medulla, each with distinct embryologic, anatomic, histologic, and secretory features. The cortex originates around the fifth week of gestation from mesodermal tissue near the gonads on the adrenogenital ridge (Fig. 38-37). Therefore, ectopic adrenocortical tissue may be found in the ovaries, spermatic cord, and testes. The cortex differentiates further into a thin, definitive cortex and a thicker, inner fetal cortex. The latter is functional and produces fetal adrenal steroids by the eighth week of gestation, but undergoes involution after birth, resulting in a decrease in adrenal weight during the first three postpartum months. The definitive cortex persists after birth to form the adult cortex over the first 3 years of life. In contrast, the adrenal medulla is ectodermal in origin and arises from the neural crest. At around the same time as cortical development, neural crest cells migrate to the para-aortic and paravertebral areas and toward the medial aspect of the developing cortex to form the medulla. Most extra-adrenal neural tissue regresses but may persist at several sites. The largest of these is located to the left of the aortic bifurcation near the inferior mesenteric artery origin and is designated as the organ of Zuckerkandl. Adrenal medullary tissue also may be found in neck, urinary bladder, and para-aortic regions. Several factors are involved in adrenal development and include insulin-like growth factor 2; gastric inhibitory peptide; and the dosage-sensitive, sex-reversal adrenal hypoplasia (*DAX1*) gene.

Anatomy

The adrenal glands are paired, retroperitoneal organs located superior and medial to the kidneys at the level of the eleventh ribs. The normal adrenal gland measures 5 x 3 x 1 cm and weighs 4 to 5 g. The right gland is pyramidal shaped and lies in close proximity to the right hemidiaphragm, liver, and inferior vena cava (IVC). The left adrenal is closely associated with the aorta, spleen, and tail of the pancreas. Each gland is supplied by three groups of vessels—the superior adrenal arteries derived from the inferior phrenic artery, the middle adrenal arteries derived from the aorta, and the inferior adrenal arteries derived from the renal artery. Other vessels originating from the intercostal and gonadal vessels may also supply the adrenals. These arteries branch into about 50 arterioles to form a rich plexus beneath the glandular capsule and require careful dissection, ligation, and division during adrenalectomy. In contrast to the arterial supply, each adrenal usually is drained by a single, major adrenal vein. The right adrenal vein is usually short and drains into the IVC, whereas the left adrenal vein is longer and empties into the left renal vein after joining the inferior phrenic vein. Accessory veins occur in 5 to 10% of patients—on the right, these vessels may drain into the right hepatic vein or the right renal vein; on the left, accessory veins may drain directly into the left renal vein. The anatomic relationships of the

adrenals and surrounding structures are depicted in Fig. 38-38.

Fig. 38-38.

Anatomy of the adrenals and surrounding structures. a. = artery; v. = vein.

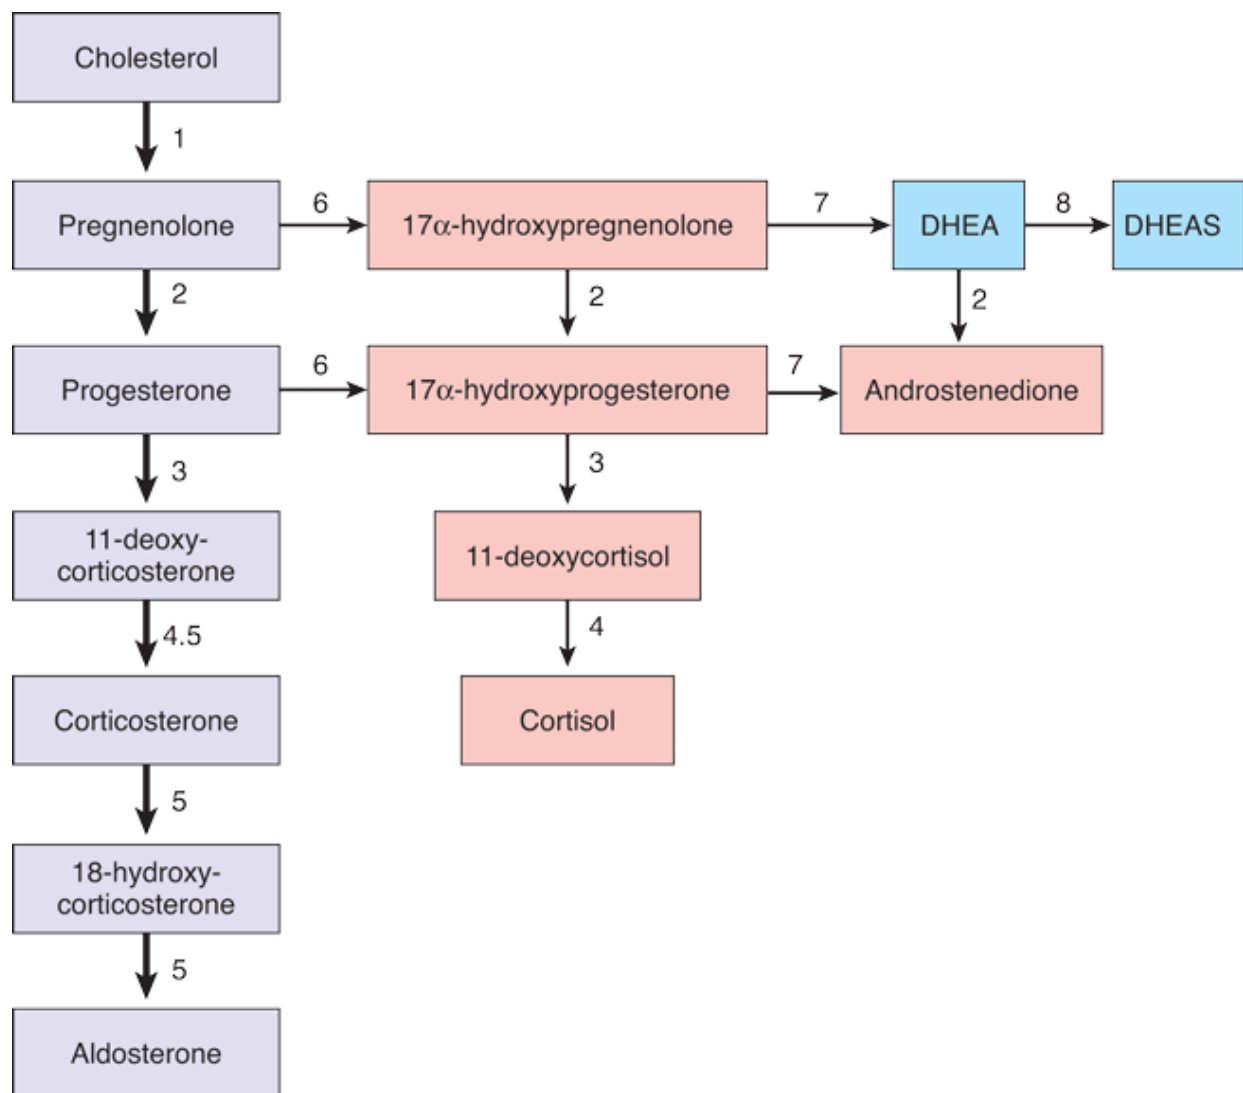

The adrenal cortex appears yellow due to its high lipid content and accounts for about 80 to 90% of the gland's volume.

Histologically, the cortex is divided into three zones—the zona glomerulosa, zona fasciculata, and zona reticularis. The outer area of the zona glomerulosa consists of small cells and is the site of production of the mineralocorticoid hormone, aldosterone. The zona fasciculata is made up of larger cells, which often appear foamy due to multiple lipid inclusions, whereas the zona reticularis cells are smaller. These latter zones are the site of production of glucocorticoids and adrenal androgens. The adrenal medulla constitutes up to 10 to 20% of the gland's volume and is reddish brown in color. It produces the catecholamine hormones epinephrine and norepinephrine. The cells of the adrenal medulla are arranged in cords and are polyhedral in shape. They often are referred to as chromaffin cells because they stain specifically with chromium salts.

Adrenal Physiology

Cholesterol, derived from the plasma or synthesized in the adrenal, is the common precursor of all steroid hormones derived from the adrenal cortex. Cholesterol initially is cleaved within mitochondria to 5- δ -pregnolone, which in turn is transported to the smooth endoplasmic reticulum where it forms the substrate for various biosynthetic pathways leading to steroidogenesis (Fig. 38-39).

Fig. 38-39.

Synthesis of adrenal steroids. The enzymes involved are (1) p450scc (cholesterol side chain cleavage), (2) 3β-hydroxysteroid dehydrogenase, (3) p450c21 (21β-hydroxylase), (4) p450c11 (11β-hydroxylase), (5) p450c11AS (aldosterone synthase), (6) p450c17 (17α-hydroxylase activity), (7) p450c17 (17,20-lyase/desmase activity), and (8) sulfokinase. DHEAS = dehydroepiandrosterone sulfate.

MINERALOCORTICIDS

The major adrenal mineralocorticoid hormones are aldosterone, 11-deoxycorticosterone (DOC), and cortisol. Cortisol has minimal effects on the kidney due to hormone degradation. Aldosterone secretion is regulated primarily by the renin-angiotensin system. Decreased renal blood flow, decreased plasma sodium, and increased sympathetic tone all stimulate the release of renin from juxtaglomerular cells. Renin, in turn, leads to the production of angiotensin I from its precursor angiotensinogen. Angiotensin I is cleaved by pulmonary angiotensin-converting enzyme (ACE) to angiotensin II; the latter is not only a potent vasoconstrictor, but also leads to increased aldosterone synthesis and release. Hyperkalemia is another potent stimulator of aldosterone synthesis, whereas ACTH, pituitary pro-opiomelanocortin, and antidiuretic hormone are weak stimulators.

Aldosterone is secreted at a rate of 50 to 250 μg/d (depending on sodium intake) and circulates in plasma chiefly as a complex with albumin. Small amounts of the hormone bind to corticosteroid-binding globulin, and approximately 30 to 50% of secreted aldosterone circulates in a free form. The hormone has a half-life of only 15 to 20 minutes and is rapidly cleared via the liver and kidney. A small quantity of free aldosterone also is excreted in the urine. Mineralocorticoids cross the cell membrane and bind to

cytosolic receptors. The receptor-ligand complex subsequently is transported into the nucleus where it induces the transcription and translation of specific genes. Aldosterone functions mainly to increase sodium reabsorption and potassium and hydrogen ion excretion at the level of the renal distal convoluted tubule. Less commonly, aldosterone increases sodium absorption in salivary glands and GI mucosal surfaces.

GLUCOCORTICOIDS

The secretion of cortisol, the major adrenal glucocorticoid, is regulated by ACTH secreted by the anterior pituitary which, in turn, is under the control of corticotrophin-releasing hormone (CRH) secreted by the hypothalamus. ACTH is a 39-amino-acid protein, which is derived by cleavage from a larger precursor, pro-opiomelanocortin. ACTH is further cleaved into α -melanocyte-stimulating hormone and corticotrophin-like-intermediate peptide. ACTH not only stimulates the secretion of glucocorticoids, mineralocorticoids, and adrenal androgens, but is also trophic for the adrenal glands. ACTH secretion may be stimulated by pain, stress, hypoxia, hypothermia, trauma, and hypoglycemia. ACTH secretion fluctuates, peaking in the morning and reaching nadir levels in the late afternoon. Thus, there is a diurnal variation in the secretion of cortisol with peak cortisol excretion also occurring in the early morning and declining during the day to its lowest levels in the evening (Fig. 38-40). Cortisol controls the secretion of both CRH and ACTH via a negative feedback loop. A similar mechanism leads to the inhibition of CRH secretion by ACTH.

Diurnal variation in cortisol levels as determined by half-hourly sampling in a 16-year-old girl.

(Reproduced with permission from Krieger DT, et al: Characterization of the normal temporal pattern of corticosteroid levels. *J Clin Endocrinol Metab* 32:269, 1971. Copyright by The Endocrine Society.)

Cortisol is transported in plasma bound primarily to corticosteroid-binding globulin (75%) and albumin (15%). Approximately 10% of circulating cortisol is free and is the biologically active component. The plasma half-life of cortisol is 60 to 90 minutes and is determined by the extent of binding and rate of inactivation. Cortisol is converted to di- and tetrahydrocortisol and cortisone metabolites in the liver and the kidney. The majority (95%) of cortisol and cortisone metabolites are conjugated with glucuronic acid in the liver, thus facilitating their renal excretion. A small amount of unmetabolized cortisol is excreted unchanged in the urine.

Glucocorticoid hormones enter the cell and bind cytosolic steroid receptors. The activated receptor-ligand complex is then transported to the nucleus where it stimulates the transcription of specific target genes via a "zinc finger" DNA binding element. Cortisol also binds the mineralocorticoid receptor with an affinity similar to aldosterone. However, the specificity of mineralocorticoid action is maintained by the production of 11 β -hydroxysteroid dehydrogenase, an enzyme that inactivates cortisol to cortisone in the kidney. Glucocorticoids have important functions in intermediary metabolism but also affect connective tissue, bone, immune, cardiovascular, renal, and central nervous systems, as outlined in Table 38-15.

Table 38-15 Functions of Glucocorticoid Hormones

Function/System	Effects
Glucose metabolism	Increased hepatic glycogen deposition, gluconeogenesis, decreased muscle glucose uptake and metabolism
Protein metabolism	Decreased muscle protein synthesis, increased catabolism
Fat metabolism	Increased lipolysis in adipose tissue
Connective tissue	Inhibition of fibroblasts, loss of collagen, thinning of skin, striae formation
Skeletal system	Inhibition of bone formation, increased osteoclast activity, potentiate the action of PTH
Immune system	Increases circulation of polymorphonuclear cells, decreases numbers of lymphocytes, monocytes, and eosinophils, reduces migration of inflammatory cells to sites of injury
Cardiovascular system	Increases cardiac output and peripheral vascular tone
Renal system	Sodium retention, hypokalemia, hypertension via mineralocorticoid effect, increased glomerular filtration via glucocorticoid effects
Endocrine system	Inhibits TSH synthesis and release, decreased TBG levels, decreased conversion of T ₄ to T ₃

PTH = parathyroid hormone; T₃ = 3,5',3-triiodothyronine; T₄ = thyroxine; TBG = thyroxine-binding globulin; TSH = thyroid-stimulating hormone.

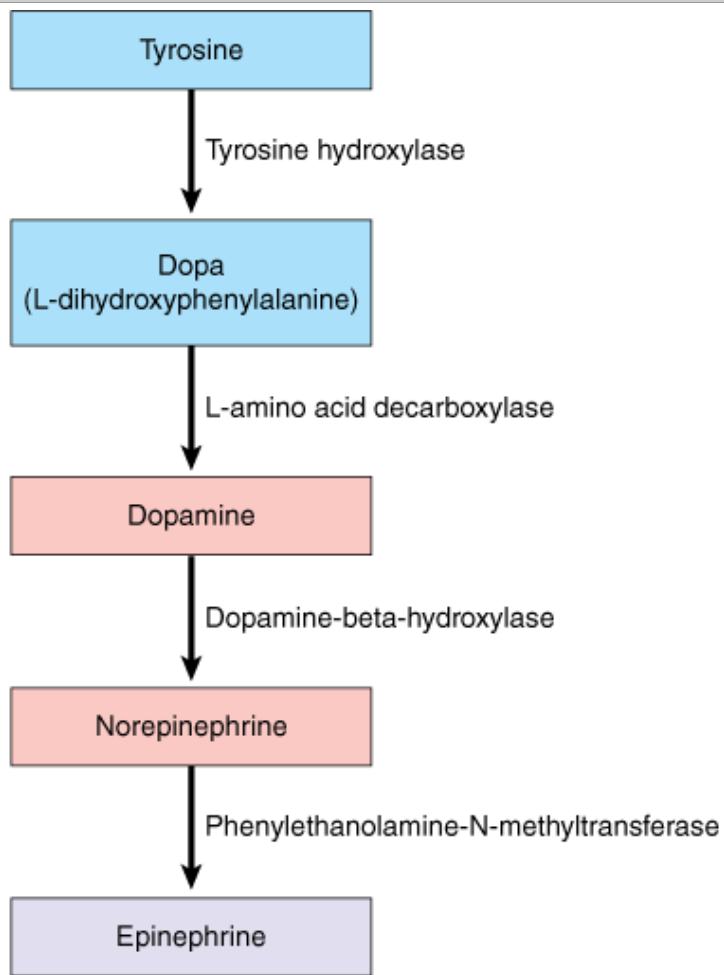

SEX STEROIDS

Adrenal androgens are produced in the zona fasciculata and reticularis from 17-hydroxypregnenolone in response to ACTH stimulation. They include dehydroepiandrosterone (DHEA) and its sulfated counterpart (DHEAS), androstenedione, and small amounts of testosterone and estrogen. Adrenal androgens are weakly bound to plasma albumin. They exert their major effects by peripheral conversion to the more potent testosterone and dihydrotestosterone but also have weak intrinsic androgen activity. Androgen metabolites are conjugated as glucuronides or sulfates and excreted in the urine. During fetal development, adrenal androgens promote the formation of male genitalia. In normal adult males, the contribution of adrenal androgens is minimal; however, they are responsible for the development of secondary sexual characteristics at puberty. Adrenal androgen excess leads to precocious puberty in boys and virilization, acne, and hirsutism in girls and women.

CATECHOLAMINES

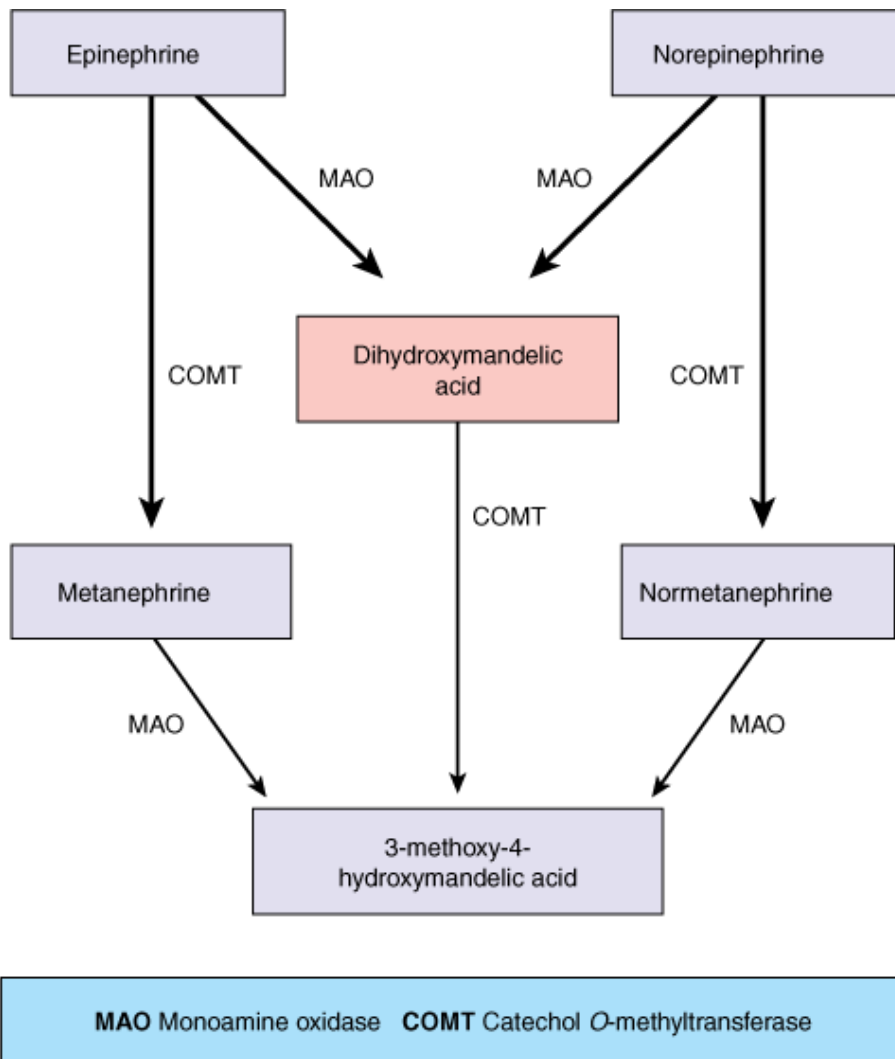

Catecholamine hormones (epinephrine, norepinephrine, and dopamine) are produced not only in the central and sympathetic nervous system but also the adrenal medulla. The substrate, tyrosine, is converted to catecholamines via a series of steps shown in Fig. 38-41A. Phenylethanolamine *N*-methyltransferase, which converts norepinephrine to epinephrine, is only present in the adrenal medulla and the organ of Zuckerkandl. Therefore, the primary catecholamine produced may be used to distinguish adrenal medullary tumors from those situated at extra-adrenal sites. Catecholamines are stored in granules in combination with other neuropeptides, ATP, calcium, magnesium, and water-soluble proteins called *chromogranins*. Hormonal secretion is stimulated by various stress stimuli and mediated by the release of acetylcholine at the preganglionic nerve terminals. In the circulation, these proteins are bound to albumin and other proteins. Catecholamines are cleared by several mechanisms including reuptake by sympathetic nerve endings, peripheral inactivation by catechol *O*-methyltransferase and monoamine oxidase, and direct excretion by the kidneys. Metabolism of catecholamines takes place primarily in the liver and kidneys and leads to the formation of metabolites such as metanephrines, normetanephrines, and VMA, which may undergo further glucuronidation or sulfation before being excreted in the urine (Fig. 38-41B).

A. Synthesis of catecholamines. **B.** Metabolism of catecholamine hormones.

Adrenergic receptors are transmembrane-spanning molecules, which are coupled to G proteins. They may be subdivided into α and β subtypes, which are localized in different tissues, have varying affinity to various catecholamines, and mediate distinct biologic effects (Table 38-16). The receptor affinities for α receptors are—epinephrine > norepinephrine >> isoproterenol; β_1 receptors— isoproterenol > epinephrine = norepinephrine; and β_2 receptors— isoproterenol > epinephrine >> norepinephrine.

Receptor	Tissue	Function
α_1	Blood vessels	Contraction
	Gut	Decreased motility, increased sphincter tone
	Pancreas	Decreased insulin and glucagon release
	Liver	Glycogenolysis, gluconeogenesis
	Eyes	Pupil dilation
	Uterus	Contraction

	Skin	Sweating
α_2	Synapse (sympathetic)	Inhibits norepinephrine release
	Platelet	Aggregation
β_1	Heart	Chronotropic, inotropic
	Adipose tissue	Lipolysis
	Gut	Decreased motility, increased sphincter tone
	Pancreas	Increased insulin and glucagon release
β_2	Blood vessels	Vasodilation
	Bronchioles	Dilation
	Uterus	Relaxation

Disorders of the Adrenal Cortex

HYPERALDOSTERONISM

Hyperaldosteronism may be secondary to stimulation of the renin-angiotensin system from renal artery stenosis and to low-flow states such as congestive heart failure and cirrhosis. Hyperaldosteronism resulting from these conditions is reversible by treatment of the underlying cause. Primary hyperaldosteronism results from autonomous aldosterone secretion which, in turn, leads to suppression of renin secretion. Primary aldosteronism usually occurs in individuals between the ages of 30 to 50 years old and accounts for 1% of hypertension cases. It is associated with hypokalemia; however, more patients with Conn's syndrome are being diagnosed with normal potassium levels. Most cases result from a solitary functioning adrenal adenoma (~70%) and idiopathic bilateral hyperplasia (30%). Adrenocortical carcinoma and glucocorticoid suppressible hyperaldosteronism are rare, each accounting for <1% of cases. Glucocorticoid-suppressible hyperaldosteronism is an autosomal dominant form of hypertension in which aldosterone secretion is abnormally regulated by ACTH. This condition is caused by recombinations between linked genes encoding closely related isozymes, 11 β -hydroxylase (CYP11B1), and aldosterone synthase (CYP11B2) generating a dysregulated chimeric gene with aldosterone synthase activity.

Symptoms and Signs

Patients typically present with hypertension, which is long-standing, moderate to severe, and may be difficult to control despite multiple-drug therapy. Other symptoms include muscle weakness, polydipsia, polyuria, nocturia, headaches, and fatigue. Weakness and fatigue are related to the presence of hypokalemia.

Diagnostic Studies

Laboratory Studies

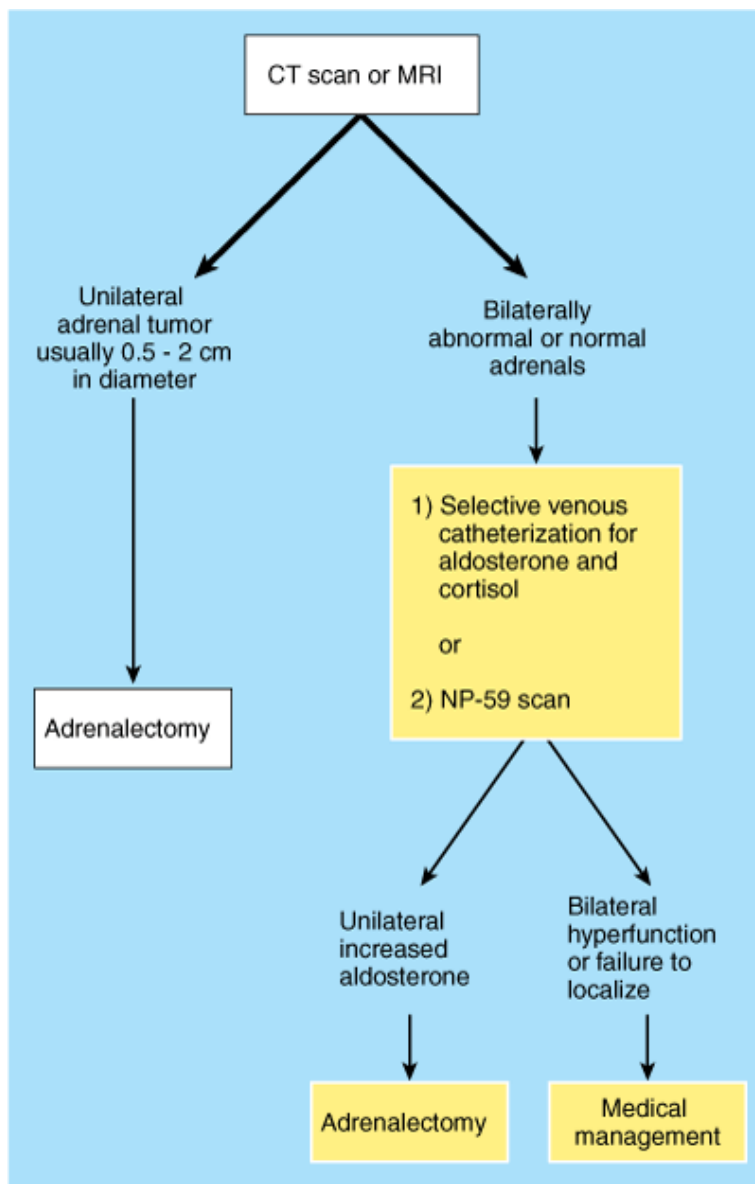

Hypokalemia is a common finding, and hyperaldosteronism must be suspected in any hypertensive patient who presents with coexisting spontaneous hypokalemia ($K < 3.2$ mmol/L), or hypokalemia (< 3 mmol/L) while on diuretic therapy, despite potassium replacements. However, it is important to note that up to 40% of patients with a confirmed aldosteronoma were normokalemic preoperatively. Once the diagnosis is suspected, further tests are necessary to confirm the diagnosis. Before testing, patients must receive adequate sodium and potassium. Antihypertensive medications should be held, if possible, and spironolactone, beta blockers, ACE inhibitors, and angiotensin II receptor blockers should be avoided. Patients with primary hyperaldosteronism have an elevated plasma aldosterone concentration level with a suppressed plasma renin activity; a plasma aldosterone concentration to plasma renin

activity ratio of 1:25 to 30 is strongly suggestive of the diagnosis. False-positive results can occur, particularly in patients with chronic renal failure. Patients with primary hyperaldosteronism also fail to suppress aldosterone levels with sodium loading. This test can be performed by performing a 24-hour urine collection for cortisol, sodium, and aldosterone after 5 days of a high-sodium diet or alternatively giving the patient 2 L of saline while in the supine position, 2 to 3 days after being on a low-sodium diet. Plasma aldosterone levels <5 ng/dL or a 24-hour urine aldosterone <14 µg after saline loading essentially rules out primary hyperaldosteronism. Once the biochemical diagnosis is confirmed, further evaluation should be directed at determining which patients have a unilateral aldosteronoma vs. bilateral hyperplasia, because surgery is almost always curative for the former, but usually not the latter. No biochemical studies can make this distinction with 100% sensitivity, thus imaging studies are necessary.

Radiologic Studies

CT scans with 0.5-cm cuts in the adrenal area can localize aldosteronomas with a sensitivity of 90%. A unilateral 0.5- to 2-cm adrenal tumor with a normal appearing contralateral gland confirms an aldosteronoma in the presence of appropriate biochemical parameters. MRI scans are less sensitive but more specific, particularly if opposed phase chemical shift images are obtained. MRI scans also have increased use in pregnant patients or those unable to tolerate IV contrast. If adrenal hyperplasia is suspected, the algorithm depicted in Fig. 38-42 is useful. Selective venous catheterization and adrenal vein sampling for aldosterone has been demonstrated to be 95% sensitive and 90% specific in localizing the aldosteronoma. In this procedure, the adrenal veins are cannulated and blood samples for aldosterone and cortisol are obtained from both adrenal veins and the vena cava after ACTH administration.⁸⁵ Measurement of cortisol levels is necessary to confirm proper placement of the catheters in the adrenal veins. A greater than fourfold difference in the aldosterone:cortisol ratios between the adrenal veins indicates the presence of a unilateral tumor. Some investigators use this study routinely, but it is invasive, requires an experienced interventional radiologist, and can lead to adrenal vein rupture in approximately 1% of cases. Therefore, most groups advocate use of this modality selectively in ambiguous cases, when the tumor cannot be localized and in patients with bilateral adrenal enlargement to determine whether there is unilateral or bilateral increased secretion of aldosterone. Scintigraphy with ¹³¹I-6β-iodomethyl noriodocholesterol (NP-59) also may be used for the same purpose. Like cholesterol, this compound is taken up by the adrenal cortex, but unlike cholesterol, it remains in the gland without undergoing further metabolism. Adrenal adenomas appear as "hot" nodules with suppressed contralateral uptake, whereas hyperplastic glands show bilaterally increased uptake. This test, however, is not widely available.

Management of an adrenal aldosteronoma. CT = computed tomography; MRI = magnetic resonance imaging.

Treatment

Preoperatively, control of hypertension and adequate potassium supplementation (to keep K >3.5 mmol/L) are important. Patients generally are treated with spironolactone (an aldosterone antagonist), amiloride (a potassium-sparing diuretic that blocks sodium channels in the distal nephron), nifedipine (a calcium channel blocker), or captopril (an ACE inhibitor). Unilateral tumors producing aldosterone are best managed by adrenalectomy, either by a laparoscopic approach (preferred) or via a posterior open approach. If a carcinoma is suspected because of the large size of the adrenal lesion or mixed hormone secretion, an anterior transabdominal approach is preferred to permit adequate determination of local invasion and distal metastases. Only 20 to 30% of patients with hyperaldosteronism secondary to bilateral adrenal hyperplasia benefit from surgery and, as described, selective venous catheterization is useful to predict which patients will respond. For the other patients, medical therapy with spironolactone, amiloride, or triamterene is the mainstay of management. Glucocorticoid suppressible hyperaldosteronism is treated by administering exogenous dexamethasone at doses of 0.5 to 1 mg daily. Treatment with spironolactone may help decrease glucocorticoid requirements in this condition and avoid symptoms of Cushing's syndrome. Postoperatively, some patients experience

transient hypoaldosteronism requiring mineralocorticoids for up to 3 months. Rarely, acute Addison's disease may occur 2 to 3 days after adrenalectomy. Adrenalectomy is >90% successful in improving hypokalemia and about 70% successful in correcting hypertension. Patients who respond to spironolactone therapy and those with a shorter duration of hypertension with minimal renal damage are more likely to achieve improvement in hypertension, whereas male patients, those >50 years old, and those with multiple adrenal nodules, are least likely to benefit from adrenalectomy.

CUSHING'S SYNDROME

Cushing described patients with a peculiar fat deposition, amenorrhea, impotence (in men), hirsutism, purple striae, hypertension, diabetes, and other features that constitute the syndrome (Fig. 38-43). He also recognized that several of these patients had basophilic tumors of the pituitary gland and concluded that these tumors produced hormones, which caused adrenocortical hyperplasia, thus resulting in the manifestations of the syndrome. Today, the term *Cushing's syndrome* refers to a complex of symptoms and signs resulting from hypersecretion of cortisol regardless of etiology. In contrast, *Cushing's disease* refers to a pituitary tumor, usually an adenoma, which leads to bilateral adrenal hyperplasia and hypercortisolism. Cushing's syndrome (endogenous) is a rare disease, affecting 10 in 1 million individuals. It is more common in adults but may occur in children. Women are more commonly affected (male:female ratio 1:8). Although most individuals have sporadic disease, Cushing's syndrome may be found in MEN1 families and can result from ACTH-secreting pituitary tumors, primary adrenal neoplasms, or an ectopic ACTH-secreting carcinoid tumor (more common in men) or bronchial adenoma (more common in women).

Some characteristic features of Cushing's syndrome—moon facies, hirsutism, and acne.

Cushing's syndrome may be classified as ACTH-dependent or ACTH-independent (Table 38-17). The most common cause of

hypercortisolism is exogenous administration of steroids. However, approximately 70% of cases of endogenous Cushing's syndrome are caused by an ACTH-producing pituitary tumor. Primary adrenal sources (adenoma, hyperplasia, and carcinoma) account for about 20% of cases and ectopic ACTH-secreting tumors account for <10% of cases. CRH also may be secreted ectopically in bronchial carcinoid tumors, pheochromocytomas, and other tumors. These patients are difficult to distinguish from those with ectopic ACTH production, but can be diagnosed by determining CRH levels. Patients with major depression, alcoholism, pregnancy, chronic renal failure, or stress also may have elevated cortisol levels and symptoms of hypercortisolism. However, these manifestations resolve with treatment of the underlying disorder, and these patients are deemed to have pseudo-Cushing's syndrome.

^a From small cell lung tumors, pancreatic islet cell tumors, medullary thyroid cancers, pheochromocytomas, and carcinoid tumors of the lung, thymus, gut, pancreas, and ovary.

ACTH = adrenocorticotrophic hormone; CTH = corticotrophin-releasing hormone.

Primary adrenal hyperplasia may be micronodular, macronodular, or massively macronodular. Adrenal hyperplasia resulting from ACTH stimulation usually is macronodular (3-cm nodules). Primary pigmented nodular adrenocortical disease is a rare cause of ACTH-independent Cushing's syndrome, which is characterized by the presence of small (<5 mm), black adrenal nodules. Primary pigmented nodular adrenocortical disease may be associated with Carney complex (atrial myxomas, schwannomas, and pigmented nevi) and is thought to be immune related.

Symptoms and Signs

The classical features of Cushing's syndrome are listed in Table 38-18. Early diagnosis of this disease requires a thorough knowledge of these manifestations, coupled with a high clinical suspicion. In some patients, symptoms are less pronounced and may be more difficult to recognize, particularly given their diversity and the absence of a single defining symptom or sign. Progressive truncal obesity is the most common symptom, occurring in up to 95% of patients. This pattern results from the lipogenic action of excessive corticosteroids centrally and catabolic effects peripherally, along with peripheral muscle wasting. Fat deposition also occurs in unusual sites, such as the supraclavicular space and posterior neck region, leading to the so-called buffalo hump. Purple striae are often visible on the protuberant abdomen. Rounding of the face leads to moon facies, and thinning of subcutaneous tissues leads to plethora. There is an increase in fine hair growth on the face, upper back, and arms although true virilization is more commonly seen with adrenocortical cancers. Endocrine abnormalities include glucose intolerance, amenorrhea, and decreased libido or

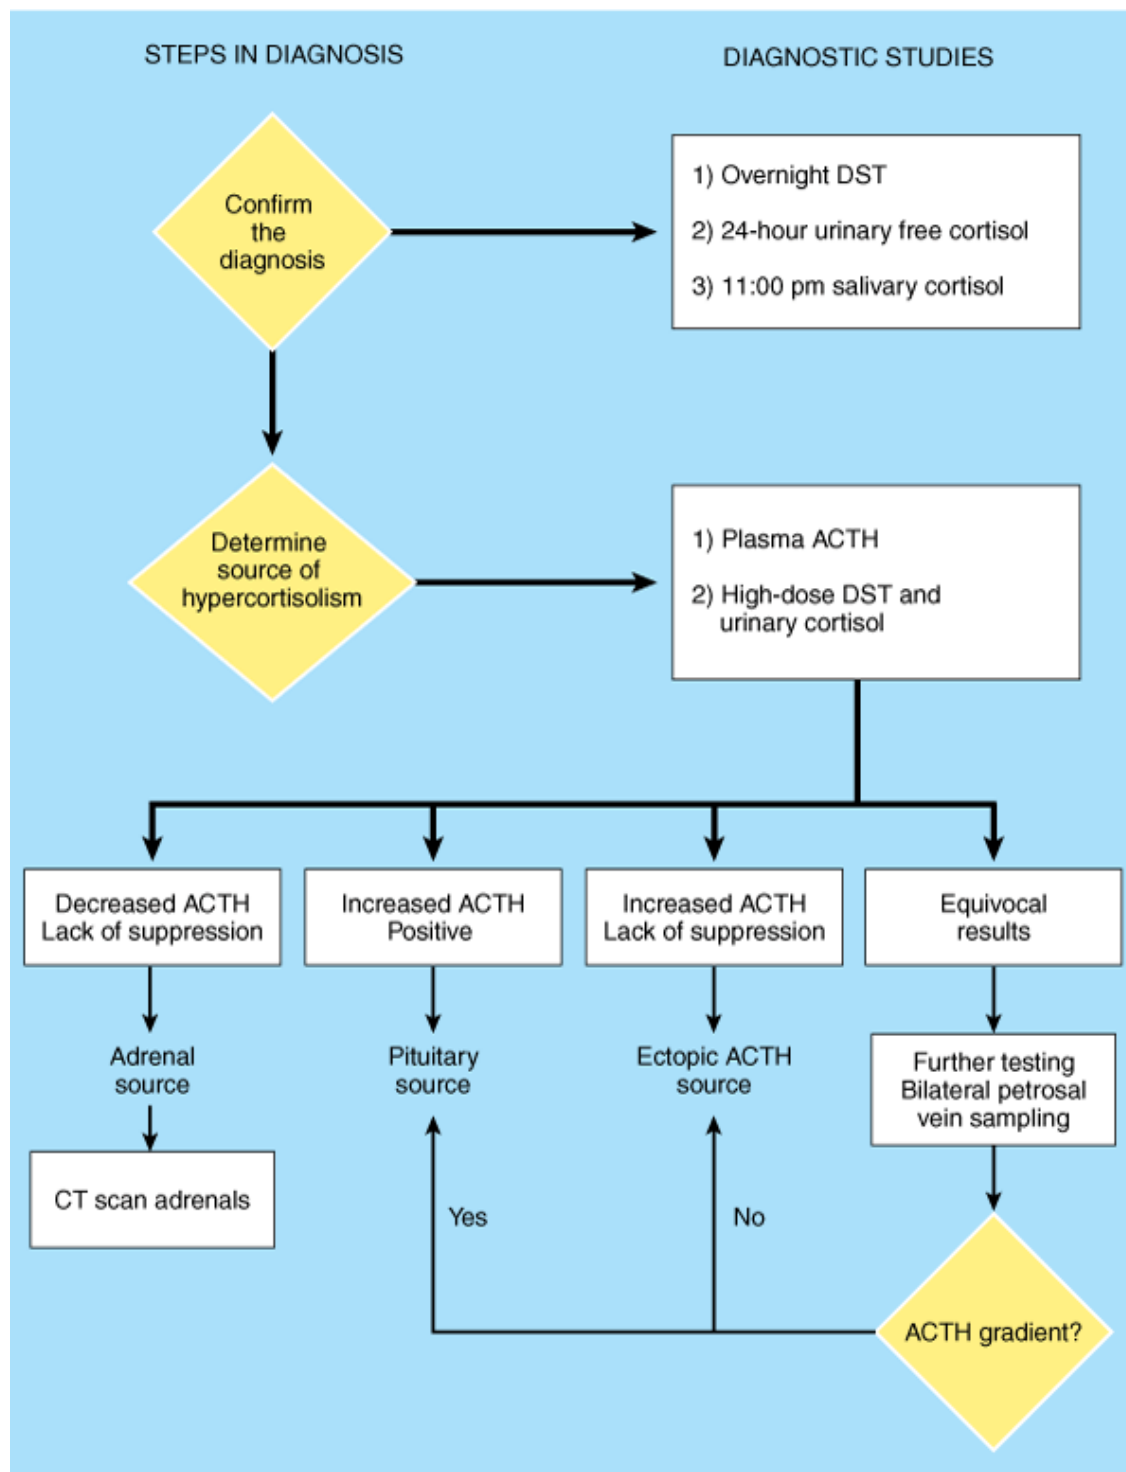

impotence. In children, Cushing's syndrome is characterized by obesity and stunted growth. Patients with Cushing's disease also may present with headaches, visual field defects, and panhypopituitarism. Hyperpigmentation of the skin, if present, suggests an ectopic ACTH-producing tumor with high levels of circulating ACTH.

Table 38-18 Features of Cushing's Syndrome	
System	Manifestation
General	Weight gain—central obesity, buffalo hump, supraclavicular fat pads
Integumentary	Hirsutism, plethora, purple striae, acne, ecchymosis
Cardiovascular	Hypertension
Musculoskeletal	Generalized weakness, osteopenia
Neuropsychiatric	Emotional lability, psychosis, depression
Metabolic	Diabetes or glucose intolerance, hyperlipidemia
Renal	Polyuria, renal stones
Gonadal	Impotence, decreased libido, menstrual irregularities

Diagnostic Tests

The aims of diagnostic tests in the evaluation of patients suspected of having Cushing's syndrome are twofold; to confirm the presence of Cushing's syndrome and to determine its etiology (Fig. 38-44).

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Diagnosis of Cushing's syndrome. ACTH = adrenocorticotrophic hormone; CT = computed tomography; DST = dexamethasone suppression test.

Laboratory Studies

Cushing's syndrome is characterized by elevated glucocorticoid levels that are not suppressible by exogenous hormone administration and loss of diurnal variation. This phenomenon is used to screen patients using the overnight low-dose dexamethasone suppression test. In this test, 1 mg of a synthetic glucocorticoid (dexamethasone) is given at 11 P.M. and plasma cortisol levels are measured at 8 A.M. the following morning. Physiologically normal adults suppress cortisol levels to $<3 \mu\text{g/dL}$,

whereas most patients with Cushing's syndrome do not. False-negative results may be obtained in patients with mild disease; therefore, some authors consider the test positive only if cortisol levels are suppressed to $<1.8 \mu\text{g/dL}$. False-positive results can occur in up to 3% of patients with chronic renal failure, depression, or those taking medications such as phenytoin, which enhance dexamethasone metabolism. In patients with a negative test but a high clinical suspicion, the classic low-dose dexamethasone (0.5 mg every 6 hours for eight doses, or 2 mg over 48 hours) suppression test or urinary cortisol measurement should be performed. Measurement of elevated 24-hour urinary cortisol levels is a very sensitive (95 to 100%) and specific (98%) modality of diagnosing Cushing's syndrome and is particularly useful for identifying patients with pseudo-Cushing's syndrome. A urinary cortisol-free excretion of less than $100 \mu\text{g/dL}$ (in most laboratories) rules out hypercortisolism. Recently, salivary cortisol measurements using commercially available kits also have demonstrated superior sensitivity in diagnosing Cushing's syndrome and are being increasingly used. Overall, 24-hour urinary tests for free cortisol and the overnight dexamethasone suppression test at the $5 \mu\text{g/dL}$ cutoff have the highest specificity for the diagnosis of Cushing's syndrome.⁸⁶

Once a diagnosis of hypercortisolism is established, further testing is aimed at determining whether it is ACTH-dependent or ACTH-independent Cushing's syndrome. This is best accomplished by measurement of plasma ACTH levels (normal 10 to 100 pg/mL). Elevated ACTH levels are found in patients with adrenal hyperplasia due to Cushing's disease (15 to 500 pg/mL) and those with CRH-secreting tumors, but the highest levels are found in patients with ectopic sources of ACTH ($>1000 \text{ pg/mL}$). In contrast, ACTH levels are characteristically suppressed ($<5 \text{ pg/mL}$) in patients with primary cortisol-secreting adrenal tumors. The high-dose dexamethasone suppression test is used to distinguish between the causes of ACTH-dependent Cushing's syndrome (pituitary vs. ectopic). The standard test (2 mg dexamethasone every 6 hours for 2 days) or the overnight test (8 mg) may be used, with 24-hour urine collections for cortisol and 17-hydroxy steroids performed over the second day. Failure to suppress urinary cortisol by 50% confirms the diagnosis of an ectopic ACTH-producing tumor. Patients suspected of having ectopic tumors should also undergo testing for MTC and pheochromocytoma. Bilateral petrosal vein sampling also is helpful for determining whether the patient has Cushing's disease or ectopic Cushing's syndrome.

The CRH test also is helpful in determining the etiology of Cushing's syndrome. Ovine CRH ($1 \mu\text{g/kg}$) is administered intravenously, followed by serial measurements of ACTH and cortisol at 15-minute intervals for 1 hour. Patients with a primary adrenal hypercortisolism exhibit a blunted response (ACTH peak $<10 \text{ pg/mL}$), whereas those with ACTH-dependent Cushing's syndrome demonstrate a higher elevation of ACTH ($>30 \text{ pg/mL}$). CRH stimulation also can enhance the usefulness of petrosal vein sampling. Patients with pituitary tumors also have a higher peak ACTH than those with ectopic ACTH-producing tumors.

Radiologic Studies

CT and MRI scans of the abdomen can identify adrenal tumors with 95% sensitivity. They also are helpful in distinguishing adrenal adenomas from carcinomas, as discussed in the subsequent section Adrenocortical Cancer. MRI scans have the added advantage of allowing assessment of vascular anatomy. Adrenal adenomas appear darker than the liver on T_2 -weighted imaging.

Radioscintigraphic imaging of the adrenals using NP-59 also can be used to distinguish adenoma from hyperplasia. Reports suggest that "cold" adrenal nodules are more likely to be cancerous, although this distinction is not absolute. NP-59 scanning is most useful in identifying patients with an adrenal source of hypercortisolism and primary pigmented micronodular hyperplasia.

Thin-section head CT scans are 22% sensitive and contrast-enhanced brain MRI scans are 33 to 67% sensitive at identifying pituitary tumors. Inferior petrosal sinus sampling for ACTH before and after CRH injection has been helpful in this regard and has a sensitivity approaching 100%. In this study, catheters are placed in both internal jugular veins and a peripheral vein. A ratio of petrosal to peripheral vein ACTH level of >2 in the basal state and >3 after CRH stimulation is diagnostic of a pituitary tumor. In patients suspected of having ectopic ACTH production, CT or MRI scans of the chest and anterior mediastinum are performed first, followed by imaging of the neck, abdomen, and pelvis if the initial studies are negative.

Treatment

Laparoscopic adrenalectomy is the treatment of choice for patients with adrenal adenomas. Open adrenalectomy is reserved for large tumors (≥ 6 cm) or those suspected to be adrenocortical cancers. Bilateral adrenalectomy is curative for primary adrenal hyperplasia.

The treatment of choice in Cushing's disease is transsphenoidal excision of the pituitary adenoma, which is successful in 80% of patients. Pituitary irradiation has been used for patients with persistent or recurrent disease after surgery. However, it is associated with a high rate of panhypopituitarism, and some patients develop visual deficits. This has led to increased use of stereotactic radiosurgery, which uses CT guidance to deliver high doses of radiotherapy to the tumor (photon or gamma knife) and also bilateral laparoscopic adrenalectomy. Patients who fail to respond to either treatment are candidates for pharmacologic therapy with adrenal inhibitors (medical adrenalectomy) such as ketoconazole, metyrapone, or aminoglutethimide.

Patients with ectopic ACTH production are best managed by treating the primary tumor, including recurrences, if possible. Medical or bilateral laparoscopic adrenalectomy have been used to palliate patients with unresectable disease and those whose ectopic ACTH-secreting tumor cannot be localized.

Patients undergoing surgery for a primary adrenal adenoma secreting glucocorticoids require preoperative and postoperative steroids due to suppression of the contralateral adrenal gland. These patients are also at increased predisposition for infectious and thromboembolic complications, the latter due to a hypercoagulable state resulting from an increase in clotting factors including factor VIII and von Willebrand's factor complex, and by impaired fibrinolysis. Duration of steroid therapy is determined by the ACTH stimulation test. Exogenous steroids may be needed for up to 2 years but are needed indefinitely in patients who have undergone bilateral adrenalectomy. This latter group of patients also may require mineralocorticoid replacement therapy. Typical replacement doses include hydrocortisone (10 to 20 mg q A.M. and 5 to 10 mg q P.M.) and fludrocortisone (0.05 to 0.1 mg/day q A.M.).

ADRENOCORTICAL CANCER

Adrenal carcinomas are rare neoplasms with a worldwide incidence of two per 1 million. These tumors have a bimodal age distribution, with an increased incidence in children and adults in the fourth and fifth decades of life. The majority are sporadic, but adrenocortical carcinomas also occur in association with germline mutations of *p53* (Li-Fraumeni syndrome) and *MEN1* (multiple endocrine neoplasia type 1) genes. Loci on 11p (Beckwith-Wiedemann syndrome), 2p (Carney complex), and 9q also have been implicated.

Symptoms and Signs

Approximately 50% of adrenocortical cancers are nonfunctioning.⁸⁷ The remaining secrete cortisol (30%), androgens (20%), estrogens (10%), aldosterone (2%), or multiple hormones (35%). Patients with functioning tumors often present with the rapid onset of Cushing's syndrome accompanied by virilizing features. Nonfunctioning tumors more commonly present with an enlarging abdominal mass and abdominal or back pain. Rarely, weight loss, anorexia, and nausea may be present.

Diagnostic Tests

Diagnostic evaluation of these patients begins with measurement of serum electrolyte levels to rule out hypokalemia, urinary catecholamines to rule out pheochromocytomas, an overnight 1-mg dexamethasone suppression test, and a 24-hour urine collection for cortisol, 17-ketosteroids.

CT and MRI scans are useful to image these tumors (Fig. 38-45). The size of the adrenal mass on imaging studies is the single most important criterion to help diagnose malignancy. In the series reported by Copeland, 92% of adrenal cancers were >6 cm in diameter.⁸⁸ The sensitivity, specificity, and likelihood ratio of tumor size in predicting malignancy (based on Surveillance; Epidemiology, and End Results program data) was recently reported as 96%, 51%, and 2 for tumors ≥ 4 cm; and 90%, 78%, and

4.1 for tumors ≥ 6 cm. Other CT imaging characteristics suggesting malignancy include tumor heterogeneity, irregular margins, and the presence of hemorrhage and adjacent lymphadenopathy or liver metastases. Moderately bright signal intensity on T₂-weighted images (adrenal mass to liver ratio 1.2:2.8), significant lesion enhancement, and slow washout after injection of gadolinium contrast also indicate malignancy, as does evidence of local invasion into adjacent structures such as the liver, blood vessels (IVC), and distant metastases. Once adrenal cancer is diagnosed, CT scans of the chest and pelvis are performed for staging. The tumor-node-metastasis (TNM) staging system for adrenocortical carcinoma is depicted in Table 38-19. Up to 70% of patients present with stage III or IV disease.

Computed tomography scan of the abdomen showing a left adrenocortical cancer with synchronous liver metastasis.

Table 38-19 TNM Staging for Adrenocortical Cancer²⁹

Stage	TNM Class
I	T1, N0, M0
II	T2, N0, M0
III	T3, N0, M0T1–2, N1, M0
IV	T3–4, N1, M0
	Any T, any N, M1

Primary tumor (T): T1, size ≤ 5 cm without local invasion; T2, size >5 cm without local invasion; T3, any size with local invasion but no involvement of adjacent organs; T4, any size with involvement of adjacent organs.

Nodes (N): N0, no involvement of regional nodes; N1, positive regional lymph nodes.

Metastasis (M): M0, no known distal metastases, M1, distant metastases present.

Pathology

Most adrenocortical cancers are large, weighing between 100 and 1000 g. On gross examination, areas of hemorrhage and necrosis often are evident. Microscopically, cells are hyperchromatic and typically have large nuclei and prominent nucleoli. It is very difficult to distinguish benign adrenal adenomas from carcinomas by histologic examination alone. Capsular or vascular invasion is the most reliable sign of cancer. Weiss and associates studied a combination of nine criteria for their usefulness in distinguishing malignant from benign adrenal tumors: nuclear grade III or IV; mitotic rate greater than 5/50 high-power fields; atypical mitoses; clear cells comprising 25% or less of the tumor; a diffuse architecture; microscopic necrosis; and invasion of venous, sinusoidal, and capsular structure. Tumors with four or more of these criteria were likely to metastasize and/or recur.⁹⁰ Rarely, the diagnosis of malignancy of a completely resected adrenal tumor is often only made in retrospect by the finding of metastatic disease many years later.

Treatment

The most important predictor of survival in patients with adrenal cancer is the adequacy of resection. Patients who undergo complete resection have 5-year actuarial survival rates ranging from 32 to 48%, whereas median survival is <1 year in those undergoing incomplete excision. Therefore, adrenocortical carcinomas are treated by excision of the tumor en bloc with any contiguously involved lymph nodes or organs such as the diaphragm, kidney, pancreas, liver, or IVC. This is best accomplished by open adrenalectomy via a generous subcostal incision or a thoracoabdominal incision (on the right side). The incisions should permit wide exposure, minimize chances of capsule rupture and tumor spillage, and allow vascular control of the aorta, IVC, and renal vessels, as needed.

Mitotane or o,p-DDD or 1,1-dichloro-2-(o-chlorophenyl)-2-(p-chlorophenyl) ethane, which is a derivative of the insecticide DDT, has adrenolytic activity and has been used in the adjuvant setting and for the treatment of unresectable or metastatic disease. However, the therapeutic effectiveness is conflicting, and consistent improvement in survival rates is lacking. Moreover, the drug is associated with significant GI and neurologic side effects, particularly at the effective doses of 2 to 6 g/d. Terzolo and associates retrospectively evaluated the use of mitotane in the adjuvant setting and reported significantly increased recurrence-free survival in the treatment group.⁹¹ However, the routine use of this medication awaits evaluation in randomized, controlled trials. Determination of blood mitotane levels is helpful to ascertain whether therapeutic and nontoxic levels are present. Adrenocortical tumors commonly metastasize to the liver, lung, and bone.

Surgical debulking is recommended for isolated, recurrent disease and has been demonstrated to prolong survival. Systemic chemotherapeutic agents used in this tumor include etoposide, cisplatin, doxorubicin, and, more recently, paclitaxel, but consistent responses are rare, possibly due to the expression of the multidrug resistance gene (*MDR-1*) in tumor cells. In vitro data indicate that mitotane may be able to reverse this resistance when combined with various chemotherapeutic agents. There has been recent interest in the use of suramin, a growth factor inhibitor, as therapy for adrenocortical carcinoma; however, this requires further study, particularly because this drug may be associated with significant neurotoxicity. Gossypol, a naturally occurring insecticide (from the cotton plant *Gossypium* species), also appears to inhibit the growth of adrenocortical cancer cell lines and tumors in vivo. However, poor response rates combined with high death rates in limited clinical studies have reduced enthusiasm for this agent. Adrenocortical cancers also are relatively insensitive to conventional external beam radiation therapy. However, this modality is used in the palliation of bony metastases. Ketoconazole, metyrapone, or aminoglutethimide may also be useful in controlling steroid hypersecretion.

SEX STEROID EXCESS

Adrenal adenomas or carcinomas that secrete adrenal androgens lead to virilizing syndromes. Although women with virilizing tumors develop hirsutism, amenorrhea, infertility, and other signs of masculinization, such as increased muscle mass, deepened voice, and temporal balding, men with these tumors are more difficult to diagnose and, hence, usually present with disease in advanced stages. Children with virilizing tumors have accelerated growth, premature development of facial and pubic hair, acne, genital enlargement, and deepening of their voice. Feminizing adrenal tumors are less common and occur in men in the third to fifth decades of life. These tumors lead to gynecomastia, impotence, and testicular atrophy. Women with these tumors develop irregular menses or dysfunctional uterine bleeding. Vaginal bleeding may occur in postmenopausal women. Girls with these tumors experience precocious puberty with breast enlargement and early menarche.

Diagnostic Tests

Virilizing tumors produce excessive amounts of the androgen precursor, DHEA, which can be measured in plasma or urine as 17-ketosteroids. Patients with feminizing tumors also have elevated urinary 17-ketosteroids in addition to increased estrogen levels. Androgen-producing tumors often are associated with production of other hormones such as glucocorticoids.

Treatment

Virilizing and feminizing tumors are treated by adrenalectomy. Malignancy is difficult to diagnose histologically but is suggested by the presence of local invasion, recurrence, or distal metastases. Adrenolytic drugs such as mitotane, aminoglutethimide, and ketoconazole may be useful in controlling symptoms in patients with metastatic disease.

CONGENITAL ADRENAL HYPERPLASIA

CAH refers to a group of disorders, which result from deficiencies or complete absence of enzymes involved in adrenal steroidogenesis. 21-Hydroxylase (CYP21A2) deficiency is the most common enzymatic defect, accounting for >90% of cases of CAH. This deficiency prevents the production of 11-deoxycortisol and 11-DOC from progesterone precursors. Deficiency of glucocorticoids and aldosterone leads to elevated ACTH levels and overproduction of adrenal androgens and corticosteroid precursors such as 17-hydroxyprogesterone and Δ^4 -androstenedione. These compounds are converted to testosterone in the peripheral tissues, thereby leading to virilization. Complete deficiency of 21-hydroxylase presents at birth with virilization, diarrhea, hypovolemia, hyponatremia, hyperkalemia, and hyperpigmentation. Partial enzyme deficiency may present at birth or later with virilizing features. These patients are less prone to the salt-wasting that characterizes complete enzyme deficiency. 11 β -hydroxylase deficiency is the second most common form of CAH and leads to hypertension (from 11-DOC accumulation), virilization, and hyperpigmentation. Other enzyme deficiencies include 3 β -hydroxydehydrogenase and 17-hydroxylase deficiency. Congenital adrenal lipid hyperplasia is the most severe form of CAH, which is caused by cholesterol desmolase deficiency. It leads to the disruption of all steroid biosynthetic pathways, thus resulting in a fatal salt-wasting syndrome in phenotypic female patients.

Diagnostic Tests

The particular enzyme deficiency can be diagnosed by karyotype analysis and measurement of plasma and urinary steroids. The most common enzyme deficiency, absence of 21-hydroxylase, leads to increased plasma 17-hydroxyprogesterone and progesterone levels, because these compounds cannot be converted to 11-deoxycortisol and 11-deoxycorticosterone, respectively. 11 β -hydroxylase deficiency is the next most common disorder and results in elevated plasma 11-DOC and 11-deoxycortisol. Urinary 17-hydroxyprogesterone, androgens, and 17-ketosteroids also are elevated. The dexamethasone suppression test (2 to 4 mg divided qid for 7 days) can be used to distinguish adrenal hyperplasia from neoplasia. CT, MRI, and iodocholesterol scans generally are used to localize the tumors.

Treatment

Patients with CAH traditionally have been managed medically, with cortisol and mineralocorticoid replacement to suppress the

hypothalamic-pituitary-adrenal axis. However, the doses of steroids required often are supraphysiologic and lead to iatrogenic hypercortisolism. More recently, bilateral laparoscopic adrenalectomy has been proposed as an alternative treatment for this disease and has been successfully performed in a limited number of patients for various forms of CAH.

Disorders of the Adrenal Medulla

PHEOCHROMOCYTOMAS

Pheochromocytomas are rare tumors with prevalence rates ranging from 0.3 to 0.95% in autopsy series and approximately 1.9% in series using biochemical screening. They can occur at any age with a peak incidence in the fourth and fifth decades of life and have no gender predilection. Extra-adrenal tumors, also called functional paragangliomas, may be found at sites of sympathetic ganglia in the organ of Zuckerkandl, neck, mediastinum, abdomen, and pelvis. Pheochromocytomas often are called the *10 percent tumor* because 10% are bilateral, 10% are malignant, 10% occur in pediatric patients, 10% are extra-adrenal, and 10% are familial.

Pheochromocytomas occur in families with MEN2A and MEN2B, in approximately 50% of patients. Both syndromes are inherited in an autosomal dominant fashion and are caused by germline mutations in the *RET* proto-oncogene. Another syndrome with an increased risk of pheochromocytomas is von Hippel-Lindau (VHL) disease, which also is inherited in an autosomal dominant manner. This syndrome also includes retinal angioma, hemangioblastomas of the central nervous system, renal cysts and carcinomas, pancreatic cysts, and epididymal cystadenomas. The incidence of pheochromocytomas in the syndrome is approximately 14%. The gene causing VHL has been mapped to chromosome 3p and is a tumor-suppressor gene. Pheochromocytomas also are included within the tumor spectrum of neurofibromatosis type 1 (NF1 gene) and other neuroectodermal disorders (Sturge-Weber syndrome and tuberous sclerosis), Carney's syndrome (gastric epithelioid leiomyosarcoma, pulmonary chondroma, and extra-adrenal paraganglioma), MEN1 syndrome, and the familial paraganglioma and pheochromocytoma syndrome caused by mutations in the succinyl dehydrogenase family of genes (SDHB, SDHC, and SDHD).⁹²

Symptoms and Signs

Headache, palpitations, and diaphoresis constitute the "classic triad" of pheochromocytomas. Symptoms such as anxiety, tremulousness, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, vomiting, and others are nonspecific and may be episodic in nature. Cardiovascular complications such as myocardial infarction and cerebrovascular accidents may ensue. These symptoms can be incited by a range of stimuli including exercise, micturition, and defecation. The most common clinical sign is hypertension. Pheochromocytomas are one of the few curable causes of hypertension and are found in 0.1 to 0.2% of hypertensive patients. Hypertension related to this tumor may be paroxysmal with intervening normotension, sustained with paroxysms or sustained hypertension alone. Sudden death may occur in patients with undiagnosed tumors who undergo other surgeries or biopsy.

Diagnostic Tests

Biochemical Studies

Pheochromocytomas are diagnosed by testing 24-hour urine samples for catecholamines and their metabolites as well as by determining plasma metanephrine levels. Urinary metanephrines are 98% sensitive and also are highly specific for pheochromocytomas, whereas VMA measurements are slightly less sensitive and specific. False-positive VMA tests may result from ingestion of caffeine, raw fruits, or medications (α -methyl dopa). Fractionated urinary catecholamines (norepinephrine, epinephrine, and dopamine) also are very sensitive but less specific for pheochromocytomas. Because extra-adrenal sites lack phenylethanolamine *N*-methyltransferase, these tumors secrete norepinephrine whereas epinephrine is the main hormone secreted from adrenal pheochromocytomas. Many physiologic and pathologic states can alter the levels of plasma catecholamines. Hence, they often are thought to be less accurate than urinary tests. Both epinephrine and norepinephrine should be measured, as tumors

often secrete one or the other hormone. Sensitivities of 85% and specificities of 95% have been reported using cutoff values of 2000 pg/mL for norepinephrine and 200 pg/mL for epinephrine. Clonidine is an agent that suppresses neurogenically mediated catecholamine excess but not secretion from pheochromocytomas. A normal clonidine suppression test is defined by a decrease of basal catecholamine levels to <500 pg/mL within 2 to 3 hours after an oral dose of 0.3 mg of clonidine. Chromogranin A is a monomeric, acidic protein, which is stored in the adrenal medulla and other neuroendocrine tumors and released along with catecholamine hormones. It has been reported to have a sensitivity of 83% and a specificity of 96% and is useful in conjunction with catecholamine measurement for diagnosing pheochromocytomas. Recent studies have shown that plasma metanephrines are the most reliable tests to identify pheochromocytomas, with sensitivity approaching 100%.

Radiologic Studies

Radiologic studies are useful to localize tumors and to assess the extent of spread once the diagnosis has been made with biochemical tests. CT scans are 85 to 95% sensitive and 70 to 100% specific for pheochromocytomas (Fig. 38-46A). The scans should be performed without contrast to minimize the risk of precipitating a hypertensive crisis although some recent studies suggest that IV contrast may be used. Images should include the region from the diaphragm to the aortic bifurcation so as to include the organ of Zuckerkandl. CT scans do not provide functional information and cannot definitively diagnose pheochromocytomas. MRI scans are 95% sensitive and almost 100% specific for pheochromocytomas because these tumors have a characteristic appearance on T₂-weighted images or after gadolinium. MRI is also the study of choice in pregnant women as there is no risk of radiation exposure. Metaiodobenzylguanidine (MIBG) is taken up and concentrated by vesicles in the adrenal medullary cells because its structure is similar to norepinephrine. Normal adrenal medullary tissue does not take up appreciable MIBG. ¹³¹I radiolabeled MIBG is, therefore, useful for localizing pheochromocytomas (Fig. 38-46B), especially those in ectopic positions. This test has a reported sensitivity of 77 to 89% and specificity ranging from 88 to 100%.

A left-sided pheochromocytoma (arrows) imaged by a computed tomography scan of the abdomen (A) and a metaiodobenzylguanidine scan viewed posteriorly (B).

Treatment

The medical management of pheochromocytomas is aimed chiefly at blood pressure control and volume repletion. Alpha blockers such as phenoxybenzamine are started 1 to 3 weeks before surgery at doses of 10 mg twice daily, which may be increased to 300 to 400 mg/d with rehydration. Patients should be warned about orthostatic hypotension. Other alpha blockers such as prazosin and other classes of drugs such as ACE inhibitors and calcium channel blockers are also useful. Beta blockers such as propranolol at doses of 10 to 40 mg every 6 to 8 hours often need to be added preoperatively in patients who have persistent tachycardia and arrhythmias. Beta blockers should only be instituted after adequate alpha blockade and hydration to avoid the effects of unopposed alpha stimulation, (i.e., hypertensive crisis and congestive heart failure). Patients also should be volume repleted preoperatively to avoid postoperative hypotension, which ensues with the loss of vasoconstriction after tumor removal.

Adrenalectomy is the treatment of choice. The chief goal of surgery is to resect the tumor completely with minimal tumor manipulation or rupture of the tumor capsule. Surgery should be performed with both noninvasive and invasive monitors, including an arterial line and central venous lines. In patients with congestive heart failure or underlying coronary artery disease, Swan-Ganz catheters may be necessary. Stress must be avoided during anesthesia induction, and use of inhaled agents like isoflurane and enflurane are preferred because they have minimal cardiac depressant effects. The common medications used for intraoperative blood pressure control include nitroprusside, nitroglycerin, and phentolamine. Intraoperative arrhythmias are best managed by short-acting beta blockers such as esmolol. Adrenalectomy usually was performed via an open anterior approach to facilitate detection of bilateral tumors, extra-adrenal lesions, or metastatic lesions. However, many pheochromocytomas <5 cm in diameter can be safely resected laparoscopically. Postoperatively, these patients are prone to hypotension due to loss of adrenergic

stimulation and consequent vasodilatation and therefore need large volume resuscitation.

HEREDITARY PHEOCHROMOCYTOMAS

Inherited pheochromocytomas tend to be multiple and bilateral. Generally, unilateral adrenalectomy is recommended in the absence of obvious lesions in the contralateral adrenal gland because of Addison disease requiring lifelong steroid replacement in patients undergoing bilateral adrenalectomy. For patients with tumors in both adrenal glands, cortical-sparing subtotal adrenalectomy may preserve adrenocortical function and avoid the morbidity of bilateral total adrenalectomy.⁷² Laparoscopic subtotal adrenalectomy has been shown to provide short-term clinical results comparable to total adrenalectomy, with reduced surgical morbidity.⁹³ However, these patients remain at risk for recurrent pheochromocytoma, which has been reported in 20% of patients with VHL disease a median of 40 months after partial adrenalectomy, and in 33% of MEN2 patients followed for 54 to 88 months after surgery. Autotransplantation of adrenocortical tissue after total adrenalectomy may be another option for these patients and removes the risk of recurrence. However, the transplanted cortical tissue rarely provides full function, and steroid replacement usually is required.

MALIGNANT PHEOCHROMOCYTOMAS

Approximately 12 to 29% of pheochromocytomas are malignant, and these tumors are associated with decreased survival. There are no definitive histologic criteria defining malignant pheochromocytomas. In fact, pleomorphism, nuclear atypia, and abundant mitotic figures are seen in benign tumors. Capsular and vascular invasion may be seen in benign lesions as well. Malignancy usually is diagnosed when there is evidence of invasion into surrounding structures or distant metastases. The most common sites for metastatic disease are bone, liver, regional lymph nodes, lung, and peritoneum, although the brain, pleura, skin, and muscles may also occasionally be involved. Some studies also suggest that older patient age and larger tumors are associated with a higher risk of malignancy. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas with local disease only.⁹⁴ Given this difficulty defining malignancy clinically (in the absence of metastatic disease), a number of other features such as DNA ploidy, tumor size, and necrosis, neuropeptide Y mRNA expression and serum neuron-specific enolase expression have been studied. Malignant pheochromocytomas are more likely to express p53 and bcl-2, and have activated telomerase. Recent data suggest that flow cytometry and molecular markers such as expression of Ki-67, tissue inhibitor of metalloproteinase, and COX-2 also have shown some use in determining malignancy. When pheochromocytomas develop in the MEN syndromes, they rarely are malignant. In contrast, patients with germline SDHB mutations appear to have a higher propensity for extra-adrenal and malignant tumors.⁹²

The Adrenal Incidentaloma

Adrenal lesions discovered during imaging performed for unrelated reasons are referred to as *incidentalomas*. This definition excludes tumors discovered on imaging studies performed for evaluating symptoms of hormone hypersecretion or staging patients with known cancer. The incidence of these lesions identified by CT scans ranges from 0.4 to 4.4%.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of adrenal incidentalomas is shown in Table 38-20. Nonfunctional cortical adenomas account for the majority (36 to 94%) of adrenal incidentalomas in patients without a history of cancer. In a series of patients from the Mayo Clinic, no nonfunctional lesion progressed to cause clinical or biochemical abnormalities. However, other studies indicate that 5 to 20% of patients with apparently nonfunctioning cortical adenomas have underlying, subtle abnormalities of glucocorticoid secretion, and a rare benign-appearing incidentaloma is a cancer.

Table 38-20 Differential Diagnosis of Adrenal Incidentaloma	
Functioning Lesions	Nonfunctioning Lesions
Benign	Benign

Aldosteronoma	Cortical adenoma
Cortisol-producing adenoma	Myelolipoma
Sex-steroid-producing adenoma	Cyst
Pheochromocytoma	Ganglioneuroma
	Hemorrhage
Malignant	Malignant
Adrenocortical cancer	Metastasis
Malignant pheochromocytoma	Adrenocortical cancer

By definition, patients with incidentalomas do not have clinically overt Cushing's syndrome, but subclinical Cushing's syndrome is estimated to occur in approximately 8% of patients. This disorder is characterized by subtle features of cortisol excess, such as weight gain, skin atrophy, facial fullness, diabetes, and hypertension, accompanied by loss of normal diurnal variation in cortisol secretion, autonomous cortisol secretion, and resistance to suppression by dexamethasone. Total cortisol produced and 24-hour urinary cortisol levels may be normal. Examination of the natural history of subclinical Cushing's syndrome indicates that, although most patients remain asymptomatic, some do progress to clinically evident Cushing's syndrome. Furthermore, cases of postoperative adrenal crisis from unrecognized suppression of the contralateral adrenal have been reported, making preoperative identification of this condition imperative, particularly in the era of early discharge following laparoscopic adrenalectomy.⁹⁵

The adrenal is a common site of metastases of lung and breast tumors, melanoma, renal cell cancer, and lymphoma. In patients with a history of nonadrenal cancer and a unilateral adrenal mass, the incidence of metastatic disease has been reported to range from 32 to 73%. Myelolipomas are benign, biochemically nonfunctioning lesions composed of elements of hematopoietic and mature adipose tissue, which are rare causes of adrenal incidentaloma. Other less commonly encountered lesions include adrenal cysts, ganglioneuromas, and hemorrhage.

DIAGNOSTIC INVESTIGATIONS

The diagnostic work-up of an adrenal incidentaloma is aimed at identifying patients that would benefit from adrenalectomy, (i.e. patients with functioning tumors and those tumors at increased risk of being malignant). It is not necessary for asymptomatic patients whose imaging studies are consistent with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease to undergo additional investigations. All other patients should be tested for underlying hormonally active tumors by (a) low-dose (1 mg) overnight dexamethasone suppression test or 24-hour urine cortisol to rule out subclinical Cushing's syndrome and 17-ketosteroids (if sex-steroid excess is suspected), (b) a 24-hour urine collection for catecholamines, metanephrines, VMA, or plasma metanephrine to rule out pheochromocytoma, and (c) in hypertensive patients, serum electrolytes, plasma aldosterone, and plasma renin to rule out an aldosteronoma. Confirmatory tests can be performed based on the results of the initial screening studies.

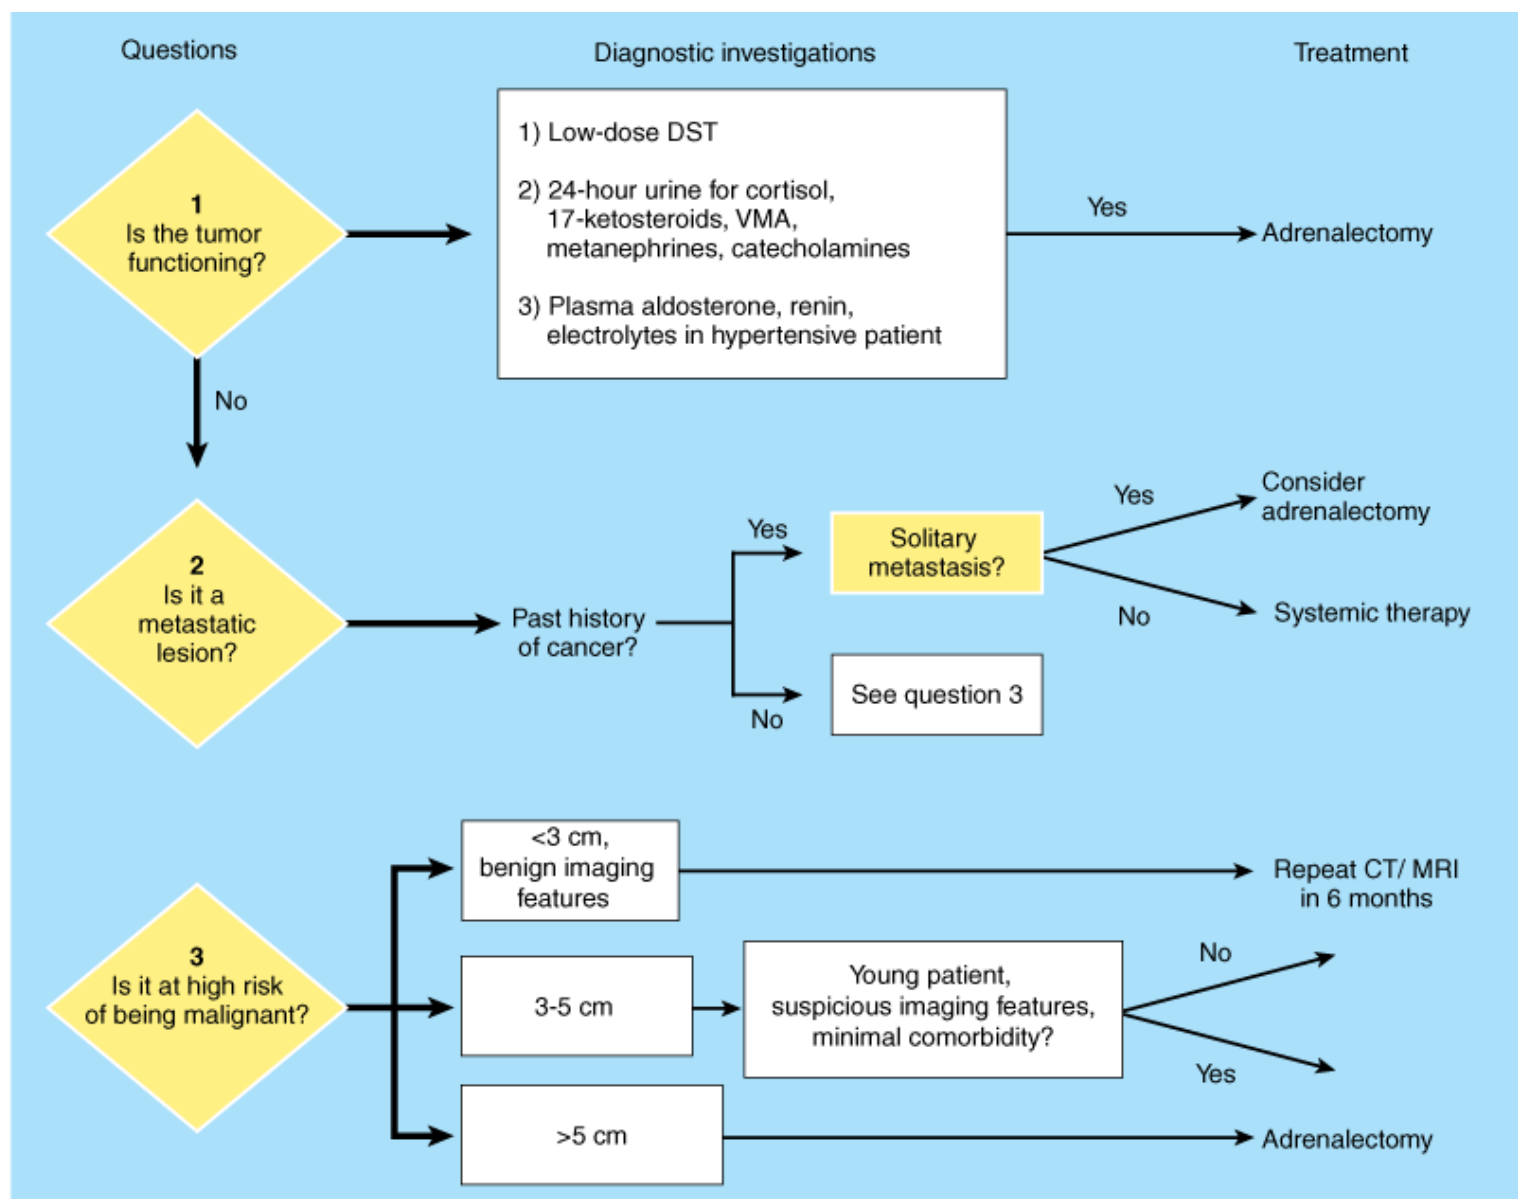

Determination of the malignant potential of an incidentaloma is more difficult. The risk of malignancy in an adrenal lesion is related to its size. Lesions >6 cm in diameter have an approximate risk of malignancy of about 35%.⁸⁸ However, this size cutoff is not absolute because adrenal carcinomas also have been reported in lesions <6 cm. This has led to increased use of the imaging characteristics of incidentalomas to predict malignancy. Benign adrenal adenomas tend to be homogeneous, well encapsulated, and have smooth and regular margins. They also tend to be hypoattenuating lesions (<10 Hounsfield units) on CT scanning. In contrast, adrenal cancers tend to be hyperattenuating (>18 Hounsfield units), inhomogeneous, have irregular borders, and may show evidence of local invasion or adjacent lymphadenopathy. On MRI T₂-weighted imaging, adenomas demonstrate low signal intensity when compared to the liver (adrenal mass to liver ratio <1.4), whereas carcinomas and metastases have moderate intensity (mass to liver ratio 1.2:2.8). Pheochromocytomas are extremely bright with mass to liver ratios >3. Unfortunately, the ranges overlap, and signal intensity is not 100% reliable for determining the nature of the lesion. Radionuclide imaging with NP-59 also has been used

to distinguish between various adrenal lesions, with some investigators suggesting that uptake of NP-59 was 100% predictive of a benign lesion (adenoma) whereas absence of imaging was 100% predictive of a nonadenomatous lesion. However, the technique has not gained widespread acceptance because patients need to be given cold iodine 1 week before the study to prevent thyroid uptake, imaging needs to be delayed by 5 to 7 days after administration of the contrast, and false-positive and false-negative results occur. FNAB cannot be used to distinguish adrenal adenomas from carcinomas. This being said, FNAB is useful in the setting of a patient with a history of cancer and a solitary adrenal mass. The positive predictive value of FNAB in this situation has been shown to be almost 100%, although false-negative rates of up to 33% have been reported. Biopsies usually are performed under CT guidance and appropriate testing to rule out pheochromocytomas should be undertaken before the procedure to avoid precipitating a hypertensive crisis.

MANAGEMENT

An algorithm for the management of patients with incidentalomas is shown in Fig. 38-47. Patients with functional tumors or obviously malignant lesions should undergo adrenalectomy. Operative intervention also is advised in patients with subclinical Cushing's syndrome with suppressed plasma ACTH levels and elevated urinary cortisol levels because these patients are at high risk for progression to overt Cushing's syndrome. Adrenalectomy also should be considered in patients with normal ACTH and urinary free cortisol if they are <50 years old or have recent weight gain, hypertension, diabetes, or osteopenia.

Management algorithm for an adrenal incidentaloma. CT = computed tomography; DST = dexamethasone suppression test; MRI = magnetic resonance imaging; VMA = vanillylmandelic acid.

For nonfunctional lesions, the risk of malignancy needs to be balanced with operative morbidity and mortality. Lesions >6 cm or those with suspicious features on imaging studies such as heterogeneity, irregular capsule, or adjacent nodes should be treated by adrenalectomy. Nonoperative therapy, with close periodic follow-up is advised for lesions <4 cm in diameter with benign imaging characteristics. However, the management of lesions 4 to 6 cm in size with benign imaging features remains controversial (i.e., this group of patients can be treated with observation or surgery). Recommendations vary from various groups of endocrine surgeons regarding this "intermediate" group of patients, with some advising adrenalectomy for tumors at cutoff sizes of 3, 4, or 5 cm. However, several important points must be considered in the management of these patients. First, size criteria for malignancy are not definitive and are derived from a selected series of patients. Second, the actual size of adrenal tumors can be underestimated by at least 1 cm by modalities such as CT and MRI scans, because tumors are larger in a cephalocaudal axis. Third, the natural history of incidentalomas is variable and depends on the underlying diagnosis, age of the study population, and the size of the mass. Older patients are more likely to have nonfunctioning adenomas. Existing data in terms of the long-term behavior of these nonfunctional lesions, although limited, indicate that malignant transformation is uncommon. Furthermore, tumors that increase in size by at least

1 cm over a 2-year follow-up period and those with subtle hormonal abnormalities appear to be more likely to enlarge. Overt hormone overproduction is more likely in tumors >3 cm and those with increased NP-59 uptake. Surgeons are more likely to operate on a 40-year-old patient with a 4-cm lesion, while electing to follow an 80-year-old patient with a similar lesion but multiple concurrent comorbidities. Based on the above considerations, our current size threshold for adrenalectomy with a nonfunctioning homogeneous tumor is 3 to 4 cm in young patients with no comorbidities and 5 cm in older patients with significant comorbidity. Lesions that grow during follow-up also are treated by adrenalectomy. Myelolipomas generally do not warrant adrenalectomy unless there is concern regarding malignancy, which is rare, or bleeding into the lesion, which is more likely in myelolipomas >4 cm in size. These tumors, even when large, can be removed laparoscopically. Resection of solitary adrenal metastases in patients with a history of nonadrenal cancer has been demonstrated to lead to prolonged patient survival. Suspected adrenal metastases also may be resected for diagnosis or for palliation, if large and symptomatic.

Adrenal Insufficiency

Adrenal insufficiency may be primary, resulting from adrenal disease, or secondary, due to a deficiency of ACTH (Table 38-21). The most commonly encountered causes of primary adrenal insufficiency are autoimmune disease, infections, and metastatic deposits. Spontaneous adrenal hemorrhage can occur in patients with fulminant meningococcal septicemia (Waterhouse-Friderichsen syndrome). Bilateral adrenal hemorrhage also can occur secondary to trauma, severe stress, infection, and coagulopathies and, if unrecognized, is lethal. Exogenous glucocorticoid therapy with suppression of the adrenal glands is the most common cause of secondary adrenal insufficiency.

Table 38-21 Etiology of Adrenal Insufficiency	
Primary	Secondary
Autoimmune (autoimmune polyglandular disease type I and II)	Exogenous glucocorticoid therapy
Infectious—TB, fungi, CMV, HIV	Bilateral adrenalectomy
Hemorrhage—spontaneous (Waterhouse-Friderichsen syndrome) and secondary to stress, trauma, infections, coagulopathy, or anticoagulants	Pituitary or hypothalamic tumors
Metastases	Pituitary hemorrhage (postpartum Sheehan's syndrome)
Infiltrative disorders—amyloidosis, hemochromatosis	Transsphenoidal resection of pituitary tumor
Adrenoleukodystrophy	
Congenital adrenal hyperplasia	
Drugs—ketoconazole, metyrapone, aminoglutethimide, mitotane	

CMV = cytomegalovirus; TB = tuberculosis.

SYMPTOMS AND SIGNS

Acute adrenal insufficiency should be suspected in stressed patients with any of the relevant risk factors. It may mimic sepsis, myocardial infarction, or pulmonary embolus and presents with fever, weakness, confusion, nausea, vomiting, lethargy, abdominal pain, or severe hypotension. Chronic adrenal insufficiency, such as that occurring in patients with metastatic tumors, may be more subtle. Symptoms include fatigue, salt-craving, weight loss, nausea, vomiting, and abdominal pain. These patients may appear hyperpigmented from increased secretion of CRH and ACTH, with increased α -melanocyte-stimulating hormone side-products.

DIAGNOSTIC STUDIES

Characteristic laboratory findings include hyponatremia, hyperkalemia, eosinophilia, mild azotemia, and fasting or reactive

hypoglycemia. The peripheral blood smear may demonstrate eosinophilia in approximately 20% of patients. Adrenal insufficiency is diagnosed by the ACTH stimulation test. ACTH (250 µg) is infused intravenously, and cortisol levels are measured at 0, 30, and 60 minutes. Peak cortisol levels <20 µg/dL suggest adrenal insufficiency. ACTH levels also allow primary insufficiency to be distinguished from secondary causes. High ACTH levels with low plasma cortisol levels are diagnostic of primary adrenal insufficiency.

TREATMENT

Treatment must be initiated based on clinical suspicion alone, even before test results are obtained or the patient is unlikely to survive. Management includes volume resuscitation with at least 2 to 3 L of a 0.9% saline solution or 5% dextrose in saline solution. Blood should be obtained for electrolyte (decreased Na⁺ and increased K⁺) and glucose (low) and cortisol (low) levels, ACTH (increased in primary and decreased in secondary), and quantitative eosinophilic count. Dexamethasone (4 mg) should be administered intravenously. Hydrocortisone (100 mg IV every 8 hours) also may be used, but it interferes with testing of cortisol levels. Once the patient has been stabilized, underlying conditions such as infection should be sought, identified, and treated. The ACTH stimulation test should be performed to confirm the diagnosis. Glucocorticoids can then be tapered to maintenance doses (oral hydrocortisone 15 to 20 mg in the morning and 10 mg in the evening). Mineralocorticoids (fludrocortisone 0.05 to 0.1 mg daily) may be required once the saline infusions are discontinued.

Adrenal Surgery

CHOICE OF PROCEDURE

Adrenalectomy may be performed via an open or laparoscopic approach. In either approach, the gland may be approached anteriorly, laterally, or posteriorly via the retroperitoneum. The choice of approach depends on the size and nature of the lesion and expertise of the surgeon. Laparoscopic adrenalectomy has rapidly become the standard procedure of choice for the excision of most benign appearing adrenal lesions <6 cm in diameter. The role of laparoscopic adrenalectomy in the management of adrenocortical cancers is controversial. The data with respect to local tumor recurrence and intra-abdominal carcinomatosis from laparoscopic adrenalectomy for malignant adrenal tumors that were not appreciated as such, preoperatively or intraoperatively, are conflicting. Although laparoscopic adrenalectomy appears to be feasible and safe for solitary adrenal metastasis⁹⁶ (provided there is no local invasion and the tumor can be resected intact), open adrenalectomy or laparoscopic-assisted open adrenalectomy is the safest option for suspected or known adrenocortical cancers and malignant pheochromocytomas. Technical considerations and surgeon experience rather than absolute tumor size usually determine the size threshold for laparoscopic resection. Hand-assisted laparoscopic adrenalectomy may provide a bridge between laparoscopic adrenalectomy and conversion to an open procedure. There have been no randomized trials directly comparing open vs. laparoscopic adrenalectomy. However, studies have shown that laparoscopic adrenalectomy is associated with decreased blood loss, postoperative pain, and narcotic use; reduced length of hospital stay; and faster return to work.

LAPAROSCOPIC ADRENALECTOMY

The procedure is performed under general anesthesia. Arterial lines are used routinely and central lines are necessary for patients in whom massive fluid shifts are anticipated (e.g., those with large, active pheochromocytomas). A nasogastric tube and Foley catheter are recommended. Routine preoperative antibiotics are not needed, except in patients with Cushing's syndrome. The adrenals can be removed laparoscopically via a transabdominal (anterior or lateral) or retroperitoneal (lateral or posterior) approach. The lateral approach is preferred by most laparoscopic surgeons and uses gravity to aid retraction of surrounding organs. Patients, however, need to be repositioned for a bilateral procedure. The anterior transabdominal approach offers the advantage of a conventional view of the abdominal cavity and allows a bilateral adrenalectomy to be performed without the necessity of repositioning the patient. The lateral transabdominal approach is widely used and described in detail below in Lateral Transabdominal Approach.

Lateral Transabdominal Approach

The patient is placed in the lateral decubitus position and the operating table is flexed at the waist to open the space between the lower rib cage and the iliac crest (Fig. 38-48). The surgeon and assistant both stand on the same side, facing the front of the patient. Pneumoperitoneum is created using a Veress needle or insufflation via a Hasson port. In general, four 10-mm trocars are placed between the midclavicular line medially and anterior axillary line laterally, one to two fingerbreadths below the costal margin (see Fig. 38-48), although additional ports may be placed, if needed. A 30° laparoscope is inserted through the second or midclavicular port. Most of the dissection is carried out via the two most lateral ports. However, the instruments and ports may be changed to provide optimum exposure, as needed.

Fig. 38-48.

Positioning of the patient and placement of trocars for a laparoscopic adrenalectomy. Four trocars are placed from the midclavicular to the anterior axillary line.

For a right adrenalectomy, a fan retractor is inserted through the most medial port to retract the liver. An atraumatic grasper and an L-hook cautery are inserted via the two lateral ports for the dissection. The right triangular ligament is divided and the liver is rotated medially (Fig. 38-49A). Rarely, the hepatic flexure of the colon may need mobilization during a right adrenalectomy. The right kidney is identified visually and by palpation with an atraumatic grasper. The adrenal gland is identified on the superomedial aspect of the kidney. Gerota's fascia is incised with the hook cautery. Dissection of the adrenal is started superomedially and then proceeds inferiorly, dissecting around the adrenal in a clockwise manner. The periadrenal tissues are grasped or moved with a blunt grasper to facilitate circumferential dissection. The right adrenal vein is identified at its junction with the IVC, ligated with clips, and divided using endoscopic scissors. Alternatively, a vascular stapler may be used to divide the vein endoscopically. There may be a second adrenal vein on the right. Generally, two clips are left on the vena cava side. Although early identification of the adrenal vein is helpful to facilitate mobilization and prevent injury, it can be dissected whenever it is safe to do so. Early ligation of the adrenal vein makes it easier to mobilize the gland but may make subsequent dissection more difficult due to venous congestion. The arterial branches to the adrenal gland can be electrocoagulated if small or clipped and divided.

Technique of laparoscopic adrenalectomy. Exposure of the right adrenal is facilitated by division of the triangular ligament (**A**) and dissection and reflection of the spleen and tail of the pancreas aids in identifying the left adrenal (**B**).

For a left adrenalectomy, the fan retractor is used to retract the spleen. The splenic flexure is mobilized early and the lateral attachments to the spleen and the tail of the pancreas are divided using the electrocautery (Fig. 38-49B). Gravity allows the spleen and the pancreatic tail to fall medially. The remainder of the dissection proceeds similarly to that described for the right adrenal. In addition to the adrenal vein, the inferior phrenic vein, which joins the left adrenal vein medially, also needs to be dissected, doubly clipped, and divided. As with the right adrenal vein, the left-sided veins also can be divided with a vascular stapler. Once the dissection is complete, the area of the adrenal bed can be irrigated and suctioned. A drain is rarely necessary. The gland is placed in a nylon specimen bag, which is brought out via one of the ports after morcellation, if necessary.

Posterior Retroperitoneal Approach

The retroperitoneal approach provides a more direct access to the adrenal gland and avoids abdominal adhesions in patients who have had previous abdominal surgery. Furthermore, bilateral adrenalectomy can be performed without repositioning the patient. Intraoperative ultrasound is helpful for identifying the adrenal but the dissection and exposure is more difficult because the working space is limited. This makes vascular control difficult and also renders it unsuitable for large (>5 cm) lesions. This technique is being increasingly used for small adenomas causing hyperaldosteronism.

The patient is placed in the prone-jackknife position, and the operating table is flexed at the waist to open the space between the posterior costal margin and the pelvis. Palpation is used to identify the position of the twelfth rib. Percutaneous ultrasound is performed to determine the outline of the underlying kidney and adrenal. When done laparoscopically, the surgeon stands on the side of the adrenal to be removed and the assistant stands on the opposite side. A 1.5-cm incision is placed 2 cm inferior and parallel to the twelfth rib, laterally at the level of the inferior pole of the kidney. Gerota's space is entered under direct vision using a 12-mm direct viewing trocar with a 0° laparoscope through the muscle layers of the posterior abdominal wall. Alternatively, blunt dissection with the surgeon's finger also can identify the space behind Gerota's fascia. The trocar is then replaced by a dissecting balloon, which is manually inflated using a hand pump under direct vision through the laparoscope. A 12-mm trocar is then reinserted into this space and CO₂ is insufflated to 12 to 15 mmHg pressure. The 0° laparoscope is replaced by a 45° laparoscope. Two additional 5- or 10-mm trocars are placed, one each on either side of the first port. Laparoscopic ultrasound then is used to help locate the adrenal gland and vessels. The adrenal dissection is begun at the superior pole and then proceeds to the lateral and inferior aspect. The medial dissection usually is performed last, and the vessels are identified and divided as described in Lateral Transabdominal Approach above.

OPEN ADRENALECTOMY

Open adrenalectomy may be performed via four approaches, each with specific advantages and disadvantages. The anterior approach allows examination of the abdominal cavity and resection of bilateral tumors via a single incision. The posterior approach avoids the morbidity of a laparotomy incision, especially in patients with cardiopulmonary disease and those prone to wound complications (Cushing's syndrome) and avoids abdominal adhesions in patients who have undergone previous abdominal surgery. Recovery time is also quicker and hospitalization shorter. However, the retroperitoneal exposure is difficult, particularly in obese patients and the small working space makes it unsuitable for tumors >6 cm in diameter. The lateral approach is best for obese patients and for large tumors because it provides a bigger working space. The thoracoabdominal approach is most useful for en bloc resection of large (>10 cm), malignant lesions. However, it is associated with significant morbidity and should be used selectively.

Anterior Approach

The adrenals may be removed via a midline incision or bilateral subcostal incision (Fig. 38-50). The former allows adequate infraumbilical exposure for examination of extra-adrenal tumors, whereas the latter provides better superior and lateral exposure. For the right side, the hepatic flexure of the colon is mobilized inferiorly, the triangular ligament is incised to retract the liver medially and superiorly. A generous Kocher maneuver is used to mobilize the duodenum anteriorly and expose the retroperitoneal fat and the IVC (Fig. 38-51A). Gerota's fascia is incised, and the gland is freed of surrounding fibro-fatty tissue and the kidney inferiorly. The lateral and superior surfaces usually are mobilized first. Then, the short, right adrenal vein is dissected, ligated, and divided, taking care not to injure the hepatic veins and IVC. On the left side, the adrenal is located cephalad to the pancreatic tail and just lateral to the aorta. For large tumors, the adrenal is best approached by medial visceral rotation to mobilize the spleen, colon, and pancreas toward the midline (Fig. 38-51B). An alternative approach is to enter the lesser sac by division of the gastrocolic ligament. The pancreas is mobilized superiorly by incision of its inferior peritoneal attachments, thus exposing the left kidney and adrenal. The gland is then mobilized as on the right side.

Technique of open adrenalectomy. Exposure of the right adrenal is facilitated by a Kocher maneuver to mobilize the duodenum and upward retraction of the liver (**A**). The left adrenal can be exposed by medial visceral rotation of the spleen and pancreas (**B**). v. = vein.

Posterior Approach

The patient is placed prone on the operating table, similar to the laparoscopic approach. A hockey stick or curvilinear incision may be used, and extended through the latissimus dorsi and sacrospinal fascia. The twelfth rib generally is excised at its base and the eleventh rib is retracted superiorly to reveal the pleura and the lateral arcuate ligament of the liver on the right side. The pleura also

is mobilized cephalad, and the adrenal and kidney are identified. The superior aspect of the gland is dissected first, and the superior vessels are identified and ligated. This prevents superior retraction of the adrenal gland. The remainder of the gland is then dissected and the adrenal gland and tumor removed. The resulting space generally is filled with perinephric fat and closed in layers. A chest x-ray is obtained postoperatively to rule out a pneumothorax.

Lateral Approach

The patient is placed in a lateral position with the table flexed and an incision is made between the eleventh and twelfth ribs or subcostally. The dissection then is performed as indicated previously in Anterior Approach.

COMPLICATIONS OF ADRENAL SURGERY

Patients with Cushing's syndrome are more prone to infectious (incisional and intra-abdominal abscess) and thrombotic complications. Creation of pneumoperitoneum may result in injury to various organs from Veress needle and trocar insertion, subcutaneous emphysema, pneumothorax, and hemodynamic compromise. Excessive retraction and dissection may lead to bleeding from injury to the IVC and renal vessels, or from injury to surrounding organs such as the liver, pancreas, spleen, and stomach. Postoperative hemodynamic instability may be evident in patients with pheochromocytomas, and patients are at risk of adrenal insufficiency after bilateral adrenalectomy and sometimes after unilateral adrenalectomy (unrecognized Cushing's syndrome or, very rarely, Conn's syndrome). Long-term morbidity results mainly from injury to nerve roots during trocar insertion, which can lead to chronic pain syndromes or muscle weakness, although this is more of an issue in case of open procedures.

Approximately 30% of patients who undergo bilateral adrenalectomy for Cushing's disease are at risk of developing Nelson's syndrome from progressive growth of the pre-existing pituitary tumor. This leads to increased ACTH levels, hyperpigmentation, visual field defects, headaches, and extraocular muscle palsies. Transsphenoidal pituitary resection is the initial mode of therapy and external beam radiotherapy is used in patients with residual tumor or extrasellar invasion.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 39. Pediatric Surgery >

KEY POINTS

1. In infants with Bochdalek type congenital diaphragmatic hernia the severity of pulmonary hypoplasia and the resultant pulmonary hypertension are key determinants of survival. Barotrauma and hypoxia should be avoided.
2. During initial management of an infant with esophageal atresia and distal tracheoesophageal fistula, every effort should be made to avoid distending the gastrointestinal tract, especially when using mechanical ventilation. The patient should be evaluated for components of the VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, limb) anomalies. Timing and extent of surgery is dictated by the stability of the patient.
3. Although malrotation with midgut volvulus occurs most commonly within the first few weeks of life, it should always be considered in the differential diagnosis in a child with bilious emesis. Volvulus is a surgical emergency; therefore in a critically ill child, prompt surgical intervention should not be delayed for any reason.
4. When evaluating a newborn infant for vomiting, it is critical to distinguish between proximal and distal causes of intestinal obstruction utilizing both prenatal and postnatal history, physical examination and abdominal radiographs.
5. Risk factors for necrotizing enterocolitis (NEC) include prematurity, formula feeding, bacterial infection, and intestinal ischemia. Critical to the management of infants with advanced (Bell stage III) or perforated NEC is timely and adequate source control of peritoneal contamination. Early sequelae of NEC include perforation, sepsis, and death. Later sequelae include short-bowel syndrome and stricture.
6. In patients with intestinal obstruction secondary to Hirschsprung's disease a leveling ostomy or endorectal pull through should be performed using ganglionated bowel, proximal to the transition zone between ganglionic and aganglionic intestine.
7. Prognosis of infants with biliary atresia is directly related to age at diagnosis and timing of portoenterostomy. Infants with advanced age at the time of diagnosis or infants who fail to demonstrate evidence of bile drainage after portoenterostomy usually require liver transplantation.
8. Infants with omphaloceles have greater associated morbidity and mortality than infants with gastroschisis due to a higher incidence of congenital anomalies and pulmonary hypoplasia. Gastroschisis can be associated with intestinal atresia, but not with other congenital anomalies. An intact omphalocele can be repaired electively, while gastroschisis requires urgent intervention to protect the exposed intestine.
9. Prognosis for children with Wilms' tumor is defined by the stage of disease at the time of diagnosis and the histologic type (favorable vs. unfavorable). Preoperative chemotherapy is indicated for bilateral involvement, a solitary kidney, or tumor in the inferior vena cava above the hepatic veins. Gross tumor rupture during surgery automatically changes the stage to 3 (at a minimum).
10. Injury is the leading cause of death in children older than 1 year of age. Blunt mechanisms account for the majority of

pediatric injuries. The central nervous system is the most commonly injured organ system and the leading cause of death in injured children.

INTRODUCTION

In his classic 1953 textbook titled *The Surgery of Infancy and Childhood*, Dr. Robert E. Gross summarized the essential challenge of pediatric surgery as follows: "Those who daily operate on adults, even with the greatest of skill, are sometimes appalled—or certainly are not at their best—when called upon to operate on and care for a tiny patient. Something more than diminutive instruments or scaled-down operative manipulations are necessary to do the job in a suitable manner." To this day, surgical residents and other trainees often approach the pediatric surgical patient with the same mix of fear and anxiety, yet generally complete their pediatric surgical experience with genuine respect for the resilience of children and for the precision required in their care both in the operating room and during the perioperative period. Over the decades, the specialty of pediatric surgery has evolved considerably. Our ability to care for the smallest of patients with surgical disorders has increased dramatically, so that even in utero surgery is now an option in certain circumstances. Similarly, our mastery of the pathophysiology of the diseases that pediatric surgeons face has increased to the point that many of these diseases are now understood at the level of molecular or cellular signaling pathways. Pediatric surgery provides the opportunity to intervene positively in a wide array of diseases and to exert a long-lasting impact on the lives of children and their grateful parents. The scope of diseases encountered in the standard practice of pediatric surgery is immense, with patients ranging in age from fetus to 18-year-olds, and includes anomalies of the head and neck, thoracic, GI, and genitourinary areas. This chapter is not designed to cover the entire spectrum of diseases a pediatric surgeon is expected to master; rather, it presents a synopsis of a handful of pediatric surgical conditions that a practicing general surgeon is likely to encounter over the course of his or her career.

PEDIATRIC SURGICAL THEMES: PITFALLS AND PEARLS

This chapter focuses on the unique considerations in the diagnosis and management of surgical diseases in the pediatric population. Many surgical trainees approach the surgical care of children with some degree of fear and trepidation. As any pediatric caregiver will attest, the surgical management of infants and children requires careful and professional interactions with their parents. The stress that the parents of sick children experience in the hospital setting can, at times, be overwhelming. It is due, in part, to the uncertainty regarding a particular prognosis, the feeling of helplessness that evolves when one is unable to care for one's child, and, in certain cases, the guilt or remorse that one feels for not seeking medical care earlier or for consenting to a particular procedure. Management of the sick child and his or her family therefore requires not only a certain set of skills but also a unique knowledge base. This section is included to summarize some important general principles in accomplishing this task.

1. Children are not little adults, but they are little people.

In practical terms, this often-heard refrain implies that children have unique fluid, electrolyte, and medication needs. Thus, the dosage of medications and the administration of IV fluids should be based on the child's weight. The corollary of this point is that infants and young children are extremely sensitive to perturbations in their normal physiology and, because of this, may be easily tipped into fluid overload or dehydration.

2. Children whisper before they shout.

Children with surgical diseases can deteriorate very quickly. But before they deteriorate, they often manifest subtle physical findings. These findings—referred to as *whispers*—may include signs such as tachycardia, bradycardia, hypothermia, fever, recurrent emesis, or feeding intolerance. Meticulous attention to these subtle findings may

unmask the development of potentially serious, life-threatening physiologic disturbances.

3. Always listen to the mother and the father.

Surgical diseases in children can be very difficult to diagnose because children are often minimally communicative and the information they do communicate may be confusing, conflicting, or both. In all cases, it is wise to listen to the child's parents, who have closely observed their child and know him or her best.

4. Children experience pain after surgery.

Careful and adequate pain management must accompany surgical interventions.

5. Pediatric tissue must be handled delicately.

GENERAL CONSIDERATIONS

Fluid and Electrolyte Balance

In management of the pediatric surgical patient, an understanding of fluid and electrolyte balance is critical, because the margin between dehydration and fluid overload is rather small. This is particularly true in infants, who have little reserve. Failure to pay meticulous attention to their hydration status can result in significant fluid overload or dehydration. Several surgical diagnoses, such as gastroschisis and short-bowel syndrome, are characterized by a predisposition to fluid loss. Others require judicious restoration of intravascular volume to prevent cardiac failure, as is the case in patients with congenital diaphragmatic hernia and associated pulmonary hypertension. The infant's physiologic day is approximately 8 hours in duration. Accordingly, careful assessment of the individual patient's fluid balance, including fluid intake and output for the previous 8 hours, is essential to prevent dehydration or fluid overload. Clinical signs of dehydration include tachycardia, decreased urine output, reduced skin turgor, a depressed fontanelle, absent tears, lethargy, and poor feeding. Fluid overload is often manifested by a new requirement for oxygen and the onset of respiratory distress, tachypnea, and tachycardia. The physical assessment of the fluid status of each child must include a complete head-to-toe evaluation, with emphasis on determining whether perturbations in normal physiology are present.

At 12 weeks' gestation, the total body water of a fetus is approximately 94 mL/kg. By the time the fetus reaches full term, the total body water has decreased to approximately 80 mL/kg. Total body water drops an additional 5% within the first week of life, and by 1 year of life, total body water approaches adult levels, 60 to 65 mL/kg. Parallel to the drop in total body water is the reduction in extracellular fluid. These changes are accelerated in the preterm infant, who may face additional fluid losses due to coexisting congenital anomalies or surgery. The volume of normal daily maintenance fluids for most children can be estimated using the following formula: 100 mL/kg for the first 10 kg, plus 50 mL/kg for 11 to 20 kg, plus 25 mL/kg for each additional kilogram of body weight thereafter. Because IV fluid orders are written as milliliters per hour, this can be conveniently converted to 4 mL/kg per hour up to 10 kg, plus 2 mL/kg per hour for 11 to 20 kg, and an additional 1 mL/kg per hour for each additional kilogram of body weight thereafter. For example, a 26-kg child has an estimated maintenance fluid requirement of $(10 \times 4) + (10 \times 2) + (6 \times 1) = 66$ mL/h in the absence of massive fluid losses or shock. A newborn infant with gastroschisis will manifest significant evaporative losses from the exposed bowel, so that fluid requirements will be in the range of 150 to 180 mL/kg per day.

Precise management of a neonate's fluid status requires an understanding of changes in the glomerular filtration rate (GFR) and tubular function of the kidney. The full-term newborn's GFR is approximately 21 mL/min per square meter compared with 70 mL/min per square meter in an adult. Within the first year GFR increases steadily to the point that it essentially reaches adult levels by the end of the first year of life. The capacity to concentrate urine is very limited in preterm and term

infants. In comparison with an adult who can concentrate urine to 1200 mOsm/kg, infants can concentrate urine at best to 600 mOsm/kg. Although infants are capable of secreting antidiuretic hormone, the aquaporin water channel-mediated osmotic water permeability of the infant's collecting tubules is severely limited compared with that of an adult, which leads to insensitivity to antidiuretic hormone.

Sodium requirements range from 2 mEq/kg per day in term infants to 5 mEq/kg per day in critically ill preterm infants as a consequence of salt wasting. Potassium requirements range from 1 to 2 mEq/kg per day. Calcium and magnesium supplementation of IV fluids is essential to prevent laryngospasm, dysrhythmias, and tetany.

Acid-Base Equilibrium

Acute metabolic acidosis usually implies inadequate tissue perfusion and is a serious disorder in children. Potentially life-threatening causes that are specific for the pediatric population must be sought. They include intestinal ischemia from necrotizing enterocolitis (in the neonate), midgut volvulus, and incarcerated hernia. Other causes include chronic bicarbonate loss from the GI tract and acid accumulation as in chronic renal failure. Respiratory acidosis implies hypoventilation, the cause of which should be apparent. Treatment of acute metabolic acidosis should be aimed at restoring tissue perfusion by addressing the underlying abnormality first. For severe metabolic acidemia in which the serum pH is <7.25 , sodium bicarbonate should be administered using the following guideline: $\text{base deficit} \times \text{weight in kilograms} \times 0.5$ (in newborns). The last factor in the equation should be 0.4 for smaller children and 0.3 for older children. The dose should be diluted to a concentration of 0.5 mEq/mL, because full-strength sodium bicarbonate is hyperosmolar. One half the corrective dose is given, and the serum pH is measured again. During cardiopulmonary resuscitation, one half the corrective dose can be given as an IV bolus and the other half given slowly IV.

Respiratory alkalosis is usually caused by hyperventilation, which is readily correctable. Metabolic alkalosis most commonly implies gastric acid loss, as in the child with pyloric stenosis, or aggressive diuretic therapy. In the child with gastric fluid loss, administration of IV fluids with 5% dextrose, 0.5% normal saline, and 20 mEq KCl/L usually corrects the alkalosis. Potassium, however, should not be administered until adequate urine output has been established.

Blood Volume and Blood Replacement

Criteria for blood transfusion in infants and children remain poorly defined. The decision to transfuse a critically ill pediatric patient may depend on a number of clinical features that include the patient's age; the primary diagnosis; the presence of ongoing bleeding, coagulopathy, hypoxia, hemodynamic compromise, lactic acidosis, and/or cyanotic heart disease; and the overall severity of the illness. A recent survey of transfusion practices among pediatric intensivists showed that the baseline hemoglobin levels that would prompt them to recommend red blood cell (RBC) transfusion ranged from 7 to 13 g/dL. Patients with cyanotic heart disease are often transfused to higher hemoglobin values, although the threshold for transfusion in this population remains to be defined. To decrease the need for transfusion, other strategies have been considered. Studies in both critically ill adults and neonates have shown that administration of erythropoietin decreases RBC transfusion requirements. In general, there is a trend toward an avoidance of the use of RBC products whenever possible, because current studies suggest that lower hemoglobin concentrations are well tolerated by many groups of patients and that administration of RBCs may have unintended negative consequences. In addition, there is increasing evidence that transfusion of packed red blood cells (PRBCs) may have adverse effects on the host immune system in both children and adults.

A useful guideline for estimating blood volume for the newborn infant is approximately 80 mL/kg of body weight. When PRBCs are required, the transfusion requirement is usually administered in 10 mL/kg increments, which is roughly equivalent to a 500-mL transfusion for a 70-kg adult. The following formula may be used to determine the volume (in milliliters) of PRBCs to be transfused:

(Target hematocrit – current hematocrit) × weight (kg) × 80/65
(65 represents the estimated hematocrit of a unit of PRBCs). One transfusion from one donor is preferable to many smaller-volume transfusions. In the child, coagulation deficiencies may rapidly assume clinical significance after extensive blood transfusion. It is advisable to have fresh-frozen plasma and platelets available if >30 mL/kg has been transfused. Plasma is given in a dose of 10 to 20 mL/kg and platelets are given in a dose of 1 unit/5 kg. Each unit of platelets consists of 40 to 60 mL of fluid (plasma plus platelets). After transfusion of PRBCs to neonates with tenuous fluid balance, a single dose of a diuretic (such as furosemide 1 mg/kg) may help to facilitate excretion of the extra fluid load.

Enteral and Parenteral Nutrition

The nutritional requirements of the surgical neonate must be met for the child to grow and for surgical wounds to heal. If inadequate protein and carbohydrate calories are given, the child may not only fail to recover from surgery but may also exhibit growth failure and impaired development of the central nervous system. In general, the adequacy of growth must be assessed frequently by determining both total body weight and head circumference. Neonates with gastroschisis, intestinal atresia, or intestinal insufficiency from other causes, such as necrotizing enterocolitis, are particularly predisposed to protein-calorie malnutrition. The protein and caloric requirements for the surgical neonate are shown in Table 39-1.

Table 39-1 Nutritional Requirements for the Pediatric Surgical Patient		
Age	Calories (kcal/kg per day)	Protein (g/kg per day)
0–6 mo	100–120	2
6 mo–1 y	100	1.5
1–3 y	100	1.2
4–6 y	90	1
7–10 y	70	1
11–14 y	55	1
15–18 y	45	1

Nutrition can be provided via either the enteral or parenteral route. Whenever possible, the enteral route is preferred, because it not only promotes the growth and function of the GI system but also ensures that the infant learns how to feed. Various enteral feeding preparations are available; these are listed in Table 39-2. The choice of formula is based on the individual clinical state of the child. Pediatric surgeons are occasionally faced with situations in which oral feeding is not possible. This problem can be seen in the extremely premature infant who has not yet developed the required feeding skills or in the infant with concomitant craniofacial anomalies that impair sucking, for example. In these instances, enteral feeds can be administered via either a nasojejunal or a gastrostomy tube.

Table 39-2 Formulas for Pediatric Surgical Neonates				
Formula	Calories (kcal/mL)	Protein (g/mL)	Fat (g/mL)	Carbohydrate (g/mL)

When the GI tract cannot be used because of mechanical, ischemic, inflammatory, or functional disorders, parenteral alimentation must be given. Prolonged parenteral nutrition is delivered via a central venous catheter. Peripheral IV alimentation can be given using less concentrated but greater volumes of solutions. Long-term parenteral nutrition should include supplemental copper, zinc, and iron to prevent the development of trace metal deficiencies. A major complication of long-term TPN is the development of parenteral nutrition–associated cholestasis, which can eventually progress to liver failure. To prevent this major complication, concomitant enteral feedings must be instituted as soon as possible. When proximal stomas are in place, GI continuity should be restored as soon as possible. When intestinal insufficiency is associated with dilatation of the small intestine, tapering or intestinal lengthening procedures may be beneficial. Other strategies to minimize the development of TPN-related liver disease include meticulous catheter care to avoid infection, which increases cholestatic symptoms, aggressive treatment of any infection, and early cycling of parenteral nutrition in older children who can tolerate not receiving continuous dextrose solution for a limited period. Preliminary evidence in a study of 18 patients suggests the possibility that substituting omega-3 fish oil lipid emulsion for the standard soybean-based emulsions in parenteral nutritional formulas may prevent the development of TPN-related cholestasis and reverse the effects of established liver disease.

Venous Access

Obtaining reliable vascular access in an infant or child is a major responsibility of the pediatric surgeon. The goal should always be to place the catheter in the least invasive, least risky, and least painful manner, and in a location that is most accessible and facilitates long-term catheter use. In infants, central venous access may be established using a cutdown approach, either in the antecubital fossa, external jugular vein, facial vein, or proximal saphenous vein. If the internal jugular vein is used, care is taken to prevent venous occlusion. In infants >2 kg and in older children, percutaneous access of the subclavian, internal jugular, or femoral vein is possible in most cases, and central access is achieved using the Seldinger technique. The catheters are tunneled to an exit site separate from the venotomy site. Where available, peripherally inserted central catheter lines may be placed, typically via the antecubital fossa. Regardless of whether the catheter is placed by a cutdown approach or percutaneously, a chest radiograph to confirm the central location of the catheter tip and to exclude the presence of a pneumothorax or hemothorax is mandatory. When discussing the placement of central venous catheters with parents, it is important to note that the complication rate for central venous lines in children is high. The incidence of

catheter-related sepsis or infection approaches 10% in many series. Superior or inferior vena caval occlusion is a significant risk after the placement of multiple lines, particularly in the smallest premature patients.

Thermoregulation

Careful regulation of the ambient environment of infants and children is crucial, because these patients are extremely thermolabile. Premature infants are particularly susceptible to changes in environmental temperature. Because they are unable to shiver and lack stores of fat, their potential for thermogenesis is impaired. This is compounded by the administration of anesthetic and paralyzing agents. Because these patients lack adaptive mechanisms to cope with the environment, the environment must be regulated. Attention to heat conservation during transport of the infant to and from the operating room is essential. Transport systems incorporating heating units are necessary for premature infants. In the operating room, the infant is kept warm by the use of overhead heating lamps, a heating blanket, warming of inspired gases, and coverage of the extremities and head with occlusive materials. During abdominal surgery, extreme care is taken to avoid wet and cold drapes. All fluids used to irrigate the chest or abdomen must be warmed to body temperature. The use of laparoscopic approaches for abdominal operations may result in more stable thermoregulation, due to decreased heat loss from the smaller wound. Constant monitoring of the child's temperature is critical in a lengthy procedure, and the surgeon should continuously communicate with the anesthesiologist regarding the temperature of the patient. The development of hypothermia in infants and children can result in cardiac arrhythmias or coagulopathy. These potentially life-threatening complications can be avoided by careful attention to thermoregulation.

Pain Control

All children, including neonates, experience pain. Therefore, the careful recognition and management of pediatric pain represents an important component of the perioperative management of all pediatric surgical patients. A range of pain management options are available that can improve the child's as well as the parents' comfort. The use of a pacifier, which may be dipped in sucrose, has been shown to decrease crying time and neonatal pain scores after minor procedures. Additional analgesic modalities include the use of topical anesthetic ointment (cream containing a eutectic mixture of local anesthetics) and the use of regional anesthesia, such as caudal blocks for hernias and epidural or incisional catheter infusions (On-Q system) for large abdominal or thoracic incisions. For situations in which more pain is expected, IV narcotic agents should be used. Morphine and fentanyl have an acceptable safety margin and can be administered judiciously to neonates and children. A recent randomized trial showed that administration of a morphine infusion in neonates receiving artificial ventilation decreased the incidence of intraventricular hemorrhage by 50%. In neonatal surgical patients who have been given large concentrations of narcotics over a prolonged period, transient physical dependence should not only be expected but anticipated. When narcotics are discontinued, symptoms of narcotic withdrawal may develop, including irritability, restlessness, episodes of hypertension, and tachycardia. Early recognition of these signs is essential, as is timely treatment using a thoughtful weaning schedule, appropriate assessment criteria, and administration of naloxone and other agents. In the postoperative period, patient-controlled analgesia is another excellent method of pain control. Additional means of achieving adequate pain control in children include the use of epidural analgesia and paraspinal blockade, which can be commenced at the time of surgery. By ensuring that the pediatric surgical patient has adequate analgesia, the surgeon ensures that the patient receives the most humane and thorough treatment, and provides important reassurance to all other members of the health care team and to the family that pain control is a very high priority.

NECK MASSES

The management of neck masses in children is determined by their location and the length of time that they have been present. Neck lesions are found in either the midline or lateral compartments. Midline masses include thyroglossal duct remnants, thyroid masses, thymic cysts, and dermoid cysts. Lateral lesions include branchial cleft remnants, cystic hygromas, vascular malformations, salivary gland tumors, torticollis, and lipoblastomas (a rare benign mesenchymal tumor of embryonal fat occurring in infants and young children). Enlarged lymph nodes and rare malignancies such as rhabdomyosarcoma can occur either in the midline or laterally.

Lymphadenopathy

The most common cause of a neck mass in a child is an enlarged lymph node, which typically can be found laterally or in the midline. The patient is usually referred to the pediatric surgeon for evaluation after the mass has been present for several weeks. A detailed history taking and physical examination often help determine the likely cause of the lymph node and the need for excisional biopsy. Enlarged tender lymph nodes are usually the result of a bacterial infection (staphylococcal or streptococcal). Treatment of the primary cause (e.g., otitis media or pharyngitis) with antibiotics often is all that is necessary. When the involved nodes become fluctuant, however, incision and drainage are indicated. In many North American institutions, there has been an increasing prevalence of methicillin-resistant *Staphylococcus aureus* infection of the skin and soft tissues, leading to increased staphylococcal lymphadenitis in children. More chronic forms of lymphadenitis, including infection with atypical mycobacteria, as well as cat-scratch fever, are diagnosed based on serologic findings or the results of excisional biopsy. The lymphadenopathy associated with infectious mononucleosis can be diagnosed based on serologic testing. When the neck nodes are firm and fixed, and other enlarged nodes are present in the axillae or groin, or the history suggests lymphoma, excisional biopsy is indicated. In these cases, it is essential to obtain a chest radiograph to look for a mediastinal mass. Significant mediastinal load portends cardiorespiratory collapse due to loss of venous return and compression of the tracheobronchial tree if general anesthesia is induced. Accordingly, in such cases biopsies should be performed under local anesthesia.

Thyroglossal Duct Remnants

PATHOLOGY AND CLINICAL MANIFESTATIONS

The thyroid gland buds off the foregut diverticulum at the base of the tongue in the region of the future foramen cecum at 3 weeks of embryonic life. As the fetal neck develops, the thyroid tissue becomes more anterior and caudad until it rests in its normal position. The "descent" of the thyroid is intimately connected with the development of the hyoid bone. Residual thyroid tissue left behind during the migration may persist and subsequently present in the midline of the neck as a thyroglossal duct cyst. The mass is most commonly appreciated in the 2- to 4-year-old child when the baby fat disappears and irregularities in the neck become more readily apparent. Usually the cyst is encountered in the midline at or below the level of the hyoid bone and moves up and down with swallowing or with protrusion of the tongue. Occasionally it presents as an intrathyroidal mass. Most thyroglossal duct cysts are asymptomatic. If the duct retains its connection with the pharynx, infection may occur, and the resulting abscess will require incision and drainage. Occasionally a salivary fistula may result. Submental lymphadenopathy and midline dermoid cysts can be confused with a thyroglossal duct cyst. Rarely, midline ectopic thyroid tissue masquerades as a thyroglossal duct cyst and may represent the patient's only thyroid tissue. Therefore, if there is any question regarding the diagnosis or if the thyroid gland cannot be palpated in its normal anatomic position, it is advisable to obtain a nuclear medicine scan to confirm the presence of a normal thyroid gland. In adults the thyroglossal duct may contain thyroid tissue that can undergo malignant degeneration, although this is rarely the case in

children. The presence of malignancy in a thyroglossal cyst should be suspected when the cyst grows rapidly or when ultrasonographic imaging demonstrates a complex anechoic pattern or the presence of calcification.

TREATMENT

If the cyst presents with an abscess, treatment should consist of drainage and administration of antibiotics. After resolution of the inflammation, resection of the cyst in continuity with the central portion of the hyoid bone and the tract connecting to the pharynx, in addition to ligation at the foramen cecum (the Sistrunk operation), is curative in >90% of patients. Lesser operations result in unacceptably high recurrence rates, and recurrence is more frequent after infection. According to a recent review, factors predictive of recurrence included more than two infections before surgery, age <2 years, and inadequate initial operation.

Branchial Cleft Anomalies

Paired branchial clefts and arches develop early in the fourth gestational week. The first cleft and the first, second, third, and fourth pouches give rise to adult organs. The embryologic communication between the pharynx and the external surface may persist as a fistula. A fistula is seen most commonly with the second branchial cleft, which normally disappears, and extends from the anterior border of the sternocleidomastoid muscle superiorly, passes inward through the bifurcation of the carotid artery, and enters the posterolateral pharynx just below the tonsillar fossa. In contrast, a third branchial cleft fistula passes posterior to the carotid bifurcation. The branchial cleft remnants may contain small pieces of cartilage and cysts, but internal fistulas are rare. A second branchial cleft sinus is suspected when clear fluid is noted draining from the external opening of the tract at the anterior border of the lower third of the sternomastoid muscle. Rarely, branchial cleft anomalies occur in association with biliary atresia and congenital cardiac anomalies, an association that is referred to as *Goldenhar's complex*.

TREATMENT

Complete excision of the cyst and sinus tract is necessary for cure. Dissection of the sinus tract is facilitated by passing a fine lacrimal duct probe through the external opening into the tract and using it as a guide for dissection. Injection of a small amount of methylene blue dye into the tract also may be useful. A series of two or sometimes three small transverse incisions in "stepladder" fashion is preferred to a long oblique incision in the neck, which is cosmetically undesirable. Branchial cleft cysts can present as abscesses. In these cases, initial treatment includes incision and drainage with a course of antibiotics to cover *Staphylococcus* and *Streptococcus* species, followed by excision of the cyst after the infection resolves.

Cystic Hygroma

ETIOLOGY AND PATHOLOGY

Cystic hygroma (lymphangioma), occurring as a result of sequestration or obstruction of developing lymph vessels, occurs in approximately 1 in 12,000 births. Although the lesion can occur anywhere, the most common sites are in the posterior triangle of the neck, axilla, groin, and mediastinum. The cysts are lined by endothelium and filled with lymph. Occasionally unilocular cysts occur, but more often there are multiple cysts "infiltrating" the surrounding structures and distorting the local anatomy. A particularly troublesome variant of cystic hygroma is that which involves the tongue, floor of the mouth, and structures deep in the neck. Adjacent connective tissue may show extensive lymphocytic infiltration. The mass may be apparent at birth or may appear and enlarge rapidly in the early weeks or months of life as lymph accumulates; most present by age 2 years (Fig. 39-1A). Extension of the lesion into the axilla or mediastinum occurs in approximately 10% of cases and can be demonstrated preoperatively by chest radiograph, ultrasonography, or computed tomographic (CT) scan. Occasionally

cystic hygromas contain nests of vascular tissue. These poorly supported vessels may bleed and produce rapid enlargement and discoloration of the hygroma. Infection within the cysts, usually caused by *Streptococcus* or *Staphylococcus*, may occur. In the neck this can cause rapid enlargement, which may result in airway compromise. Rarely, it may be necessary to carry out percutaneous aspiration of a cyst to relieve respiratory distress.

A. Left cervical cystic hygroma in a 2-day-old infant. **B.** Intraoperative photograph showing a vessel loop around the spinal accessory nerve.

A diagnosis of cystic hygroma by prenatal ultrasonography before 30 weeks' gestation has detected a cause of hidden mortality as well as a condition with a high incidence of associated anomalies, including abnormal karyotypes and hydrops fetalis. Occasionally, very large lesions can cause obstruction of the fetal airway. Such obstruction can result in the development of polyhydramnios by impairing the ability of the fetus to swallow amniotic fluid. In these circumstances, the airway is usually markedly distorted, which can result in immediate airway obstruction unless the airway is secured at the time of delivery. Orotracheal intubation or emergency tracheostomy while the infant remains attached to the placenta, the so-called ex utero intrapartum therapy (EXIT) procedure, may be necessary to secure the airway.

TREATMENT

The modern management of most cystic hygromas includes the combination of surgical excision and image-guided sclerotherapy. The initial treatment typically involves surgery in an attempt to safely remove all gross disease without damaging vital structures. Total removal of all gross disease may not be possible because of the extent of the hygroma and its proximity to, and intimate relationship with, adjacent nerves, muscles, and blood vessels (Fig. 39-1B). Radical ablative surgery is not indicated for this lesion. Conservative excision and unroofing of remaining cysts is advised, with repeated partial excision of residual hygroma and sclerotherapy if necessary and with preservation of all adjacent crucial structures. Postoperative wound drainage is important and is best accomplished by closed-suction technique. Nevertheless, fluid may accumulate beneath the surgically created flaps in the area from which the hygroma was excised, requiring multiple needle aspirations. One report notes recurrence rates of 20% after gross total resection, primarily along the surgical wound. Parents should be counseled that subtotal resections are associated with higher rates of recurrence or persistence. A combined sclerotherapy/resectional approach is particularly useful for masses that extend to the base of the tongue or the floor of the mouth.

Torticollis

The presence of a lateral neck mass in infancy in association with rotation of the head toward the opposite side of the mass indicates the presence of congenital torticollis. This lesion results from fibrosis of the sternocleidomastoid muscle. The mass may be palpated in the affected muscle in approximately two thirds of cases. Histologically, the lesion is characterized by the deposition of collagen and fibroblasts around atrophied muscle cells. In the overwhelming majority of cases, physical therapy based on passive stretching of the affected muscle is of benefit. Rarely, surgical transection of the sternocleidomastoid muscle may be indicated.

RESPIRATORY SYSTEM

Congenital Diaphragmatic Hernia (Bochdalek's Hernia)

PATHOLOGY

The septum transversum extends to divide the pleural and coelomic cavities during fetal development. This precursor of the diaphragm normally completes separation of these two cavities at the posterolateral aspects of this mesenchymally derived structure. The most common variant of a congenital diaphragmatic hernia (CDH) is a posterolateral defect, also known as a *Bochdalek's hernia*. This anomaly is encountered more commonly on the left (80 to 90% of cases). Linkage analyses have recently implicated genetic mutations in syndromic variants of CDHs. Diaphragmatic defects allow abdominal viscera to fill the chest cavity. The abdominal cavity is small and underdeveloped and remains scaphoid after birth. Both lungs are hypoplastic, with decreased bronchial and pulmonary artery branching. Lung weight, lung volume, and DNA content are also decreased, but these findings are more striking on the ipsilateral side. In many instances, evidence suggests that a paucity of surfactant is present, which compounds the degree of respiratory insufficiency. Amniocentesis with karyotyping may show chromosomal defects, especially trisomy 18 and 21. Associated anomalies, once thought to be uncommon, are identified in 40% of these infants, and most commonly involve the heart, brain, genitourinary system, craniofacial structures, or limbs.

Prenatal ultrasonography is successful in making the diagnosis of CDH as early as 15 weeks' gestation. Ultrasonographic findings include herniated abdominal viscera, abnormal anatomy of the upper abdomen, and mediastinal shift away from the herniated viscera (Fig. 39-2). Accurate prenatal prediction of outcome for fetuses that have CDH is very difficult. A useful index of severity for patients with left CDH is the lung-to-head ratio (LHR), which is the product of the length and the width of the right lung at the level of the cardiac atria divided by the head circumference (all measurements in millimeters). An LHR value of <1.0 is associated with a very poor prognosis, whereas an LHR of >1.4 predicts a more favorable outcome. The usefulness of the LHR in predicting outcome in patients with CDH has recently been questioned, due to the tremendous interobserver variability in calculating this ratio for a particular patient as well as the lack of reliable measures to determine postnatal disease severity.

Prenatal ultrasonographic scan of a fetus with a congenital diaphragmatic hernia. *Arrows* point to the location of the diaphragm. *Arrowhead* points to the stomach, which is in the thoracic cavity.

After delivery, the diagnosis of CDH is made by chest radiograph (Fig. 39-3). The differential diagnosis includes congenital pulmonary airway malformation, in which the intrathoracic loops of bowel may be confused with multiple lung cysts. The vast majority of infants with CDH develop immediate respiratory distress, which is due to the combined effects of three factors. First, the air-filled bowel in the chest compresses the mobile mediastinum, which shifts to the opposite side of the chest, so that air exchange in the contralateral lung is compromised. Second, pulmonary hypertension develops. This phenomenon results in persistent fetal circulation, with resultant decreased pulmonary perfusion, and impaired gas exchange. Finally, the lung on the affected side is often markedly hypoplastic, so that it is essentially nonfunctional. Varying degrees of pulmonary hypoplasia on the opposite side may compound these effects. As a result, neonates with CDH are extremely sick, and the overall mortality in most series is approximately 50%.

Chest radiograph showing a left congenital diaphragmatic hernia.

TREATMENT

Significant strides have been made in the treatment of CDH through the effective application of improved methods of ventilation and timely use of extracorporeal membrane oxygenation (ECMO). Many infants are symptomatic at birth due to hypoxia, hypercarbia, and metabolic acidosis. Prompt cardiorespiratory stabilization is mandatory. It is noteworthy that the first 24 to 48 hours after birth are often characterized by a period of relative stability with high levels of partial pressure of arterial oxygen and relatively good perfusion. This has been termed the *honeymoon period*, and is followed by progressive cardiorespiratory deterioration in the majority of patients. In the past, correction of the hernia was felt to be a surgical emergency, and these patients underwent surgery shortly after birth. It is now accepted that the presence of persistent pulmonary hypertension which results in right-to-left shunting across the open foramen ovale or the ductus arteriosus and pulmonary hypoplasia are the leading causes of cardiorespiratory insufficiency. Current management therefore is directed toward preventing or reversing the pulmonary hypertension and minimizing barotrauma while optimizing oxygen delivery. To achieve this goal, infants are placed on mechanical ventilation using relatively low or "gentle" settings that prevent overinflation of the noninvolved lung. A partial pressure of arterial carbon dioxide in the range of 50 to 60 mmHg or higher is accepted as long as the pH remains ≥ 7.25 . If these objectives cannot be achieved with conventional ventilation, high-frequency oscillatory ventilation may be used to avoid the injurious effects of conventional tidal volume ventilation. Echocardiography is used to assess the degree of pulmonary hypertension and to identify the presence of a coexisting cardiac anomaly. Minimal sedation is used, and meticulous attention to endotracheal tube patency is required. To minimize

the degree of pulmonary hypertension, inhaled nitric oxide may be used. In certain patients, this agent significantly improves pulmonary perfusion, as manifested by improved oxygenation. Nitric oxide is administered into the ventilatory circuit and is used in concentrations of up to 40 parts per million. Correction of acidosis using bicarbonate solution may minimize the degree of pulmonary hypertension. As the degree of pulmonary hypertension becomes hemodynamically significant, right-sided heart failure develops and systemic perfusion is impaired. Administration of excess IV fluid will compound the degree of cardiac failure and lead to marked peripheral edema. Inotropic support using epinephrine, dopamine, and milrinone alone or in combination may be helpful in optimizing cardiac contractility and maintaining mean arterial pressure.

Infants with CDH who remain severely hypoxic despite maximal ventilatory care may be candidates for treatment of their respiratory failure by ECMO. Venovenous or venoarterial bypass is used. Venovenous bypass is established with a single cannula through the internal jugular vein, with blood removed from and infused into the right atrium by separate ports. Venoarterial bypass is used preferentially by many centers because it provides the cardiac support that is often needed. The right atrium is cannulated by means of the internal jugular vein, and the aortic arch through the right common carotid artery. Deoxygenated blood from the right atrium is directed through the membrane oxygenator, which removes carbon dioxide from and supplies oxygen to the blood before it is returned to the infant via the carotid artery cannula. The infant is maintained on bypass until the pulmonary hypertension is reversed and lung function, as measured by compliance, is improved. This process typically occurs within 7 to 10 days, but in some infants it may take up to 3 weeks. The use of ECMO is associated with significant risk. Because patients require systemic anticoagulation, bleeding complications are the most significant, regardless of whether venoarterial or venovenous ECMO is used. Bleeding may occur intracranially or at the site of cannula insertion and can be life-threatening. Systemic sepsis is a significant problem and may necessitate decannulation. Criteria for placing infants on ECMO include the presence of normal cardiac anatomy by echocardiography, the absence of fatal chromosome anomalies, and the expectation that the infant will die without ECMO. Traditionally, a threshold of a weight of >2.5 kg and a gestational age of >34 weeks has been used to select patients for ECMO, although success has been achieved in infants with weights as low as 1.8 kg. It must be emphasized that, although ECMO may allow successful treatment of a population of neonates with refractory pulmonary hypertension, the use of this technique remains controversial. On decannulation, a decision should be made regarding whether to repair the carotid artery or not. In instances in which the child is cannulated for a brief period (≤ 5 days) this may be feasible. A recent study failed to show any benefit from repairing the carotid artery, although this finding remains controversial.

A strategy that does not involve the use of ECMO but instead emphasizes the use of permissive hypercapnia and the avoidance of barotrauma may provide equal overall outcome in patients with CDH. This likely reflects the fact that mortality is related to the degree of pulmonary hypoplasia and the presence of congenital anomalies, neither of which is correctable by ECMO.

The timing of diaphragmatic hernia repair remains controversial, particularly when the infant is supported on ECMO. In patients who are not placed on ECMO, repair should be performed once the hemodynamic status has been optimized. In neonates who are on ECMO, some surgeons perform early repair on bypass; others wait until the infant's lungs are fully recovered and the pulmonary hypertension has subsided, repair the diaphragm, and discontinue bypass within hours of surgery. Still others repair the diaphragm only after the infant is off bypass. Repair of the diaphragmatic hernia may be accomplished by either an abdominal or a transthoracic approach and can be performed using open or minimally invasive techniques. In the abdominal approach, through a subcostal incision, the abdominal viscera are withdrawn from the chest to expose the defect in the diaphragm. Care must be taken when reducing the spleen and liver, because bleeding from these

structures can be fatal. The anterior margin is often apparent, whereas the posterior muscular rim is attenuated. If the infant undergoes heparinization on bypass, minimal dissection of the muscular margins is performed. Electrocautery is used liberally to minimize postoperative bleeding. Most infants who require ECMO support before hernia repair have large defects, often lacking the medial and posterior margins. Before the availability of ECMO therapy, most of these infants died. In about three fourths of infants who undergo repair on bypass, the use of prosthetic material is required to patch the defect, and it is sutured to the diaphragmatic remnant or around ribs or costal cartilages for large defects. If there is adequate muscle for closure, a single layer of nonabsorbable horizontal mattress suture is used to close the defect. Just before the repair is complete, a chest tube may be positioned in the thoracic cavity. The authors tend to reserve the use of chest tubes for patients who are repaired while on ECMO, because these patients are at risk for developing a hemothorax, which can significantly impair ventilation. Anatomic closure of the abdominal wall may be impossible after reduction of the viscera. Occasionally a prosthetic patch may be sutured to the fascia to facilitate closure. The patch can be removed at a later time, and the ventral hernia can be closed at that time or subsequently. In patients who are deemed to be candidates for a minimally invasive approach (stable condition, >2 kg, no pulmonary hypertension), a thoroscopic repair may be safely performed. If the diaphragm has been repaired with the patient on ECMO, weaning and decannulation are accomplished as soon as possible. All infants are ventilated postoperatively to maintain preductal arterial oxygenation of 80 to 100 mmHg. Very slow weaning from the ventilator is necessary to avoid recurrent pulmonary hypertension.

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) is a condition manifested during the first few months of life as a progressive hyperexpansion of one or more lobes of the lung. It can be life-threatening in the newborn period, but in the older infant it causes less respiratory distress. Air entering during inspiration is trapped in the lobe. On expiration, the lobe cannot deflate and progressively overexpands, which causes atelectasis of the adjacent lobe or lobes. This hyperexpansion eventually shifts the mediastinum to the opposite side and compromises the other lung. CLE usually occurs in the upper lobes of the lung (left more often than right), followed next in frequency by the right middle lobe; however, it can occur in the lower lobes as well. It is caused by intrinsic bronchial obstruction from poor bronchial cartilage development or extrinsic compression. Approximately 14% of children with this condition have cardiac defects, with an enlarged left atrium or a major vessel causing compression of the ipsilateral bronchus.

Symptoms range from mild respiratory distress to full-fledged respiratory failure with tachypnea, dyspnea, cough, and late cyanosis. These symptoms may be static or they may progress rapidly or result in recurrent pneumonia. Occasionally, infants with CLE present with failure to thrive, which likely reflects the increased work associated with the overexpanded lung. A hyperexpanded hemithorax on the ipsilateral side is pathognomonic for CLE. Diagnosis is typically confirmed by chest radiograph, which shows a hyperlucent affected lobe with adjacent lobar compression and atelectasis. As a consequence of mass effect, the mediastinum may be shifted to the contralateral side, resulting in compression and atelectasis of the contralateral lung (Fig. 39-4). Although a chest radiograph is usually sufficient, it is sometimes important to obtain a CT scan of the chest to clearly establish the diagnosis of CLE. This should be done only in patients in stable condition. Unless foreign body or mucus plugging is suspected as a cause of hyperinflation, bronchoscopy is not advisable, because it can lead to more air trapping and cause life-threatening respiratory distress in an infant in stable condition. Treatment is resection of the affected lobe, which can be safely performed using either an open or thoroscopic approach. Unless symptoms necessitate earlier surgery, resection can usually be performed after the infant is several months of age. The prognosis is excellent. Ongoing lung development in pediatric patients results in the generation of new alveoli in the remaining lung tissue, unlike in

adult patients.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM) consists of cystic proliferation of the terminal airway, which produces cysts lined by mucus-producing respiratory epithelium and elastic tissue in the cyst walls without cartilage formation. There may be a single cyst with a wall of connective tissue containing smooth muscle. Formerly known as *congenital cystic adenomatoid malformation*, CPAM may consist of a single large cyst or multiple cysts (type I), may be characterized by smaller and more numerous cysts (type II), or may resemble fetal lung without macroscopic cysts (type III). CPAMs frequently occur in the left lower lobe. However, this lesion can occur in any lobe or may occur in both lungs simultaneously. In the left lower lobe, a type I CPAM may be confused at birth with a CDH. Clinical symptoms may range from none at all to severe respiratory failure at birth. Both single and multiple cysts can produce air trapping and may be confused with CLE, pneumatoceles, or even pulmonary sequestrations. The cysts also can be involved with repeated infections and produce fever and cough in older infants and children. The diagnosis often can be made by chest radiograph. In certain cases, ultrasonographic or CT scan may be definitive (Fig. 39-5). Prenatal ultrasonography may suggest the diagnosis. In the newborn period, ultrasonography may also be useful, especially to distinguish between CPAM and CDH. Resection is curative and may need to be performed urgently in the infant with severe respiratory distress. Long term, there is a risk of malignant degeneration to pulmonary blastoma. As a result, resection of the affected lobe is usually required (Fig. 39-6). Prognosis is

excellent.

Pulmonary Sequestration

In pulmonary sequestration, a mass of lung tissue, usually in the left lower chest, lacks the usual connections to the pulmonary artery or tracheobronchial tree and its blood supply is derived directly from the aorta. There are two kinds of sequestration. In extralobar sequestration a small area of nonaerated lung is separated from the main lung mass, has a systemic blood supply, and usually is located immediately above the left diaphragm. It is commonly found in cases of CDH. Intralobar sequestration more commonly occurs within the parenchyma of the left lower lobe but also can occur on the right. There is no major connection to the tracheobronchial tree, but a secondary connection may be established, perhaps through infection or via adjacent intrapulmonary shunts. The blood supply frequently originates from the aorta below the diaphragm; multiple vessels may be present (Fig. 39-7). Venous drainage of both types can be systemic or pulmonary. The cause of sequestration is unknown but most probably involves an abnormal budding of the developing lung that picks up a systemic blood supply and never becomes connected with the bronchus or pulmonary vessels. Sequestrations may, in some cases, exhibit mixed pathology showing components consistent with CPAMs. Extralobar sequestration is asymptomatic and is usually discovered incidentally on chest radiograph. If the diagnosis can be confirmed, for example by CT scan, resection is not necessary unless the sequestration becomes symptomatic. Diagnosis of intralobar sequestration may be made prenatally and confirmed on postnatal CT scan. Alternatively, the diagnosis of intralobar sequestration may be established after repeated infections manifested by cough, fever, and consolidation in the posterior basal segment of the left lower lobe. Increasingly the diagnosis is being made in the early months of life by ultrasonography. Color Doppler ultrasonography often can be helpful in delineating the systemic arterial supply. Removal of the entire left lower lobe is usually necessary, because the diagnosis often is made late after multiple infections. Occasionally segmental resection of the sequestered part of the lung can be performed using an open, or ideally a thoracoscopic, approach. If an open approach is used, it is important to open the chest through a low intercostal space (sixth or seventh), to gain access to the vascular attachments to the aorta. These attachments may insert into the aorta below the diaphragm; in these cases division of the vessels as they traverse the thoracic cavity is essential. Prognosis is generally excellent. However, failure to obtain adequate control of these vessels may result in their retraction into the abdomen and lead to uncontrollable hemorrhage.

Arteriogram showing large systemic artery supply to an intralobar sequestration of the left lower lobe.

Bronchogenic Cyst

Bronchogenic cysts can occur anywhere along the respiratory tract from the neck to the lung parenchyma. They are probably embryonic rests of foregut origin that have been pinched off from the main portion of the developing tracheobronchial tree and are closely associated in causation with other foregut duplication cysts arising from the esophagus. For purists, foregut duplication cysts are named by their origin rather than their mucosal tissue type, therefore bronchogenic cysts may contain GI epithelium. However, although *foregut duplication cyst* is the correct terminology, it is not generally used. Bronchogenic cysts can present at any age. They may be seen on prenatal ultrasonographic scan but are discovered most often incidentally on postnatal chest radiograph. Histologically, they are hamartomatous and usually consist of a single cyst lined with respiratory epithelium, containing cartilage and smooth muscle. Although they may be completely asymptomatic, bronchogenic cysts may produce symptoms that depend on their anatomic location. In the paratracheal region of the neck they can produce airway compression and respiratory distress. In the lung parenchyma, they may become infected and present with fever and cough. In addition, they may cause obstruction of the bronchial lumen with distal atelectasis and infection. They may also cause mediastinal compression. Rarely, rupture of the cyst can occur. Chest radiograph usually shows a dense mass, and CT scan or magnetic resonance imaging (MRI) delineates the precise anatomic location of the lesion. Treatment consists of resection of the cyst, which may need to be undertaken in emergency circumstances because of airway or cardiac compression. Resection can be performed either as an open procedure or, more commonly, using a thoracoscopic approach.

Bronchiectasis

Bronchiectasis is an abnormal and irreversible dilatation of the bronchi and bronchioles associated with chronic suppurative disease of the airways. Usually the children have an underlying congenital pulmonary anomaly, cystic fibrosis, or immune deficiency. Bronchiectasis also can result from chronic infection secondary to a neglected bronchial foreign body. The symptoms include a chronic cough, often productive of purulent secretions; recurrent pulmonary infection; and hemoptysis. The diagnosis is suggested by a chest radiograph that shows increased bronchovascular markings in the affected lobe. Chest CT delineates bronchiectasis with excellent resolution. The preferred treatment for bronchiectasis is medical, consisting of antibiotics, postural drainage, and bronchodilator therapy, because many children with the disease show signs of airflow obstruction and bronchial hyperresponsiveness. Lobectomy or segmental resection is indicated for localized disease that has not responded appropriately to medical therapy. In severe cases, lung transplantation may be required to replace the terminally damaged, septic lung.

Foreign Bodies

The inherent curiosity of children and their innate propensity to place new objects into their mouths to fully explore them place them at great risk for aspiration. Ingested objects can be found in the airway or in the esophagus; in both cases the results can be life-threatening.

ASPIRATION

Aspiration of foreign bodies most commonly occurs in the toddler age group. Peanuts are the object most frequently aspirated, although other materials (popcorn, for instance) may also be involved. A solid foreign body often will cause air trapping, with hyperlucency of the affected lobe or lung seen especially on expiration. Oil from a peanut is very irritating and may cause pneumonia. Delay in diagnosis can lead to atelectasis and infection. The most common anatomic location for a foreign body is the right main stem bronchus or the right lower lobe. The child usually will cough or choke while eating but may then become asymptomatic. Total respiratory obstruction may occur with a tracheal foreign body; however, respiratory distress is usually mild if present at all. A unilateral wheeze is often heard on auscultation. This wheeze often leads to an inappropriate diagnosis of asthma and may delay the correct diagnosis for some time. A chest radiograph will show a radiopaque foreign body, but in the case of nuts, seeds, or plastic toy parts, the only clue may be hyperexpansion of the affected lobe on an expiratory film or fluoroscopy. Bronchoscopy confirms the diagnosis and allows removal of the foreign body. It may be a very simple procedure or it may be extremely difficult, especially with a smooth foreign body that cannot be grasped easily or one that has been retained for some time. A rigid bronchoscope should be employed in all cases, and use of optical forceps facilitates grasping of the inhaled object. Epinephrine may be injected into the mucosa when the object has been present for a long period of time to minimize bleeding. Bronchiectasis may be seen as an extremely late phenomenon after repeated infections of the poorly aerated lung and may require partial or total resection of the affected lobe. The differential diagnosis of a bronchial foreign body includes an intraluminal tumor (i.e., carcinoid, hemangioma, or neurofibroma).

CAUSTIC INGESTION AND ESOPHAGEAL INJURY

The most common foreign body in the esophagus is a coin, followed by small toy parts. Toddlers are most frequently affected. The coin is retained in the esophagus at one of three locations: the cricopharyngeus, the area of the aortic arch, or the gastroesophageal junction, all areas of normal anatomic narrowing. Symptoms are variable depending on the anatomic

position of the foreign body and the degree of obstruction. There is often a relatively asymptomatic period after ingestion. The initial symptoms are GI symptoms and include dysphagia, drooling, and vomiting. The longer the foreign body remains in the esophagus, the greater the incidence of respiratory symptoms, which include cough, stridor, and wheezing. These findings may be interpreted as signs of upper respiratory tract infections. Objects that are present for a long period of time—particularly in children who have underlying neurologic impairment—may manifest as chronic dysphagia. The chest radiograph is diagnostic in the case of an ingested coin. A contrast swallow evaluation may be required for nonradiopaque foreign bodies. Coins lodged in the upper esophagus for <24 hours may be removed using Magill forceps. In all other situations, the treatment is by esophagoscopy, rigid or flexible, for removal of the foreign body. In the case of sharp foreign bodies such as open safety pins, extreme care is required on extraction to avoid injury to the esophagus. Rarely, esophagotomy is required for removal, particularly of sharp objects. Diligent follow-up is required after removal of foreign bodies—especially batteries, which can cause liquefactive necrosis followed by strictures, and sharp objects, which can injure the underlying esophagus.

ESOPHAGUS

Esophageal Atresia and Tracheoesophageal Fistula

Repair of esophageal atresia (EA) and tracheoesophageal fistula (TEF) is an area of pediatric surgery that shows significantly better outcomes than in the past. Originally, nearly all infants born with EA and TEF died. In 1939 William E. Ladd and N. Logan Leven achieved the first successful repair by ligating the fistula, placing a gastrostomy, and reconstructing the esophagus at a later time. Subsequently, Dr. Cameron Haight in Ann Arbor, Michigan, performed the first successful primary anastomosis for EA, which remains the current approach for treatment of this condition. Despite the fact that there are several common varieties of this anomaly and the underlying cause remains obscure, a careful approach consisting of meticulous perioperative care and attention to the technical details of the operation can result in an excellent prognosis in most cases.

ANATOMIC VARIETIES

The five major varieties of EA and TEF are shown in Fig. 39-8. The most commonly seen variety is EA with distal TEF (type C), which occurs in approximately 85% of the cases in most series. The next most frequent is pure EA (type A), occurring in 8 to 10% of patients, followed by TEF without EA (type E). The latter occurs in 8% of cases and is also referred to as an *H-type fistula*, based on the anatomic similarity to that letter (Fig. 39-9). EA with fistula between both the proximal and distal ends of the esophagus and trachea (type D) is seen in approximately 2% of cases, and type B, EA with TEF between the proximal esophagus and trachea, is seen in approximately 1% of cases.

Barium esophagram showing an H-type tracheoesophageal fistula (arrow).

ETIOLOGY AND PATHOLOGIC PRESENTATION

The esophagus and trachea share a common embryologic origin. At approximately 4 weeks' gestation, a diverticulum forms off the anterior aspect of the proximal foregut in the region of the primitive pharynx. This diverticulum extends caudally with progressive formation of the laryngotracheal groove, which thus creates a separate trachea and esophagus. Successful development of these structures is the consequence of a complex interplay among growth and transcription factors necessary for rostral-caudal and anterior-posterior specification. The variations in clinically observed EA and TEF that result from failure of successful formation of these structures are depicted in Fig. 39-8. Although definitive genetic mutations have been difficult to identify in isolated EA-TEF, mutations in *N-myc*, *Sox2*, and *CHD7* have been characterized in syndromic EA-TEF with associated anomalies.

Other congenital anomalies commonly occur in association with EA-TEF. For instance, VACTERL syndrome is associated with vertebral anomalies (absent vertebrae or hemivertebrae), anorectal anomalies (imperforate anus), cardiac defects, tracheoesophageal fistula, renal anomalies (renal agenesis, renal anomalies), and radial/limb anomalies (most often radial dysplasia). In nearly 20% of the infants born with EA, some variant of congenital heart disease occurs.

CLINICAL PRESENTATION

The anatomic variant of EA-TEF in the infant predicts the clinical presentation. When the esophagus ends either as a blind pouch or as a fistula into the trachea (as in types A, B, C, and D), infants present with excessive drooling, followed by choking or coughing immediately after feeding is initiated as a result of aspiration through the fistula tract. Air in the distal intestine indicates either a patent esophagus or a fistula to the respiratory tract. In type C TEF, as the neonate coughs and cries, air is transmitted through the fistula into the stomach, which results in abdominal distention. As the abdomen distends, it becomes increasingly more difficult for the infant to breathe. This leads to further atelectasis, which compounds the pulmonary dysfunction. In patients with the C and D varieties, the regurgitated gastric juice passes through the fistula,

collecting in the trachea and lungs and leading to a chemical pneumonitis, which further exacerbates the pulmonary status. In many instances, the diagnosis is actually made by the nursing staff who attempt to feed the baby and notice the accumulation of oral secretions.

The diagnosis of EA is confirmed by the inability to pass an orogastric tube into the stomach (Fig. 39-10). The dilated upper pouch occasionally may be seen on a plain chest radiograph. If a soft feeding tube is used, the tube will coil in the upper pouch, which provides further diagnostic certainty. An important alternative diagnosis that must be considered when an orogastric tube does not enter the stomach is that of an esophageal perforation. This problem can occur in infants after traumatic insertion of a nasogastric or orogastric tube. In this instance, the perforation classically occurs at the level of the piriform sinus, and a false passage is created that prevents the tube from entering the stomach. Whenever there is any diagnostic uncertainty, a contrast study can confirm the diagnosis of EA and occasionally document the TEF; however, the obvious risks of aspiration associated with an undrained blind pouch cannot be overstated. The presence of a TEF can be demonstrated clinically by the finding of air in the GI tract. This can be proven at the bedside by percussion of the abdomen and confirmed by plain abdominal radiograph. Occasionally, a diagnosis of EA-TEF can be suspected prenatally on ultrasonographic evaluation. Typical features include failure to visualize the stomach and the presence of polyhydramnios. These findings reflect the absence of efficient swallowing by the fetus.

Type C esophageal atresia with tracheoesophageal fistula. Note the catheter coiled in the upper pouch and the presence of gas below the diaphragm, which confirms the presence of the tracheoesophageal fistula.

In a child with EA, it is important to identify whether coexisting anomalies are present. These include cardiac defects in 38%, skeletal defects in 19%, neurologic defects in 15%, renal defects in 15%, anorectal defects in 8%, and other abnormalities in 13%. Examination of the heart and great vessels with echocardiography is important to exclude cardiac defects, because these are often the most important predictors of survival in these infants. The echocardiogram also demonstrates whether the aortic arch is left sided or right sided, which may influence the approach to surgical repair. Vertebral anomalies are assessed by plain radiography, and a spinal ultrasonographic scan is obtained. A patent anus should be confirmed clinically. The kidneys in a newborn may be assessed clinically by palpation. An ultrasonographic scan of the abdomen will demonstrate the presence of renal anomalies, which should be suspected in the child who fails to produce urine. The presence of other extremity anomalies is suspected when there are missing digits and can be confirmed by plain radiographs of the hands, feet, forearms, and legs. Rib anomalies may also be present. These may include the presence of a thirteenth rib.

INITIAL MANAGEMENT

The initial treatment of infants with EA-TEF includes attention to respiratory status, decompression of the upper pouch, and appropriate timing of surgery. Because the major determinant of poor survival is the presence of other severe anomalies, a search for other defects, including congenital cardiac disease, is undertaken. The initial strategy after the diagnosis is confirmed is to place the neonate in an infant warmer with the head elevated at least 30 degrees. A sump catheter on continuous suction is placed in the upper pouch. Both of these strategies are designed to minimize the degree of aspiration from the esophageal pouch. Acid prophylaxis is given to reduce the chemical irritation of any refluxed contents. When saliva accumulates in the upper pouch and is aspirated into the lungs, coughing, bronchospasm, and desaturation episodes can occur, which may be minimized by ensuring the patency of the sump catheter. IV antibiotic therapy is initiated, and warmed electrolyte solution is administered. When possible, the right upper extremity is avoided as a site to start an IV line, because this location may interfere with positioning of the patient during the surgical repair.

The timing of repair is influenced by the stability of the patient's condition. Definitive repair of the EA-TEF is rarely a surgical emergency. If the child is hemodynamically stable and is oxygenating well, definitive repair may be performed within 1 to 2 days after birth. This allows a careful examination for the presence of coexisting anomalies and selection of an experienced anesthetic team.

MANAGEMENT IN THE PRETERM INFANT

The ventilated premature neonate with EA-TEF and associated hyaline membrane disease is a patient who may develop severe, progressive cardiopulmonary dysfunction. The tracheoesophageal fistula can worsen the fragile pulmonary status as a result of recurrent aspiration through the fistula and increased abdominal distention, which impairs lung expansion. Moreover, the elevated airway pressure that is required to ventilate these patients can worsen the clinical course by forcing air through the fistula into the stomach, which exacerbates the degree of abdominal distention and compromises lung expansion. In this situation, the first priority is to minimize the degree of positive pressure needed to adequately ventilate the child. This can be accomplished using high-frequency oscillatory ventilation. If the gastric distention becomes severe, a gastrostomy tube should be placed. This procedure can be performed at the bedside under local anesthetic, if necessary. The dilated, air-filled stomach can easily be accessed through an incision in the left upper quadrant of the abdomen. Once the gastrostomy tube is placed and the abdominal pressure is relieved, the pulmonary status can paradoxically worsen. This is because the ventilation gas may pass preferentially through the fistula, which is the path of least resistance, and bypass the lungs, which thereby worsens the hypoxemia. To correct this problem, the gastrostomy tube may be placed under water seal,

elevated, or intermittently clamped. If these maneuvers are to no avail, ligation of the fistula may be required. This procedure can be performed in the neonatal intensive care unit if the infant's condition is too unstable for the infant to be transported to the operating room. Some surgeons believe that division rather than ligation alone leads to reduced rates of recurrence in the initial period before definitive treatment. These interventions allow for the infant's underlying hyaline membrane disease to improve, for the pulmonary secretions to clear, and for the infant's condition to stabilize so that definitive repair can be performed.

PRIMARY SURGICAL CORRECTION

In an infant in stable condition, definitive repair is achieved through performance of a primary esophagoesophagostomy. There are two approaches to this operation: open thoracotomy and thoracoscopy. In the open approach, the infant is brought to the operating room, intubated, and placed in the lateral decubitus position with the right side up in preparation for right posterolateral thoracotomy. If a right-sided arch was determined previously to be present by echocardiography, consideration is given to performing the repair through the left chest, although most surgeons believe that the repair can be performed safely from the right side as well. Bronchoscopy may be performed to exclude the presence of additional upper pouch fistulas in cases of EA (i.e., differentiation of types B, C, and D), and to identify a laryngotracheoesophageal cleft.

The operative technique for primary repair is as described below (Fig. 39-11). A retropleural approach is generally used, because this technique prevents widespread contamination of the thorax if an anastomotic leak occurs postoperatively. The sequence of steps is the following: (a) The pleura is mobilized to expose the structures in the posterior mediastinum. (b) The fistula is divided and the tracheal opening is closed. (c) The upper esophagus is mobilized sufficiently to permit an anastomosis without tension and to determine whether a fistula is present between the upper esophagus and the trachea. Forward pressure by the anesthesia staff on the sump drain in the pouch can greatly facilitate dissection at this stage of the operation. Care must be taken when dissecting posteriorly to avoid violation of the lumen of the trachea or the esophagus. (d) The distal esophagus is mobilized. This needs to be accomplished judiciously to avoid devascularization, because the blood supply to the distal esophagus is segmental from the aorta. Most of the esophageal length is obtained by mobilizing the upper pouch, because the blood supply travels via the submucosa from above. (e) Primary esophagoesophagostomy is performed. Most surgeons create the anastomosis in a single layer using interrupted 5-0 sutures. If there is excess tension, the muscle of the upper pouch can be circumferentially incised without compromising blood supply to increase its length. Many surgeons place a transanastomotic feeding tube to institute feeds in the early postoperative period. (f) A retropleural drain is placed, and the incision is closed in layers.

Primary repair of type C tracheoesophageal fistula. **A.** Right thoracotomy incision. **B.** Azygous vein transected, proximal and distal esophagus demonstrated, and fistula identified. **C.** Tracheoesophageal fistula transected and defect in the trachea closed. **D.** End-to-end anastomosis between the proximal and distal esophagus. **E.** Completed anastomosis.

When a minimally invasive approach is selected, the patient is prepared for right-sided transthoracic thoracoscopic repair. The same steps as described earlier for the open repair are undertaken. The telescope provides excellent visualization. Identification of the fistula is performed as a first step; the fistula can be readily ligated and divided between thoracoscopically placed sutures. The anastomosis is performed in a single layer. The thoracoscopically performed TEF repair requires clear and ongoing communication between the operating surgeons and the anesthesiologist; visualization can be significantly reduced with sudden changes in lung inflation, which can potentially lead to the need to convert to an open repair. Although clear guidelines for patient selection for a thoracoscopic repair have not been established, a requirement that patients weigh >2.5 kg, be in hemodynamically stable condition, and have no comorbidities represents a reasonable starting point.

POSTOPERATIVE COURSE

The postoperative management strategy for patients with EA-TEF is influenced to a great degree by the preference of the individual surgeon and the institutional culture. Many surgeons prefer not to leave the infants intubated postoperatively to avoid the effects of positive pressure on the site of tracheal closure. However, early extubation may not be possible in infants with preoperative lung disease, either from prematurity or pneumonia, or in infants with any vocal cord edema. When a transanastomotic tube is placed, feedings are begun slowly in the postoperative period. Some surgeons institute parenteral nutrition for several days, using a central line. The retropleural drain is assessed daily for the presence of saliva, which indicates an anastomotic leak. Many surgeons order a contrast swallow evaluation 1 week after repair to assess the caliber of the anastomosis and to determine whether a leak is present. If there is no leak, feeding is started. The principal benefit of the thoracoscopic approach is that postoperative pain is significantly reduced, as is the requirement for postoperative narcotic analgesia.

COMPLICATIONS OF SURGERY

Anastomotic leakage occurs in 10 to 15% of patients and may be seen either in the immediately postoperative period or after several days. Early leakage (i.e., within the first 24 to 48 hours) is manifested by a new pleural effusion, pneumothorax, and sepsis, and requires immediate exploration. In these circumstances, the anastomosis may be completely disrupted, possibly due to excessive tension. Revision of the anastomosis may be possible. If not, cervical esophagostomy and gastrostomy placement is required, with a subsequent procedure to re-establish esophageal continuity. Anastomotic leakage that is detected after several days usually heals without intervention, particularly if a retropleural approach is used. Under these circumstances, administration of broad-spectrum antibiotics, pulmonary toilet, and optimization of nutrition are important. After approximately 1 week, a repeat esophagram should be taken to determine whether the leakage has resolved.

Strictures are not infrequent (10 to 20% of cases), particularly if a leak has occurred. A stricture may become apparent at any time, from the early postoperative period to months or years later. It may present as choking, gagging, or failure to thrive but often becomes clinically apparent with the transition to consumption of solid food. A contrast swallow test or esophagoscopy is confirmatory, and simple dilation is usually corrective. Occasionally, repeated dilations are required. These may be performed in a retrograde procedure in which a silk suture is placed into the oropharynx and delivered from the esophagus through a gastrostomy tube. Tucker dilators are then tied to the suture and passed in a retrograde fashion from the gastrostomy tube and delivered out of the oropharynx. Increasing sizes are used, and the silk is replaced at the end of the procedure, with one end of the silk taped to the side of the face and the other end to the gastrostomy tube. Alternatively, image-guided balloon dilation over a guidewire may be performed, with intraoperative contrast radiography used to determine the precise location of the stricture and to assess the immediate response to the dilation.

Recurrent tracheoesophageal fistula may represent a missed upper pouch fistula or a true recurrence. This may occur after an anastomotic disruption, during which the recurrent fistula may heal spontaneously. Otherwise, reoperation may be required.

Gastroesophageal reflux commonly occurs after repair of EA-TEF, potentially due to alterations in esophageal motility and the anatomy of the gastroesophageal junction. The clinical manifestations of such reflux are similar to those seen in other infants with primary gastroesophageal reflux disease. A loose antireflux procedure, such as a Nissen fundoplication, is used to prevent further reflux, but the child may have feeding problems after antireflux surgery as a result of the intrinsic dysmotility of the distal esophagus. To minimize this latter problem, some surgeons prefer to perform an incomplete wrap (such as a Toupet or a Thal wrap) rather than a 360-degree wrap. The fundoplication may be safely performed laparoscopically in experienced hands, although care should be taken to ensure that the wrap is not excessively tight.

SPECIAL CIRCUMSTANCES

Patients with type E TEFs (commonly referred to as *H-type*) present beyond the newborn period. Presenting symptoms include recurrent chest infections, bronchospasm, and failure to thrive. The diagnosis can be suspected from the results of barium esophagography and confirmed by endoscopic visualization of the fistula. Surgical correction is generally possible through a cervical approach after placement of a balloon catheter across the fistula and requires mobilization and division of the fistula. Outcome is usually excellent.

Patients with duodenal atresia and EA-TEF may require urgent treatment due to the presence of a closed obstruction of the stomach and proximal duodenum. In patients in stable condition, treatment consists of repair of the esophageal anomaly and correction of the duodenal atresia if the infant's condition is stable during surgery. If not, a staged approach should be used

consisting of ligation of the fistula and placement of a gastrostomy tube. Definitive repair can then be performed at a later time.

Primary EA (type A) represents a challenging problem, particularly if the upper and lower ends of the esophagus are too far apart for an anastomosis to be created. Under these circumstances, treatment strategies include placing a gastrostomy tube and performing serial bougienage to increase the length of the upper pouch. This occasionally permits primary anastomosis to be performed. When the two ends cannot be brought together safely, esophageal replacement is required using either a gastric pull-up or colon interposition (see later).

OUTCOME

Various classification systems have been used to predict survival in patients with EA-TEF and to stratify treatment. A system devised by Waterston in 1962 was used to stratify neonates based on birth weight, the presence of pneumonia, and the identification of other congenital anomalies. In response to advances in neonatal care, surgeons at the Montreal Children's Hospital proposed a new classification system in 1993. In the Montreal experience only two characteristics were found to independently affect survival: preoperative ventilator dependence and associated major anomalies. Pulmonary disease, as defined by ventilator dependence, appeared to be a more accurate predictor than pneumonia. Spitz and colleagues analyzed risk factors in infants who died with EA-TEF. Two criteria were found to be important predictors of outcome: birth weight of <1500 g and the presence of major congenital cardiac disease. A new classification for predicting outcome in EA was therefore proposed: group I—birth weight of ≥ 1500 g without major cardiac disease, survival 97% (283 of 293); group II—birth weight of <1500 g or major cardiac disease, survival 59% (41 of 70); and group III—birth weight of <1500 g and major cardiac disease, survival 22% (2 of 9).

In general, surgical correction of EA-TEF leads to a satisfactory outcome with nearly normal esophageal function in most patients. Overall survival rates of >90% have been achieved in patients classified as in stable condition according to all the various staging systems. Infants in unstable condition have an increased mortality (40 to 60% survival) because of potentially fatal associated cardiac and chromosomal anomalies or prematurity. However, the use of a staged procedure has increased survival in even these high-risk infants.

Corrosive Injury of the Esophagus

Injury to the esophagus after ingestion of corrosive substances occurs most commonly in the toddler age group. Both strong alkalis and strong acids produce injury by liquefaction or coagulation necrosis, and because all corrosive agents are extremely hygroscopic, the caustic substance will cling to the esophageal epithelium. Subsequent strictures occur at the intrinsically narrower areas of the esophagus: the cricopharyngeus, middle esophagus, and gastroesophageal junction. A child who has swallowed an injurious substance may be symptom free but usually is drooling and unable to swallow saliva. The injury may be restricted to the oropharynx and esophagus or may extend to the stomach. There is no effective immediate antidote. Diagnosis is made by careful physical examination of the mouth and endoscopy with a flexible or rigid esophagoscope. The endoscope should be advanced only to the first level of the burn to avoid perforation. Early barium swallow testing may delineate the extent of the mucosal injury. The practitioner should be aware that the esophagus may be burned without evidence of injury to the mouth. Although previously steroids were used routinely, they have not been shown to alter stricture development or modify the extent of injury. Therefore, they are no longer part of the management of caustic injuries. Antibiotics are administered during the acute period.

The extent of injury is graded endoscopically as either mild, moderate, or severe (grade I, II or III). Circumferential

esophageal injuries with necrosis have an extremely high likelihood of stricture formation. These patients should undergo placement of a gastrostomy tube once they are in clinically stable condition. A string should be inserted through the esophagus either immediately or during repeat esophagoscopy several weeks later. When established strictures are present (usually 3 to 4 weeks), dilatation is performed. The safest are retrograde dilations, in which graduated dilators are brought through the gastrostomy and advanced into the esophagus via the transesophageal string. For less severe injuries, dilatation may be attempted in antegrade fashion using either graded bougies or balloons. Management of esophageal perforation during dilation should include administration of antibiotics, irrigation, and closed drainage of the thoracic cavity to prevent systemic sepsis. If recognition is delayed or if the patient is systemically ill, esophageal diversion may be required with staged reconstruction at a later time.

Although the native esophagus can and should be preserved in most cases, severe stricture formation that does not respond to dilation is best managed by esophageal replacement. The most commonly used options for esophageal substitution are the colon (right colon or transverse/left colon) and the stomach (gastric tube or gastric pull-up). Pedicled or free grafts of the jejunum are less commonly used. The right colon graft is based on a pedicle of the middle colic artery and the left colon graft on a pedicle of the middle colic or left colic artery. Gastric tubes are fashioned from the greater curvature of the stomach based on the pedicle of the left gastroepiploic artery. When the entire stomach is used, as in gastric pull-up, the blood supply is provided by the right gastric artery. The neoesophagus may pass (a) substernally, (b) through a transthoracic route, or (c) through the posterior mediastinum to reach the neck. A feeding jejunostomy is placed at the time of surgery and tube feedings are instituted once the postoperative ileus has resolved. In a recent review of patients treated by gastric pull-up, long-term outcome was very good. Complications included esophagogastric anastomotic leak ($n = 15$, or 36%), which uniformly resolved without intervention, and stricture formation ($n = 20$, or 49%), which responded to a course of dilation. Long-term follow up has shown that all methods of esophageal substitution can support normal growth and development, and the children enjoy reasonably normal eating habits. Because of the potential for late complications such as ulceration and stricture, follow-up into adulthood is mandatory, but complications appear to diminish with time.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) occurs to some degree in all children and refers to the passage of gastric contents into the esophagus. By contrast, gastroesophageal reflux disease (GERD) describes a situation in which reflux is symptomatic. Typical symptoms include failure to thrive, bleeding, stricture formation, reactive airway disease, aspiration pneumonia, and apnea. Failure to thrive and pulmonary problems are particularly common in infants with GERD, whereas strictures and esophagitis are more common in older children and adolescents. GERD is particularly problematic in neurologically impaired children.

CLINICAL MANIFESTATIONS

Because all infants experience occasional episodes of GER, care must be taken before labeling a child as having pathologic reflux. A history of repeated episodes of vomiting that interferes with growth and development or the presence of life-threatening events is required for the diagnosis of GERD. In older children, esophageal bleeding, stricture formation, severe heartburn, or the development of Barrett's esophagus unequivocally connotes pathologic reflux or GERD. In neurologically impaired children, vomiting due to GER must be distinguished from chronic retching.

The work-up of patients suspected of having GERD includes documentation of the episodes of reflux and evaluation of the anatomy. A barium swallow examination should be performed as an initial test. The results will indicate whether there is obstruction of the stomach or duodenum (due to duodenal webs or pyloric stenosis) and will determine whether malrotation

is present. The frequency and severity of reflux should be assessed using a 24-hour pH probe study. Although this test is poorly tolerated, it provides the most accurate determination that GERD is present. Esophageal endoscopy with biopsies may identify the presence of esophagitis and is useful to determine the length of the intra-abdominal esophagus and detect the presence of Barrett's esophagus. Some surgeons order a radioisotope "milk scan" to evaluate gastric emptying, although there is little evidence to show that this test changes management when a diagnosis of GERD has been confirmed using the aforementioned modalities.

TREATMENT

Most patients with GERD are treated initially by conservative means. In the infant, propping up the child and thickening the formula with rice cereal are generally recommended. Some authors prefer a prone, head-up position. In the infant unresponsive to position and formula changes and the older child with severe GERD, medical therapy based on gastric acid reduction with an H₂ blocking agent and/or a proton pump inhibitor is initiated. Medical therapy is successful in most neurologically normal infants and younger children, many of whom will outgrow their need for medications. In certain patients, however, medical treatment does not provide symptomatic relief and surgery is therefore indicated. The least invasive surgical option is the placement of a nasojejunal or gastrojejunal feeding tube. Because the stomach is bypassed, food contents do not enter the esophagus, and symptoms are often improved. As a long-term remedy, however, this therapy is associated with several problems. The tubes often become dislodged, acid reflux still occurs, and bolus feeding is generally not possible. Fundoplication provides definitive treatment for gastroesophageal reflux and is highly effective in most circumstances. The fundus may be wrapped around the distal esophagus either 360 degrees (i.e., Nissen fundoplication) or to lesser degrees (i.e., Thal or Toupet fundoplication). At present, the standard approach in most children is to perform these procedures laparoscopically whenever possible. In children with feeding difficulties and in infants <1 year of age, a gastrostomy tube should be placed at the time of surgery. Early postoperative complications include pneumonia and atelectasis, often due to inadequate pulmonary toilet and inadequate pain control with abdominal splinting. Late postoperative complications include wrap breakdown with recurrent reflux, which may require repeat fundoplication, and dysphagia due to a wrap that is too tight, which generally responds to dilation. These complications are more common in children with neurologic impairment. The keys to successful surgical management of patients with GERD include careful patient selection and meticulous operative technique.

GASTROINTESTINAL TRACT

Approach to the Vomiting Infant

The majority of infants vomit. Because infant vomiting is so common, it is important to differentiate between normal vomiting—as occurs in almost all infants, to some degree—and abnormal vomiting, which may be indicative of a potentially serious underlying disorder. The color of the emesis and the child's overall condition must be assessed. Vomit that looks like feeds and comes up immediately after a feeding is almost always *gastroesophageal reflux*. This may or may not be of concern, as described earlier. Vomiting that occurs a short while after feeding, or indeed vomiting that projects out of the baby's mouth, may be indicative of *pyloric stenosis*. By contrast, *vomit that has any green color in it is always worrisome*. This may be reflective of intestinal *volvulus*, an underlying infection, or some other cause of intestinal obstruction. A more detailed description of the management of these conditions is provided in the following sections.

Hypertrophic Pyloric Stenosis

CLINICAL MANIFESTATIONS

The ability to provide timely diagnosis and treatment of infants with hypertrophic pyloric stenosis (HPS) is another milestone in the history of pediatric surgery. HPS occurs in approximately 1 in 300 live births and originally was believed to occur in first-born males between 3 and 6 weeks of age. Subsequent studies determined that this was a statistical error; investigators did not account for the incidence of first-born males as a group. However, children with HPS outside of this age range are commonly seen, and the cause of HPS has not been determined. Studies have shown that HPS is found in several generations of the same family, which suggests a familial link. Administration of erythromycin in early infancy was also thought to be linked to the subsequent development of HPS, but rates of HPS have not decreased with the decline in the use of erythromycin, so this may also have been an erroneous conclusion.

Infants with HPS present with nonbilious vomiting that becomes increasingly projectile over the course of several days to weeks. Eventually, the infant develops almost complete gastric outlet obstruction and is no longer able to tolerate even clear liquids. Despite the recurrent emesis, the child normally has a voracious appetite, which leads to a cycle of feeding and vomiting that invariably results in severe dehydration if the condition is untreated. Jaundice may occur in association with HPS, although the reason for this is unclear. Particularly perceptive caregivers will mention that the infant is passing less flatus, which provides a further clue that gastric outlet obstruction is complete.

Infants with HPS develop a hypochloremic, hypokalemic metabolic alkalosis. The urine pH is high initially but eventually drops because hydrogen ions are preferentially exchanged for sodium ions in the distal tubule of the kidney as the hypochloremia becomes severe. The diagnosis of pyloric stenosis usually can be made on physical examination by palpation of the typical "olive" in the right upper quadrant and the presence of visible gastric waves on the abdomen. When the olive cannot be palpated, ultrasonography can diagnose the condition accurately in 95% of patients. Criteria for ultrasonographic diagnosis include a channel length of >16 mm and pyloric thickness of >4 mm.

TREATMENT

Pyloric stenosis is never a surgical emergency, although the dehydration and electrolyte abnormalities may present a medical emergency. Fluid resuscitation with correction of electrolyte abnormalities and metabolic alkalosis is essential before induction of general anesthesia for operation. For most infants, administration of fluid containing 5% dextrose and 0.45% saline with 2 to 4 mEq/kg of added potassium at a rate of approximately 150 to 175 mL/kg for 24 hours will correct the underlying deficit. It is important to ensure that the child has an adequate urine output (>1 mL/kg per hour) as further evidence that rehydration has occurred. After resuscitation, a Fredet-Ramstedt pyloromyotomy is performed (Fig. 39-12). The procedure may be performed using an open or laparoscopic approach. Open pyloromyotomy is performed through either an umbilical or a right upper quadrant transverse abdominal incision. The former route is cosmetically more appealing, although the transverse incision provides easier access to the antrum and pylorus. In recent years, the laparoscopic approach has gained great popularity. Two randomized trials have demonstrated that both the open and laparoscopic approaches may be performed safely with equal incidence of postoperative complications, although the cosmetic result is definitely superior after the laparoscopic approach. Whether performed using an open or laparoscopic approach, surgical treatment of pyloric stenosis involves splitting the pyloric muscle until the submucosa bulges upward. The incision begins at the pyloric vein of Mayo and extends onto the gastric antrum; it typically measures between 1 and 2 cm in length. Postoperatively, IV fluids are continued for several hours, after which an oral electrolyte solution (Pedialyte) is offered, followed by formula or breast milk, which is gradually increased to 60 mL every 3 hours. Most infants can be discharged home within 24 to 48 hours after surgery. Recently, several authors have shown that ad lib feedings are safely tolerated by the neonate and result in a shorter

hospital stay.

Fredet-Ramstedt pyloromyotomy. **A.** Pylorus delivered into wound and seromuscular layer incised. **B.** Seromuscular layer separated down to the submucosal base to permit herniation of mucosa through the pyloric incision. **C.** Cross-section demonstrating the hypertrophied pylorus, depth of incision, and spreading of muscle to permit mucosa to be herniated through the incision.

The complications of pyloromyotomy include perforation of the mucosa (1 to 3%), bleeding, wound infection, and recurrent symptoms due to inadequate myotomy. When perforation occurs, the mucosa is repaired with a stitch that is placed to tack the mucosa down and reapproximate the serosa in the region of the tear. A nasogastric tube is left in place for 24 hours and taped securely to prevent it from reinjuring the repaired mucosa. The outcome is generally very good.

Intestinal Obstruction in the Newborn

The cardinal symptom of intestinal obstruction in the newborn is bilious emesis. Prompt recognition and treatment of neonatal intestinal obstruction can truly be lifesaving.

Intestinal obstruction can be classified as either proximal or distal, based on the clinical presentation. Proximal obstruction presents as bilious vomiting with minimal abdominal distention. In cases of complete obstruction, there may be a paucity of gas, or no distal air may be seen on the supine and upright films of the abdomen. In this case, the diagnosis of malrotation and midgut volvulus must be excluded. Distal obstruction presents with abdominal distention and bilious emesis. The physical examination will determine whether the anus is patent. Calcifications on the plain abdominal radiograph may indicate meconium peritonitis; pneumatosis and/or free abdominal air indicates necrotizing enterocolitis with or without intestinal perforation. A contrast enema study will show whether there is a microcolon indicative of jejunoileal atresia or meconium ileus. If a microcolon is not present, then the diagnoses of Hirschsprung's disease, small left colon syndrome, or meconium plug syndrome should be considered. In all cases of intestinal obstruction, it is vital to obtain abdominal films in the supine and upright (lateral decubitus) views. This is the only way to assess the presence of air-fluid levels or free air and to characterize the obstruction as proximal or distal. Moreover, unless a contrast agent is used, it is difficult to determine whether a loop of dilated bowel is part of the small or of the large intestine, because the neonatal bowel lacks typical features, such as haustra or plicae circulares, that characterize these loops in older children or adults. For this reason, care must be taken to take a complete prenatal history, to perform a thorough physical examination, and to determine the need for further contrast studies as opposed to immediate abdominal exploration.

DUODENAL OBSTRUCTION

Whenever the diagnosis of duodenal obstruction is entertained, malrotation and midgut volvulus must be excluded. This topic is covered in further detail later. Other causes of duodenal obstruction include duodenal atresia, duodenal web, stenosis, annular pancreas, and duodenal duplication cyst. Duodenal obstruction is easily diagnosed by prenatal ultrasonography, which demonstrates the fluid-filled stomach and proximal duodenum as two discrete cystic structures in the upper abdomen. Associated polyhydramnios is common and presents in the third trimester. In 85% of infants with duodenal obstruction, the entry of the bile duct is proximal to the level of obstruction, so that vomiting is bilious. Abdominal distention is typically not present because of the proximal level of obstruction. In those infants with obstruction proximal to the bile duct entry, the emesis is nonbilious. The classic finding on abdominal radiograph is the "double bubble" sign, which represents the dilated stomach and duodenum (Fig. 39-13). In association with the appropriate clinical picture, this finding is sufficient to confirm the diagnosis of duodenal obstruction. If there is any uncertainty, however, particularly when a partial obstruction is suspected, an upper GI series with contrast is diagnostic.

Fig. 39-13.

Abdominal radiograph showing the "double bubble" sign in a newborn infant with duodenal atresia. The two bubbles are numbered.

Treatment

An orogastric tube is inserted to decompress the stomach and duodenum, and the infant is given IV fluids to maintain adequate urine output. If the infant appears ill, or if abdominal tenderness is present, a diagnosis of malrotation and midgut volvulus should be considered, and surgery should not be delayed. Typically, the abdomen is soft and the infant is in very stable condition. Under these circumstances, the infant should be evaluated thoroughly for other associated anomalies. Approximately one third of newborns with duodenal atresia have associated Down syndrome (trisomy 21). These patients should be evaluated for associated cardiac anomalies. Once the work-up is complete and the infant's condition is stable, he or she is taken to the operating room and the abdomen is entered through a transverse right upper quadrant supraumbilical incision under general endotracheal anesthesia. A search for associated anomalies should be performed at the time of the operation. These include malrotation, anterior portal vein, a second distal web, and biliary atresia. The surgical treatment of choice for duodenal obstruction due to duodenal stenosis or atresia or annular pancreas is a duodenoduodenostomy. This procedure can be most easily performed using a proximal transverse-to-distal longitudinal (diamond-shaped) anastomosis. In cases in which the duodenum is extremely dilated, the lumen may be tapered using a linear stapler with a large Foley catheter (24F or greater) in the duodenal lumen. It is important to emphasize that an annular pancreas is never divided. Treatment of duodenal web includes vertical duodenotomy, partial excision of the web (to avoid injury to the inserting pancreatobiliary ducts), oversewing of the mucosa, and horizontal closure of the duodenotomy. Gastrostomy tubes are not placed routinely. Recently reported survival rates exceed 90%. Late complications from repair of duodenal atresia occur in approximately 12 to 15% of patients and include megaduodenum, intestinal motility disorders, and gastroesophageal reflux.

Intestinal Atresia

Obstruction due to intestinal atresia can occur at any point along the intestinal tract. Based on early studies in which various types of atresia were modeled in dogs by creating vascular injuries, most small intestine atresias (but not duodenal atresias) are believed to be caused by in utero mesenteric vascular accidents leading to segmental loss of the intestinal lumen. Work with transgenic mouse models currently calls this hypothesis into question, however, and suggests that atresias may be multifactorial. The incidence of intestinal atresia has been estimated to be between 1 in 2000 to 1 in 5000 live births, with equal representation of the sexes. Infants with jejunal or ileal atresia present with bilious vomiting and progressive abdominal distention. The more distal the obstruction, the more distended the abdomen and the greater the number of obstructed loops on upright abdominal films (Fig. 39-14).

Intestinal obstruction in the newborn showing several loops of distended bowel with air-fluid levels. This child has jejunal atresia.

In cases in which the diagnosis of complete intestinal obstruction is determined based on the clinical picture and the presence of staggered air-fluid levels on plain abdominal films, the child can be brought to the operating room after appropriate resuscitation. In these circumstances, there is little extra information to be gained by performing a barium enema study. In contrast, when diagnostic uncertainty exists, or when distal intestinal obstruction is apparent, a barium

enema study is useful to establish whether a microcolon is present and to diagnose the presence of meconium plugs, small left colon syndrome, Hirschsprung's disease, or meconium ileus. Use of barium enema testing is therefore required to safely manage neonatal intestinal obstruction, based on an understanding of the expected level of obstruction.

Surgical correction of the small intestinal atresia should be performed urgently. At laparotomy, one of several types of atresia will be encountered. In type I there is a mucosal atresia with intact muscularis. In type 1 the atretic ends are connected by a fibrous band. In type 3A the two ends of the atresia are separated by a V-shaped defect in the mesentery. Type 3B is an "apple-peel" deformity or "Christmas tree" deformity in which the bowel distal to the atresia receives its blood supply in a retrograde fashion from the ileocolic or right colic artery (Fig. 39-15). In type 4 there are multiple atresias that have a "string of sausage" or "string of beads" appearance. The disparity in lumen size between the proximal distended bowel and the small-diameter collapsed bowel distal to the atresia has led to a number of innovative techniques of anastomosis. Under most circumstances, however, an anastomosis can be performed using the end-to-back technique in which the distal, compressed loop is "fish-mouthed" along its antimesenteric border. The proximal distended loop can be tapered as described earlier. Because the distended proximal bowel rarely has normal motility, the extremely dilated portion should be resected before the anastomosis is performed.

Intraoperative photograph of newborn with "Christmas tree" type of ileal atresia.

Occasionally the infant with intestinal atresia will develop ischemia or necrosis of the proximal segment secondary to volvulus

of the dilated, bulbous, blind-ending proximal bowel. Under these conditions, an end ileostomy and mucus fistula should be created, and the anastomosis should be deferred to another time after the infant stabilizes.

MALROTATION AND MIDGUT VOLVULUS

Embryology

During the sixth week of fetal development, the midgut grows too rapidly to be accommodated in the abdominal cavity and therefore prolapses into the umbilical cord. Between the tenth and twelfth weeks, the midgut returns to the abdominal cavity, undergoing a 270-degree counterclockwise rotation around the superior mesenteric artery. Because the duodenum also rotates caudal to the artery, it acquires a C loop that traces this path. The cecum rotates cephalad to the artery, which determines the location of the transverse and ascending colon. Subsequently, the duodenum becomes fixed retroperitoneally in its third portion and at the ligament of Treitz, whereas the cecum becomes fixed to the lateral abdominal wall by peritoneal bands. The takeoff of the branches of the superior mesenteric artery elongates and becomes fixed along a line extending from its emergence from the aorta to the cecum in the right lower quadrant. Although the process is not well understood, genetic mutations may predispose the host to malrotation. For instance, mutations in the gene *BCL6* resulting in absence of left-sided expression of its transcript lead to reversed cardiac orientation, defective ocular development, and malrotation. If rotation is incomplete, the cecum remains in the epigastrium, but the bands fixing the duodenum to the retroperitoneum and cecum continue to form. This results in the creation of (Ladd's) bands extending from the cecum to the lateral abdominal wall and crossing the duodenum, which creates the potential for obstruction. The mesenteric takeoff remains confined to the epigastrium, so that a narrow pedicle suspends all the branches of the superior mesenteric artery and the entire midgut. A volvulus may therefore occur around the mesentery. This twist not only obstructs the proximal jejunum but also cuts off the blood supply to the midgut. Intestinal obstruction and complete infarction of the midgut occur unless the problem is promptly corrected surgically.

PRESENTATION AND MANAGEMENT

Midgut volvulus can occur at any age, although it is seen most often in the first few weeks of life. Bilious vomiting is usually the first sign of volvulus, and all infants with bilious vomiting must be evaluated rapidly to ensure that they do not have intestinal malrotation with volvulus. This diagnosis should be suspected in a child with irritability and bilious emesis. If the condition is left untreated, vascular compromise of the midgut initially causes bloody stools but eventually results in circulatory collapse. Additional clues to the presence of advanced ischemia of the intestine include erythema and edema of the abdominal wall, which progresses to shock and death. It must be re-emphasized that the index of suspicion for this condition must be high, because abdominal signs are minimal in the early stages. Abdominal films show a paucity of gas throughout the intestine with a few scattered air-fluid levels (Fig. 39-16). When these findings are present, the patient should undergo immediate fluid resuscitation to ensure adequate perfusion and urine output, followed by prompt exploratory laparotomy.

Abdominal radiograph of a 10-day-old infant with bilious emesis. Note the dilated proximal bowel and the paucity of distal bowel gas, characteristic of a volvulus.

Often the patient will not appear ill, and the plain films may suggest partial duodenal obstruction. Under these conditions, the patient may have malrotation without volvulus. This is best diagnosed by an upper GI series, which will show incomplete rotation with the duodenojejunal junction displaced to the right. The duodenum may show a corkscrew appearance, which is diagnostic of volvulus, or complete duodenal obstruction, with the small bowel loops entirely in the right side of the abdomen. A barium enema study may show a displaced cecum, but this sign is unreliable, especially in the small infant in whom the cecum is normally in a somewhat higher position than in the older child.

When volvulus is suspected, early surgical intervention is mandatory if the ischemic process is to be avoided or reversed. Volvulus occurs clockwise, and it is therefore untwisted counterclockwise. This can be remembered by using the memory aid "Turn back the hands of time." Subsequently, Ladd's procedure is performed. This operation does not correct the malrotation but does broaden the narrow mesenteric pedicle to prevent volvulus from recurring. This procedure is performed as follows (Fig. 39-17): The bands between the cecum and the abdominal wall and between the duodenum and terminal ileum are divided sharply to splay out the superior mesenteric artery and its branches. This maneuver brings the straightened duodenum into the right lower quadrant and the cecum into the left lower quadrant. The appendix is removed to avoid diagnostic errors in later life. No attempt is made to suture the cecum or duodenum in place. When ischemia is advanced, the volvulus is reduced without performing Ladd's procedure, and a second look is taken 24 to 36 hours later, which often shows some vascular recovery. A plastic transparent silo may be placed to facilitate constant evaluation of the intestine and to plan

for the timing of re-exploration. Frankly necrotic bowel can then be resected conservatively. With early diagnosis and correction the prognosis is excellent. However, diagnostic delay can lead to mortality or to short-bowel syndrome requiring intestinal transplantation.

Ladd's procedure for malrotation. **A.** Lysis of cecal and duodenal bands. **B.** Broadening of the mesentery. **C.** Appendectomy.

A subset of patients with malrotation show chronic obstructive symptoms. These symptoms may result from Ladd's bands across the duodenum or, occasionally, from intermittent volvulus. Symptoms include intermittent abdominal pain and intermittent vomiting, which may occasionally be bilious. Infants with malrotation may demonstrate failure to thrive, and they

may be diagnosed initially as having gastroesophageal reflux disease. Surgical correction using Ladd's procedure as described earlier can prevent volvulus from occurring and improve symptoms in many instances. One should note, however, that volvulus can still occur after Ladd's procedure is performed, although this is uncommon.

MECONIUM ILEUS

Pathogenesis and Clinical Presentation

Infants with cystic fibrosis have characteristic pancreatic enzyme deficiencies and abnormal chloride secretion in the intestine that result in the production of viscous, water-poor meconium. Meconium ileus occurs when this thick, highly viscous meconium becomes impacted in the ileum and leads to high-grade intestinal obstruction. Meconium ileus can be either uncomplicated, in which there is no intestinal perforation, or complicated, in which prenatal perforation of the intestine has occurred or vascular compromise of the distended ileum develops. Antenatal ultrasonography may reveal the presence of intra-abdominal or scrotal calcifications, or distended bowel loops. These infants present shortly after birth with progressive abdominal distention, intermittent bilious emesis, and failure to pass meconium. Abdominal radiographs show dilated loops of intestine. Because the enteric contents are so viscous, air-fluid levels do not form, even when obstruction is complete. Small bubbles of gas become entrapped in the inspissated meconium in the distal ileum, where they produce a characteristic ground-glass appearance.

The diagnosis of meconium ileus is confirmed by a contrast enema study, which typically demonstrates a microcolon. In patients with uncomplicated meconium ileus, the terminal ileum is filled with pellets of meconium. In patients with complicated meconium ileus, intraperitoneal calcifications form, producing an eggshell pattern on plain abdominal radiograph.

Management

The treatment strategy depends on whether the patient has complicated or uncomplicated meconium ileus. Patients with uncomplicated meconium ileus can be treated nonoperatively. A dilute water-soluble contrast agent is advanced through the colon under fluoroscopic control into the dilated portion of the ileum. Because these contrast agents act partially by absorbing fluid from the bowel wall into the intestinal lumen, maintaining adequate hydration of the infant during this maneuver is extremely important. The enema may be repeated at 12-hour intervals over several days until all the meconium is evacuated. Failure to reflux the contrast into the dilated portion of the ileum signifies the presence of an associated atresia or complicated meconium ileus and thus warrants exploratory laparotomy. If surgical intervention is required because of failure of contrast enemas to relieve obstruction, operative irrigation with dilute contrast agent, *N*-acetylcysteine (Mucomyst), or saline through a purse-string suture may be successful. Alternatively, resection of the distended terminal ileum is performed, and the meconium pellets are flushed from the distal small bowel. At this point, ileostomy and mucus fistula may be created from the proximal and distal ends, respectively. Alternatively, a Bishop-Koop anastomosis or an end-to-end anastomosis may be performed (Fig. 39-18).

Techniques of intestinal anastomosis for infants with small-bowel obstruction. **A.** End-to-back anastomosis. The distal limb has been incised to create a "fish mouth" to enlarge the lumen. **B.** Bishop-Koop anastomosis. The proximal distended limb is joined to the side of the distal small bowel, which is vented by "chimney" to the abdominal wall. **C.** Tapering anastomosis. A portion of the antimesenteric wall of the proximal bowel is excised, with longitudinal closure to minimize disparity in the limbs. **D.** A Mikulicz double-barreled enterostomy is constructed by suturing the two limbs together and then exteriorizing the double stoma. The common wall can be crushed with a special clamp to create one large stoma. The stoma can be closed in an extraperitoneal manner.

NECROTIZING ENTEROCOLITIS

Clinical Features

Necrotizing enterocolitis (NEC) is the most frequent and lethal GI tract disorder affecting the intestine of the stressed, preterm neonate. Over 25,000 cases of NEC are reported annually. The overall mortality ranges between 10 and 50%. As a result of advances in neonatal care such as surfactant therapy as well as improved methods of mechanical ventilation, an increasing number of low-birth-weight infants are surviving neonatal hyaline membrane disease. This growing group of survivors of neonatal respiratory distress syndrome increases the number of infants at risk for developing NEC. Consequently, it is estimated that NEC soon will surpass respiratory distress syndrome as the principal cause of death in the preterm infant.

Multiple risk factors have been associated with the development of NEC. These include prematurity, initiation of enteral feeding, bacterial infection, intestinal ischemia resulting from birth asphyxia, umbilical artery cannulation, persistence of a patent ductus arteriosus, cyanotic heart disease, and maternal cocaine abuse. Nonetheless, the mechanisms by which these complex interacting causes lead to the development of NEC remain undefined. The only consistent epidemiologic precursors for NEC are prematurity and enteral alimentation, which represent the commonly encountered clinical situation of a stressed infant who is fed enterally. Of note, there is some debate regarding the importance of enteral alimentation in the pathogenesis of NEC. A prospective randomized study showed no increase in the incidence of NEC despite adoption of an aggressive feeding strategy, and up to 10% of infants with NEC have never received any form of enteral nutrition.

The indigenous intestinal microbial flora has been postulated to play a central role in the pathogenesis of NEC. Bacterial colonization may be a prerequisite for the development of this disease, because oral prophylaxis with vancomycin or gentamicin reduces the incidence of NEC. The importance of bacteria in the pathogenesis of NEC is further supported by the finding that NEC occurs in episodic waves that can be abrogated by infection control measures and the fact that NEC usually develops at least 10 days postnatally, when the GI tract is colonized by coliforms. More recently, outbreaks of NEC have been reported in infants fed formula contaminated with *Enterobacter sakazakii*. Common bacterial isolates from the blood, peritoneal fluid, and stool of infants with advanced NEC include *Escherichia coli*, *Enterobacter*, *Klebsiella*, and occasionally coagulase-negative *Staphylococcus* species.

NEC may involve single or multiple segments of the intestine, most commonly the terminal ileum, followed by the colon. The gross findings in NEC include bowel distention with patchy areas of thinning, pneumatosis, gangrene, and frank perforation. The microscopic features include the appearance of a bland infarct characterized by full-thickness necrosis.

Clinical Manifestations

Infants with NEC present with a spectrum of disease. In general, the infants are premature and may have sustained one or more episodes of stress, such as birth asphyxia, or they may have congenital cardiac disease. The clinical picture of NEC has been characterized by Bell and colleagues as progressing from a period of mild illness to a period of severe, life-threatening sepsis. Although not all infants progress through the various Bell stages, this classification scheme provides a useful format to describe the clinical picture associated with the development of NEC. In the earliest stage (Bell stage I), infants present with feeding intolerance. This is suggested by vomiting or by the presence of a large residual volume from a previous feeding in the stomach at the time of the next feeding. If they receive appropriate treatment, which consists of bowel rest and IV antibiotics, many of these infants will not progress to more advanced stages of NEC. These infants are colloquially described as experiencing a "NEC scare" and represent a population of neonates who are at risk of developing more severe NEC if a more prolonged period of stress supervenes.

Infants with Bell stage II disease have established NEC that is not immediately life-threatening. Clinical findings include abdominal distention and tenderness, bilious nasogastric aspirate, and bloody stools. These findings indicate the development

of intestinal ileus and mucosal ischemia. Abdominal examination may reveal a palpable mass indicating the presence of an inflamed loop of bowel, diffuse abdominal tenderness, cellulitis, and edema of the anterior abdominal wall. The infant may appear systemically ill, with decreased urine output, hypotension, tachycardia, and noncardiac pulmonary edema. Hematologic evaluation reveals either leukocytosis or leukopenia, an increase in the number of bands, and thrombocytopenia. An increase in the blood urea nitrogen and plasma creatinine levels may be found, which signifies the development of renal dysfunction. The diagnosis of NEC may be confirmed by abdominal radiography. The pathognomonic radiographic finding in NEC is pneumatosis intestinalis, which represents invasion of the ischemic mucosa by gas-producing microbes (Fig. 39-19). Other findings include the presence of ileus or portal venous gas. The latter is a transient finding that indicates severe NEC with intestinal necrosis. A fixed loop of bowel may be seen on serial abdominal radiographs, which suggests the possibility that a diseased loop of bowel, potentially with a localized perforation, is present. Although these infants are at risk of progressing to more severe disease, with timely and appropriate treatment, they often recover.

Abdominal radiograph of infant with necrotizing enterocolitis. Arrows point to area of pneumatosis intestinalis.

Infants with Bell stage III disease have the most advanced form of NEC. Abdominal radiographs often demonstrate the presence of pneumoperitoneum, which indicates that intestinal perforation has occurred. In these patients NEC may follow a fulminant course with progressive peritonitis, acidosis, sepsis, disseminated intravascular coagulopathy, and death.

PATHOGENESIS OF NECROTIZING ENTEROCOLITIS

Several theories have been proposed to explain the development of NEC. To more precisely understand the mechanisms that

contribute to the pathogenesis of NEC, several groups have focused on understanding the potential clues that may be revealed by studying patients who have progressed from Bell stage I to Bell stage III disease. In general, the development of diffuse pneumatosis intestinalis—which is associated with the development of stage II NEC—is thought to be due to the presence of gas within the wall of the intestine from enteric bacteria, which suggests a causative role of bacteria in the pathogenesis of NEC. Furthermore, the development of pneumoperitoneum indicates disease progression with severe disruption of the intestinal barrier (intestinal perforation). Finally, systemic sepsis with diffuse multisystem organ dysfunction suggests a role for circulating proinflammatory cytokines in the pathogenesis of NEC. It has also been demonstrated that the premature intestine responds in an exaggerated fashion to bacterial products, which renders the host susceptible to barrier dysfunction and the development of NEC.

TREATMENT

In all infants suspected of having NEC, feedings are discontinued, a nasogastric tube is placed, and broad-spectrum parenteral antibiotics are given. The infant is resuscitated, and inotropes are administered to maintain perfusion as needed. Intubation and mechanical ventilation may be required to maintain oxygenation. TPN is started. Subsequent treatment may be influenced by the particular stage of NEC that is present. Patients with Bell stage I disease are closely monitored and generally remain on nil per os (NPO) status and are given IV antibiotics for 7 to 10 days before enteral nutrition is resumed. After this time, provided the infant fully recovers, feedings may be reinitiated.

Patients with Bell II disease merit close observation. Serial physical examinations are performed to look for the development of diffuse peritonitis, a fixed mass, progressive abdominal wall cellulitis, or systemic sepsis. If the infant fails to improve after several days of treatment, consideration should be given to exploratory laparotomy. Paracentesis may be performed, and if Gram's stain demonstrates multiple organisms and leukocytes, perforation of the bowel should be suspected, and the patient should undergo laparotomy.

In the most severe form of NEC (Bell stage III), patients have definite intestinal perforation or have not responded to nonoperative therapy. Two schools of thought exist regarding further management. One group favors exploratory laparotomy. At laparotomy, frankly gangrenous or perforated bowel is resected, and the intestinal ends are brought out as stomas. When there is massive intestinal involvement, marginally viable bowel is retained and a second-look procedure is carried out after the infant's condition stabilizes (24 to 48 hours). Patients with extensive necrosis at the second look may be managed by placing a proximal diverting stoma, resecting bowel that is definitely not viable, and leaving questionably viable bowel behind, distal to the diverted segment. If the intestine is viable except for a localized perforation without diffuse peritonitis, and if the infant's clinical condition permits, intestinal anastomosis may be performed. In cases in which the diseased, perforated segment cannot be safely resected, drainage catheters may be left in the region of the diseased bowel, and the infant is allowed to reach stable condition.

An alternative approach to the management of infants with perforated NEC involves drainage of the peritoneal cavity. This may be performed under local anesthesia at the bedside and can be an effective means of stabilizing the desperately ill infant by relieving increased intra-abdominal pressure and allowing ventilation. When successful, this method also permits drainage of perforated bowel by establishment of a controlled fistula. Approximately one third of infants treated with drainage alone survive without requiring additional operations. Infants who do not respond to peritoneal drainage alone after 48 to 72 hours should undergo laparotomy. This procedure allows for the resection of frankly necrotic bowel and diversion of the fecal stream, and facilitates more effective drainage. It is noteworthy that a recent randomized controlled trial demonstrated that

outcomes were similar in infants with NEC who were treated with primary peritoneal drainage and in those who were treated with laparotomy.

NECROTIZING ENTEROCOLITIS IN OLDER INFANTS

Although NEC is typically a disease that affects preterm infants, several independent groups have reported a tendency for early onset of NEC in term and near-term infants. In these patients, the pattern of disease was found to be different from that found in premature infants. Specifically, NEC in older infants typically is localized to the end of the small intestine and beginning of the colon, which suggests an ischemic pathophysiology. Four pertinent associated conditions are observed in term infants who develop NEC: congenital heart disease, in utero growth restriction, polycythemia, and perinatal hypoxic-ischemic events. As with NEC in preterm infants, NEC in older patients is also associated with formula consumption and is very rare in exclusively breastfed infants. Infants with NEC at full term typically present with bloody stools, and the disease is characterized by rapid onset of symptoms and a fulminant course. Thus, although it is true that NEC is typically a disease of premature infants, in the appropriate setting, NEC can develop at any age.

SPONTANEOUS INTESTINAL PERFORATION VS. NECROTIZING ENTEROCOLITIS

In addition to NEC, preterm infants with intestinal pathology may develop spontaneous intestinal perforation (SIP). SIP is a distinct clinical entity from NEC and is essentially a perforation in the terminal ileum. The histopathologic features of SIP are different from those of NEC. Specifically, the mucosa is not necrotic, there is no sign of ischemia, and the submucosa is thinned at the site of perforation. Unlike in NEC, in SIP pneumatosis intestinalis is absent. Moreover, the demographics of NEC and SIP are slightly different, in that infants with SIP tend to be slightly more premature, smaller, and more likely to have been receiving inotropic support. However, NEC and SIP occur with similar frequency in low-birth-weight infants. The outcome of patients in the two groups is slightly different. Because infants with SIP have isolated disease without necrosis or systemic inflammation, they tend to have a better outcome. In short, the diagnosis of SIP vs. NEC has important prognostic significance. The treatment strategies, however, are essentially the same.

Outcome

Survival of patients with NEC is dependent on the stage of disease, the extent of prematurity, and the presence of associated comorbidities. Survival by stage has recently been shown to be approximately 85, 65, and 35% for infants with stages I, II, and III NEC, respectively. Strictures develop in 20% of medically or surgically treated patients, and a contrast enema study is mandatory before intestinal continuity is re-established. If all other factors are favorable, the ileostomy is closed when the child is between 2 and 2.5 kg. At the time of stoma closure, the entire intestine should be examined to search for possible strictures or other stigmata of NEC. Patients who have massive intestinal necrosis are at risk of developing short-bowel syndrome, particularly when the total length of the viable intestinal segment is <40 cm. These patients require TPN to provide adequate calories for growth and development, and may develop parenteral nutrition–associated cholestasis and hepatic fibrosis. In a significant number of these patients, transplantation of the liver and small bowel may be required.

SHORT-BOWEL SYNDROME

Short-bowel syndrome (SBS) is an expensive, morbid condition that is increasing in incidence. Congenital and perinatal conditions such as gastroschisis, malrotation, atresia, and NEC may lead to SBS. As noted previously, NEC is the most common GI emergency in neonates and occurs primarily in premature infants. As rates of prematurity are rising, so are the numbers of children with SBS and NEC. In addition, prevalence is increased for other diagnoses such as gastroschisis, which

has nearly doubled. Medical and surgical treatment options carry high dollar and human costs and morbidities, including multiple infections and hospitalizations for vascular access, liver failure in conjunction with parenteral nutrition–associated cholestasis, and death. Small bowel transplantation has a reported 5-year graft survival of 48% but is attended by rejection, the morbidity of major surgery, and a lifelong need for antirejection medication. A report on 989 grafts in 923 patients by the Intestine Transplant Registry reveals improving outcomes, but 1-year graft and patient survival rates are 65 and 77%, respectively. Preliminary data from research in a Lewis rat model of SBS indicate that transplantation of autologous cells may also aid patients someday. Tissue-engineered intestine proved an effective rescue therapy after massive small bowel resection. In the human, engineered intestine from autologous cells would avoid the problems of transplant-donor supply and immunosuppression. Because engineered small and large intestine, esophagus, stomach, and specific portions of the GI tract such as the gastroesophageal junction are formed by the same process, other intestinal deficiencies may possibly be addressed.

INTUSSUSCEPTION

Intussusception is the leading cause of intestinal obstruction in the young child. The term refers to the condition in which a segment of intestine becomes drawn into the lumen of the more proximal bowel. The process usually begins in the region of the terminal ileum and extends distally into the ascending, transverse, or descending colon. Rarely, an intussusception may prolapse through the rectum.

The cause of intussusception is not clear, although one hypothesis suggests that hypertrophy of Peyer's patches in the terminal ileum from an antecedent viral infection acts as a lead point. Peristaltic action of the intestine then causes the bowel distal to the lead point to invaginate into itself. Idiopathic intussusception occurs in children between approximately 6 and 24 months of age. Beyond this age group, one should consider the possibility that a pathologic lead point may be present. These include polyps, malignant tumors such as lymphoma, enteric duplication cysts, and Meckel's diverticulum. Such intussusceptions are rarely reduced by air or contrast enema, and thus the lead point is identified when operative reduction of the intussusception is performed.

Clinical Manifestations

Because intussusception is frequently preceded by a GI tract viral illness, the onset may not be easily determined. Typically, the infant develops paroxysms of crampy abdominal pain and intermittent vomiting. Between attacks, the infant may act normally, but as symptoms progress, increasing lethargy develops. Bloody mucus (currant jelly stool) may be passed per rectum. Ultimately, if reduction is not accomplished, gangrene of the intussusceptum occurs, and perforation may ensue. On physical examination, an elongated mass is detected in the right upper quadrant or epigastrium with an absence of bowel in the right lower quadrant (Dance's sign). The mass may be seen on plain abdominal radiograph but is more easily demonstrated on air or contrast enema.

Treatment

Patients with intussusception should be assessed for the presence of peritonitis and for the severity of systemic illness. After resuscitation and administration of IV antibiotics, the child is evaluated for suitability to proceed with radiographic vs. surgical reduction. In the absence of peritonitis, the child should undergo radiographic reduction. If peritonitis is present, or if the child appears systemically ill, urgent laparotomy is indicated.

In the patient in stable condition, the air enema is both diagnostic and often curative. It constitutes the preferred method of

diagnosis and nonoperative treatment of intussusception. Air is introduced with a manometer and the pressure that is administered is carefully monitored. Under most instances, this should not exceed 120 mmHg. Successful reduction is marked by free reflux of air into multiple loops of small bowel and symptomatic improvement as the infant suddenly becomes pain free. Unless both of these indications are observed, it cannot be assumed that the intussusception is reduced. If reduction is unsuccessful and the infant's condition remains stable, the infant should be brought back to the radiology suite for a repeat attempt at reduction after a few hours. This strategy has improved the success rate of nonoperative reduction in many centers. In addition, hydrostatic reduction with barium may be useful if pneumatic reduction is unsuccessful. The overall success rate of radiographic reduction varies based on the experience of the center but is typically between 60 and 90%.

If nonoperative reduction is successful, the infant may be given oral fluids after a period of observation. Failure to reduce the intussusception mandates surgery. Two approaches are used. In an open procedure, exploration is carried out through a right lower quadrant incision, with delivery of the intussuscepted mass into the wound. Reduction usually can be accomplished by gentle distal pressure, with the intussusceptum gently milked out of the intussusciens (Fig. 39-20). Care should be taken not to pull the bowel out, as this can cause damage to the bowel wall. The blood supply to the appendix is often compromised, and appendectomy is performed. If the bowel is frankly gangrenous, resection and primary anastomosis is performed. In experienced hands, laparoscopic reduction may be performed, even in very young infants. The procedure is carried out using a 5-mm laparoscope placed in the umbilicus and two additional 5-mm ports in the left and right lower quadrants. The bowel is inspected, and if it appears to be viable, reduction is performed by milking the bowel or using gentle traction, although this approach is normally discouraged during manual reduction. Atraumatic bowel graspers allow the bowel to be handled without injuring it.

Fig. 39-20.

Open reduction of intussusception. The bowel is milked backward to relieve the obstruction.

IV fluids are continued until the postoperative ileus subsides. Patients are started on clear liquids, and the diet is advanced as tolerated. Of note, recurrent intussusception occurs in 5 to 10% of patients, independent of whether the bowel is reduced radiographically or surgically. Patients present with recurrent symptoms in the immediate postoperative period. Treatment involves repeat air enema, which is successful in most cases. In patients who experience three or more episodes of intussusception, the presence of a pathologic lead point should be suspected and carefully evaluated using contrast studies. After the third episode of intussusception, many pediatric surgeons will perform an exploratory laparotomy to reduce the bowel and to resect a pathologic lead point if identified.

APPENDICITIS

Presentation

Correct diagnosis of appendicitis in children can be one of the most humbling and challenging tasks facing the pediatric surgeon. The classic presentation is generalized abdominal pain that localizes to the right lower quadrant followed by nausea, vomiting, fever, and peritoneal irritation in the region of the McBurney point. When children present in this manner, there should be little diagnostic delay. The child should be put on NPO status, administered IV fluids and broad-spectrum antibiotics, and brought to the operating room for an appendectomy. However, children often do not present in this manner. The coexistence of viral syndromes and the inability of young children to describe the location and quality of their pain often result in diagnostic delay. As a result, children with appendicitis, particularly those who are <5 years of age, often present with perforation. Perforation increases the length of hospital stay and makes the overall course of the illness significantly more complex.

Diagnosis of Appendicitis in Children

Controversy exists regarding the role of radiographic studies in the diagnosis of acute appendicitis. Because children have less periappendiceal fat than adults, CT is less reliable in making the diagnosis. In addition, radiation exposure resulting from the CT scan may have potentially long-term adverse effects. Likewise, ultrasonography is not sufficiently sensitive or specific to allow accurate diagnosis of appendicitis, although it is very useful for excluding ovarian causes of abdominal pain. Therefore, the diagnosis of appendicitis remains largely clinical, and each clinician should develop his or her own threshold to operate or to observe the patient. A reasonable practice guideline is as follows: When the diagnosis is clinically apparent, appendectomy should be performed with minimal delay. Localized right lower quadrant tenderness associated with low-grade fever and leukocytosis in boys should prompt surgical exploration. In girls, ovarian or uterine pathology must also be considered. When there is diagnostic uncertainty, the child may be observed, rehydrated, and reassessed. In girls of menstruating age, ultrasonography may be performed to exclude ovarian pathology (cysts, torsion, or tumor). If results of all studies are negative, yet the pain persists and the abdominal findings remain equivocal, diagnostic laparoscopy may be used to determine the cause of the abdominal pain. The appendix should be removed even if it appears to be normal, unless another pathologic cause of the abdominal pain is definitively identified and the appendectomy would substantially increase morbidity.

Surgical Treatment of Appendicitis

The definitive treatment for acute appendicitis is appendectomy. Before surgery, it is important that patients receive adequate IV fluids to correct the dehydration that commonly develops as a result of fever and vomiting in patients with appendicitis. Patients should also be started on antibiotics (such as a second-generation cephalosporin). Most surgeons perform a laparoscopic appendectomy, which may have some advantage over removal of the appendix through a single larger incision. During the laparoscopic appendectomy, a small incision is made at the umbilicus and two additional incisions

are made in the lower abdomen. The appendix is typically delivered through the umbilicus, and all incisions are then closed with dissolvable sutures. If the appendix is not ruptured, the patient may start drinking liquids shortly after waking up from the operation and may be advanced to a solid diet the next day. In general, the same steps are taken when appendectomy is performed through an open approach. The most common complication after appendectomy is a surgical site infection. Other complications—including bleeding and damage to other structures inside the abdomen—are extremely rare. Recovery from surgery is dependent on the individual patient. Most children go back to school approximately 1 week after surgery and usually are allowed to return to full physical activity after 2 to 3 weeks. During the recovery period, over-the-counter pain medication may be required. Older patients tend to require a longer time for full recovery.

Management of the Child with Perforated Appendicitis

The signs and symptoms of perforated appendicitis can closely mimic those of gastroenteritis and include abdominal pain, vomiting, and diarrhea. Alternatively, the child may present with symptoms of intestinal obstruction. An abdominal mass may be present in the lower abdomen. When the symptoms have been present for longer than 4 or 5 days and an abscess is suspected, it is reasonable to obtain a CT scan of the abdomen and pelvis with IV, oral, and rectal contrast to visualize the appendix and look for an associated abscess, phlegmon, or fecalith (Fig. 39-21).

Fig. 39-21.

Computed tomographic scan of the abdomen showing the presence of a ruptured appendix with pelvic fluid and a fecalith (arrow).

An individualized approach is necessary for the child who presents with perforated appendicitis. When there is evidence of generalized peritonitis, intestinal obstruction, or systemic toxicity, the child should undergo appendectomy. This should be delayed only for as long as is required to ensure adequate fluid resuscitation and administration of broad-spectrum antibiotics. The operation can be performed using an open or a laparoscopic approach. One distinct advantage of the

laparoscopic approach is that it provides excellent visualization of the pelvis and all four quadrants of the abdomen. At the time of surgery, adhesions are gently lysed, abscess cavities are drained, and the appendix is removed. Drains are seldom used, and the skin incisions can be closed primarily. If a fecalith is identified outside the appendix on CT, every effort should be made to retrieve it and to remove it along with the appendix, if at all possible. Often, the child in whom symptoms have been present for longer than 4 or 5 days will present with an abscess without evidence of generalized peritonitis. Under these circumstances, it is appropriate to perform image-guided percutaneous drainage of the abscess followed by broad-spectrum antibiotic therapy. The inflammation will generally subside within several days, and the appendix can be safely removed on an outpatient basis 6 to 8 weeks later. If the child's symptoms do not improve, or if the abscess is not amenable to percutaneous drainage, then laparoscopic or open appendectomy and abscess drainage is required. Patients who present with a phlegmon in the region of a perforated appendix may be managed in a similar manner. In general, children who are younger than 4 or 5 years of age do not respond as well to an initially nonoperative approach, because their bodies do not localize or isolate the inflammatory process. Thus, these patients are more likely to require early surgical intervention. Patients who have had symptoms of appendicitis for no more than 4 days should probably undergo early appendectomy, because the inflammatory response is not as excessive during that initial period and the procedure can be performed safely.

If appendicitis isn't causing the pain, what could be causing it? As mentioned earlier, appendicitis can be one of the most difficult diagnoses to establish in children with abdominal pain, in part because of the large number of diseases that present in a similar fashion. Patients with urinary tract infection can have signs and symptoms similar to those of patients with appendicitis. However, patients with urinary tract infection are less likely to present with vomiting and are likely also to experience difficulty with urination, characterized by pressure, burning, and frequency. Constipation is commonly confused with appendicitis in its earliest stages. However, patients with constipation rarely have fever, and abnormalities will not be seen in the results of their blood work. Ovarian torsion can mimic appendicitis, given the severe abdominal pain that accompanies this condition. However, patients with ovarian torsion are generally asymptomatic until the acute onset of severe pain. By contrast, patients with appendicitis generally experience gradual onset of pain associated with nausea and vomiting. Finally, children and young adults are always at risk for the development of gastroenteritis. Unlike patients with appendicitis, however, patients with gastroenteritis generally present with persistent vomiting and occasionally diarrhea, which precedes the onset of the abdominal pain.

INTESTINAL DUPLICATIONS

Intestinal duplications are mucosa-lined structures that are in continuity with the GI tract. Although they can occur at any level in the GI tract, duplications are found most commonly in the ileum within the leaves of the mesentery. Duplications may be long and tubular, but usually are cystic masses. In all cases, they share a common wall with the intestine. Symptoms associated with enteric duplication cysts include recurrent abdominal pain, emesis from intestinal obstruction, and hematochezia. Such bleeding typically results from ulceration in the duplication or in the adjacent intestine if the duplication contains ectopic gastric mucosa. On examination, a palpable mass is often identified. Children may also develop intestinal obstruction. Torsion may produce gangrene and perforation.

The ability to make a preoperative diagnosis of enteric duplication cyst usually depends on the presentation. CT, ultrasonography, and technetium pertechnetate scanning can be very helpful. Occasionally, a duplication can be seen on small bowel follow-through or barium enema study. For short duplications, resection of the cyst and adjacent intestine with end-to-end anastomosis can be performed. If resection of long duplications would compromise intestinal length, multiple enterotomies and mucosal stripping can be performed in the duplicated segment, which will allow the walls to collapse and

become adherent. An alternative method is to divide the common wall using a linear cutting stapler to form a common lumen. Patients with duplications who undergo complete excision without compromise of the length of remaining intestine have an excellent prognosis.

MECKEL'S DIVERTICULUM

Meckel's diverticulum is a remnant of a portion of the embryonic omphalomesenteric (vitelline) duct. It is located on the antimesenteric border of the ileum, usually within 2 ft of the ileocecal valve (Fig. 39-22). It may be found incidentally at surgery or may present with inflammation masquerading as appendicitis. Perforation of Meckel's diverticulum may occur if the outpouching becomes impacted with food, which leads to distention and necrosis. Occasionally, bands of tissue extend from the diverticulum to the anterior abdominal wall, and these may represent lead points around which internal hernias may develop. This is an important cause of intestinal obstruction in the older child who has a scarless abdomen. As with intestinal duplications, ectopic gastric mucosa may produce ileal ulcerations that bleed and lead to the passage of maroon stools. Pancreatic mucosa may also be present. Diagnosis may be made by technetium pertechnetate scans when the patient presents with bleeding. Treatment is surgical. If the base is narrow and there is no mass present in the lumen of the diverticulum, a wedge resection of the diverticulum with transverse closure of the ileum can be performed. A linear stapler is especially useful in this circumstance. When a mass of ectopic tissue is palpable, when the base is wide, or when there is inflammation, a resection of the involved bowel followed by end-to-end ileoileostomy is preferable.

Intraoperative photograph showing the presence of Meckel's diverticulum (arrow).

MESENTERIC CYSTS

Mesenteric cysts are similar to duplications in their location within the mesentery. However, they do not contain any mucosa or muscular wall. Chylous cysts may result from congenital lymphatic obstruction. Mesenteric cysts can cause intestinal obstruction or may present as an abdominal mass. The diagnosis may be made by abdominal ultrasonography or CT.

Treatment is surgical excision. This may require resection of the adjacent intestine, particularly for extensive, multicystic lesions. In cases in which complete excision is not possible due to the close proximity of the cyst to vital structures, partial excision or marsupialization should be performed.

HIRSCHSPRUNG'S DISEASE

Pathogenesis

In his classic textbook entitled *Pediatric Surgery*, Dr. Orvar Swenson, who is eponymously associated with one of the classic surgical treatments for Hirschsprung's disease, described this condition as follows: "Congenital megacolon is caused by a malformation in the pelvic parasympathetic system which results in the absence of ganglion cells in Auerbach's plexus of a segment of distal colon. Not only is there an absence of ganglion cells, but the nerve fibers are large and excessive in number, indicating that the anomaly may be more extensive than the absence of ganglion cells." This description of Hirschsprung's disease is as accurate today as it was >50 years ago and summarizes the essential pathologic features of this disease: absence of ganglion cells in Auerbach's plexus and hypertrophy of associated nerve trunks. The cause of Hirschsprung's disease remains incompletely understood, although current thinking is that the disease results from a defect in the migration of neural crest cells, which are the embryonic precursors of the intestinal ganglion cell. Under normal conditions, the neural crest cells migrate into the intestine from cephalad to caudad. The process is completed by the twelfth week of gestation, but the migration from midtransverse colon to anus takes 4 weeks. During this latter period, the fetus is most vulnerable to defects in migration of neural crest cells. This may explain why most cases of aganglionosis involve the rectum and rectosigmoid. The length of the aganglionic segment of bowel is therefore determined by the most distal region that the migrating neural crest cells reach. In rare instances, total colonic aganglionosis may occur.

Recent studies have shed light on the molecular basis for Hirschsprung's disease. Patients with Hirschsprung's disease have an increased frequency of mutations in several genes, including *GDNF*, its receptor *Ret*, and its coreceptor *Gfra-1*. Moreover, mutations in these genes also lead to aganglionic megacolon in mice, which provides the opportunity to study the function of the encoded proteins. Initial investigations indicate that *GDNF* promotes the survival, proliferation, and migration of mixed populations of neural crest cells in culture. Other studies have revealed that *GDNF* is expressed in the gut in advance of migrating neural crest cells and is chemoattractive for neural crest cells in culture. These findings raise the possibility that mutations in the *GDNF* or *Ret* genes could lead to impaired neural crest migration in utero and the development of Hirschsprung's disease.

Clinical Presentation

The incidence of sporadic Hirschsprung's disease is 1 in 5000 live births. There are reports of increased frequency of Hirschsprung's disease in multiple generations of the same family, especially in families with long-segment Hirschsprung's disease. Occasionally, such families have mutations in the genes described earlier, including the *Ret* gene. Because normal peristalsis cannot occur in the aganglionic colon, children with Hirschsprung's disease present with a functional distal intestinal obstruction. In the newborn period, the most common symptoms are abdominal distention, failure to pass meconium, and bilious emesis. Any infant who does not pass meconium by 48 hours from birth must be investigated for the presence of Hirschsprung's disease. Occasionally, infants present with a dramatic complication of Hirschsprung's disease called *enterocolitis*. This pattern of presentation is characterized by abdominal distention and tenderness, and is associated with manifestations of systemic toxicity that include fever, failure to thrive, and lethargy. Infants are often dehydrated and demonstrate leukocytosis or an increase in circulating band forms on hematologic evaluation. On rectal examination, forceful

expulsion of foul-smelling liquid feces is typically observed and represents the accumulation of stool under pressure in an obstructed distal colon. Treatment includes rehydration, systemic antibiotics, nasogastric decompression, and rectal irrigations while the diagnosis of Hirschsprung's disease is being confirmed. In children who do not respond to nonoperative management, a decompressive stoma is required. The surgeon must ensure that this stoma is placed in ganglion-containing bowel, and this must be confirmed by frozen-section analysis of bowel tissue performed at the time of stoma creation.

In approximately 20% of cases, the diagnosis of Hirschsprung's disease is made beyond the newborn period. These children have severe constipation, which has usually been treated with laxatives and enemas. Abdominal distention and failure to thrive may also be present at diagnosis.

Diagnosis

The definitive diagnosis of Hirschsprung's disease is made by rectal biopsy. Samples of mucosa and submucosa are obtained at 1 cm, 2 cm, and 3 cm from the dentate line. In the neonatal period this biopsy can be performed at the bedside without anesthesia, because samples are taken in bowel that does not have somatic innervation and thus the procedure is not painful to the child. In older children, the procedure should be performed as an open rectal biopsy using IV sedation. The histopathologic features of Hirschsprung's disease are the absence of ganglion cells in the myenteric plexuses, increased acetylcholinesterase staining, and the presence of hypertrophied nerve bundles.

A barium enema examination should be performed in children in whom the diagnosis of Hirschsprung's disease is suspected. This test may demonstrate the location of the transition zone between the dilated ganglionic colon and the distal constricted aganglionic rectal segment. The authors' practice is to order this test before instituting rectal irrigations if possible, so that the difference in size between the proximal and distal bowel is preserved. Although a barium enema study can only suggest the diagnosis of Hirschsprung's disease, and not reliably establish it, the test is very useful in excluding other causes of distal intestinal obstruction. These include small left colon syndrome (as occurs in infants of diabetic mothers), colonic atresia, meconium plug syndrome, and the unused colon observed in infants after the administration of magnesium or tocolytic agents. In cases of total colonic aganglionosis, the barium enema study may reveal a markedly shortened colon. Some surgeons have found the use of rectal manometry helpful, particularly in older children, although the results are relatively inaccurate.

Treatment

A diagnosis of Hirschsprung's disease requires surgery in all cases. The classic surgical approach consisted of a multiple-stage procedure. This included a colostomy in the newborn period, followed by a definitive pull-through operation after the child weighed >10 kg. There are three viable options for the definitive pull-through procedure that are currently used. Although individual surgeons may advocate one procedure over another, studies have demonstrated that the outcome after each type of operation is similar. For each of the operations that is performed, the principles of treatment include confirming the location in the bowel where the transition zone between ganglionic and aganglionic bowel exists, resecting the aganglionic segment of bowel, and performing an anastomosis of ganglionated bowel to either the anus or a cuff of rectal mucosa (Fig. 39-23).

Three operations for surgical correction of Hirschsprung's disease. **A.** The Duhamel procedure leaves the rectum in place

and brings ganglionic bowel into the retrorectal space. **B.** Swenson's procedure is a resection with end-to-end anastomosis performed by exteriorizing bowel ends through the anus. **C.** In the Soave operation endorectal dissection is performed and mucosa is removed from the aganglionic distal segment. The ganglionic bowel is then brought down to the anus within the seromuscular tunnel.

It is now well established that a primary pull-through procedure can be performed safely, even in the newborn period. This approach follows the same treatment principles as a staged procedure and saves the patient from an additional operation. Many surgeons perform the intra-abdominal dissection using the laparoscope. This approach is especially useful in the newborn period, because it provides excellent visualization of the pelvis. In children with significant colonic distention, it is important to allow for a period of decompression using a rectal tube if a single-staged pull-through is to be performed. In older children with a very distended, hypertrophied colon, it may be prudent to perform a colostomy to allow the bowel to decompress, before performing a pull-through procedure. However, one should emphasize that there is no upper age limit for performing a primary pull-through.

Of the three pull-through procedures performed for Hirschsprung's disease, the first is the original Swenson's procedure. In this operation, the aganglionic rectum is dissected in the pelvis and removed down to the anus. The ganglionic colon is then anastomosed to the anus via a perineal approach. In the Duhamel procedure, dissection outside the rectum is confined to the retrorectal space, and the ganglionic colon is anastomosed posteriorly just above the anus. The anterior wall of the ganglionic colon and the posterior wall of the aganglionic rectum are anastomosed using a stapler. Although both of these procedures are extremely effective, they are limited by the possibility of damage to the parasympathetic nerves that are adjacent to the rectum. To circumvent this potential problem, the Soave procedure calls for dissection entirely within the rectum. The rectal mucosa is stripped from the muscular sleeve, and the ganglionic colon is brought through this sleeve and anastomosed to the anus. This operation may be performed completely from below. In all cases, it is critical that the level at which ganglionated bowel exists be determined. Most surgeons believe that the anastomosis should be performed at least 5 cm from the point at which ganglion cells are found. This avoids performing a pull-through in the transition zone, which is associated with a high incidence of complications due to inadequate emptying of the pull-through segment. Up to one third of patients who undergo a transition zone pull-through will require a reoperation.

The main complications of all procedures include postoperative enterocolitis, constipation, and anastomotic stricture. As mentioned earlier, long-term results for the three procedures are comparable and are generally excellent in experienced hands. These three procedures also can be adapted for total colonic aganglionosis in which the ileum is used for the pull-through segment.

ANORECTAL MALFORMATIONS

Anatomic Description

Anorectal malformations are a spectrum of congenital anomalies that include imperforate anus and persistent cloaca. Anorectal malformations occur in approximately 1 in 5000 live births and affect males and females almost equally. The embryologic basis includes failure of descent of the urorectal septum. The level to which this septum descends determines the type of anomaly that is present, which subsequently influences the surgical approach.

In patients with imperforate anus, the rectum fails to descend through the external sphincter complex. Instead, the rectal pouch ends blindly in the pelvis, above or below the levator ani muscle. In most cases, the blind rectal pouch communicates more distally with the genitourinary system or with the perineum through a fistulous tract. Traditionally, the anatomic description of imperforate anus has characterized it as either "high" or "low" depending on whether the rectum ends above

the levator ani muscle complex or partially descends through this muscle (Fig. 39-24). Based on this classification system, in male patients with high imperforate anus the rectum usually ends as a fistula into the membranous urethra. In females, high imperforate anus often occurs in the context of a persistent cloaca. In both males and females, low lesions are associated with a fistula to the perineum. In males, the fistula connects with the median raphe of the scrotum or penis. In females, the fistula may end within the vestibule of the vagina, which is located immediately outside the hymen, or at the perineum.

Fig. 39-24.

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Low imperforate anus in a male. Note the well-developed buttocks. The perineal fistula was found at the midline raphe.

Because this classification system is somewhat arbitrary, Peña proposed a classification system that specifically and unambiguously describes the location of the fistulous opening. In males the fistula may communicate with (a) the perineum (cutaneous perineal fistula), (b) the lowest portion of the posterior urethra (rectourethral bulbar fistula), (c) the upper portion of the posterior urethra (rectourethral prostatic fistula), or (d) the bladder neck (rectovesicular fistula). In females, the urethra may open to the perineum between the female genitalia and the center of the sphincter (cutaneous perineal fistula) or into the vestibule of the vagina (vestibular fistula) (Fig. 39-25). In both sexes, the rectum may end in a completely blind fashion (imperforate anus without fistula). In rare cases, patients may have a normal anal canal yet there may be total atresia or severe stenosis of the rectum.

Fig. 39-25.

Imperforate anus in a female. A catheter has been placed into the fistula, which is in the vestibule of the vagina.

In males the most frequent defect is imperforate anus with rectourethral fistula, followed by rectoperineal fistula, then rectovesicular or recto–bladder neck fistula. In females, the most frequent defect is rectovestibular defect, followed by cutaneous perineal fistula. The third most common defect in females is persistent cloaca. The latter lesion represents a wide spectrum of malformations in which the rectum, vagina, and urinary tract meet and fuse into a single common channel. On physical examination, a single perineal orifice is observed, located at the place where the urethra normally opens. Typically, the external genitalia are hypoplastic.

Associated Malformations

Approximately 60% of patients with an anorectal malformation have another associated malformation. The most common is a urinary tract defect, which occurs in approximately 50% of patients. Skeletal defects are also seen, and the sacrum is most commonly involved. Spinal cord anomalies, especially tethered cord, are common, particularly in children with high lesions. GI tract anomalies occur, most commonly esophageal atresia. Cardiac anomalies may be noted, and occasionally patients present with a constellation of defects as part of the VACTERL syndrome (described earlier).

Management of Patients with Imperforate Anus

Patients with imperforate anus are usually in stable condition, and the diagnosis is readily apparent. Despite the obstruction, the abdomen initially is not distended, and there is rarely any urgency to intervene. The principles of management center around diagnosing the type of defect that is present (high vs. low) and evaluating for the presence of associated anomalies. It may take up to 24 hours before the presence of a fistula on the skin is noted, and thus the neonate should be observed for some period before definitive surgery is undertaken. All patients should therefore have an orogastric tube placed and should be monitored for the appearance of meconium in or around the perineum, or in the urine. Investigation for associated defects should include ultrasonography of the abdomen to assess for the presence of a urinary tract anomaly. Other tests should include an echocardiogram and spinal radiographs. Ultrasonography of the spine should be performed to look for the

presence of a tethered cord. To further classify the location of the fistula as either high or low, a lateral abdominal radiograph can be obtained with a radiopaque marker on the perineum. Placing the infant in the inverted position allows the distance between the most distal extent of air in the rectum and the perineal surface to be measured. This study is imprecise, however, and may add little to the overall management of these patients.

The surgical management of infants with imperforate anus is determined by the anatomic defect. In general, when a low lesion is present, only a perineal operation is required without a colostomy. Infants with a high lesion require a colostomy in the newborn period, followed by a pull-through procedure at approximately 2 months of age. When a persistent cloaca is present, the urinary tract needs to be carefully evaluated at the time of colostomy formation to ensure that normal emptying can occur and to determine whether the bladder needs to be drained by means of a vesicostomy. If there is any doubt about the type of lesion, it is safer to perform a colostomy rather than jeopardize the infant's long-term chances for continence by an injudicious perineal operation.

The type of pull-through procedure favored by most pediatric surgeons today is the posterior sagittal anorectoplasty, as described by Peña and DeVries. In this procedure, the patient is placed in the prone jackknife position, the levator ani and external sphincter complex is divided in the midline posteriorly, the communication between the GI tract and the urinary tract is divided, and the rectum is brought down after sufficient length is achieved. The muscles are then reconstructed and sutured to the rectum. The outcome for 1192 patients who underwent this procedure was recently reviewed by Peña and Hong. Seventy-five percent of patients were found to have voluntary bowel movements, and nearly 40% were considered totally continent. As a rule, the incidence of incontinence is increased in patients with high lesions, whereas those with low lesions are more likely to be constipated. Management of the patient with high imperforate anus can be greatly facilitated by the use of a laparoscopically assisted approach, in which the patient is operated on in the supine position and the rectum is mobilized down to the fistulous connection to the bladder neck. This fistulous connection is then divided, and the rectum is completely mobilized to below the peritoneal reflection. The operation then proceeds at the perineum, and the location of the muscle complex is determined using a nerve stimulator. A Veress needle is then advanced through the skin at the indicated site, with the laparoscope providing guidance to the exact intrapelvic orientation. Dilators are then placed over the Veress needle, the rectum is pulled through this peritoneal opening, and an anoplasty is performed.

JAUNDICE

Approach to the Jaundiced Infant

Jaundice is present during the first week of life in 60% of term infants and 80% of preterm infants. There is usually an accumulation of unconjugated bilirubin, but there may also be deposition of direct bilirubin. During fetal life, the placenta is the principal route of elimination of unconjugated bilirubin. In the newborn infant, bilirubin is conjugated through the activity of *glucuronyl transferase*. In the conjugated form, bilirubin is water soluble, which results in its excretion into the biliary system and then into the GI tract. Newborns have a relatively high level of circulating hemoglobin and relative immaturity of the conjugating machinery. This results in a transient accumulation of bilirubin in the tissues, which is manifested as jaundice. Physiologic jaundice is evident by the second or third day of life and usually resolves within approximately 5 to 7 days. By definition, jaundice that persists beyond 2 weeks is considered pathologic.

Pathologic jaundice may be due to biliary obstruction, increased hemoglobin load, or liver dysfunction. The work-up of the jaundiced infant therefore should include a search for the following possibilities: (a) obstructive disorders, including biliary atresia, choledochal cyst, and inspissated bile syndrome; (b) hematologic disorders, including ABO incompatibility, Rh

incompatibility, and spherocytosis; (c) metabolic disorders, including alpha1-antitrypsin deficiency, galactosemia, and pyruvate kinase deficiency; and (d) congenital infection, including syphilis and rubella.

Biliary Atresia

PATHOGENESIS

Biliary atresia is a rare disease associated with significant morbidity and mortality. This disease is characterized by a fibroproliferative obliteration of the biliary tree that progresses toward hepatic fibrosis, cirrhosis, and end-stage liver failure. The incidence of this disease is approximately 1 in 5000 to 1 in 12,000. The etiology of biliary atresia is likely multifactorial. In the classic textbook *Abdominal Surgery of Infancy and Childhood*, Ladd and Gross described the cause of biliary atresia as an "arrest of development during the solid stage of bile duct formation." Previously proposed theories of the cause of biliary atresia have focused on defects in hepatogenesis, prenatal vasculogenesis, immune dysregulation, infectious agents, and exposure to toxins. More recently, genetic mutations in the *cfc1* gene, implicated in left-right axis determinations, were identified in patients with biliary atresia–splenic malformation syndrome. In addition, the finding of a higher incidence of maternal microchimerism in the livers of males with biliary atresia has led to the suggestion that consequent expression of maternal antigens may lead to an autoimmune process that results in inflammation and obliteration of the biliary tree. Recent animal studies strongly implicate perinatal exposure to reovirus or rotavirus. Such viral exposure may lead to periportal inflammation mediated by interferon- γ and other cytokines.

CLINICAL PRESENTATION

Infants with biliary atresia present with jaundice at birth or shortly thereafter. The diagnosis of biliary atresia is frequently not entertained by pediatricians, in part because physiologic jaundice of the newborn is so common and biliary atresia is so uncommon. For this reason, a delay in diagnosis is not unusual. However, infants with biliary atresia characteristically have acholic, pale gray stools, secondary to obstructed bile flow. With further passage of time, these infants manifest progressive failure to thrive and, if untreated, develop stigmata of liver failure and portal hypertension, particularly splenomegaly and esophageal varices.

The obliterative process of biliary atresia involves the common duct, cystic duct, one or both hepatic ducts, and the gallbladder, in a variety of combinations. Histopathologic findings for patients with biliary atresia include inflammatory changes in the parenchyma of the liver as well as fibrous deposition at the portal plates observed on trichrome staining of frozen tissue sections. In certain cases, bile duct proliferation may be seen, a relatively nonspecific marker of liver injury. Approximately 25% of patients with biliary atresia have coincidental malformations that are often associated with polysplenia and may include intestinal malrotation, preduodenal portal vein, and intrahepatic vena cava.

DIAGNOSIS

In general, the diagnosis of biliary atresia is made using a combination of studies, because no single test is sufficiently sensitive or specific. Fractionation of the serum bilirubin is performed to determine if the associated hyperbilirubinemia is conjugated or unconjugated. Work-up commonly includes the analysis of TORCH (*toxoplasmosis, other infections, rubella, cytomegalovirus infection, and herpes simplex*) infection titers as well as tests for viral hepatitis. Typically ultrasonography is performed to assess for the presence of other causes of biliary tract obstruction, including choledochal cyst. The absence of a gallbladder is highly suggestive of the diagnosis of biliary atresia. However, the presence of a gallbladder does not exclude the diagnosis of biliary atresia, because in approximately 10% of biliary atresia patients, the distal biliary tract is patent and

a gallbladder may be visualized, even though the proximal ducts are atretic. One should note that the intrahepatic bile ducts are never dilated in patients with biliary atresia. In many centers, a nuclear medicine scan using technetium TC 99m disofenin, performed after pretreatment of the patient with phenobarbital, has proven to be an accurate and reliable study. If radionuclide appears in the intestine, the biliary tree is patent and the diagnosis of biliary atresia is excluded. If radionuclide is concentrated by the liver but is not excreted despite treatment with phenobarbital, and results of the metabolic screen, particularly alpha₁-antitrypsin level, are normal, the presumptive diagnosis is biliary atresia. Percutaneous liver biopsy findings might potentially distinguish between biliary atresia and other sources of jaundice such as neonatal hepatitis. When the results of these tests point to or cannot exclude the diagnosis of biliary atresia, surgical exploration is warranted. At surgery, a cholangiogram may be performed if possible, using the gallbladder as a point of access. This may be accomplished using a laparoscope. The cholangiogram demonstrates the anatomy of the biliary tree, reveals whether extrahepatic bile duct atresia is present, and indicates whether there is distal bile flow into the duodenum. The cholangiogram may demonstrate hypoplasia of the extrahepatic biliary system. This condition is associated with hepatic parenchymal disorders that cause severe intrahepatic cholestasis, including alpha₁-antitrypsin deficiency and biliary hypoplasia (Alagille syndrome). Alternatively, a cursory assessment of the extrahepatic biliary tree may clearly delineate the atresia.

Inspissated Bile Syndrome

The term *inspissated bile syndrome* is applied to patients with normal biliary tracts who have persistent obstructive jaundice. Increased viscosity of bile and obstruction of the canaliculi are implicated as causes. The condition has been seen in infants receiving parenteral nutrition, but it is also encountered in patients with disorders associated with hemolysis and in patients with cystic fibrosis. In some instances, no etiologic factors can be defined. Cholangiography is both diagnostic and therapeutic in inspissated bile syndrome.

Neonatal Hepatitis

Neonatal hepatitis may present in a similar fashion to biliary atresia. This disease is characterized by persistent jaundice due to acquired biliary inflammation without obliteration of the bile ducts. There may be a viral cause. The disease is usually self-limited.

TREATMENT

If the diagnosis of biliary atresia is confirmed intraoperatively, then surgical treatment is undertaken during the same procedure. Currently, first-line therapy consists of creation of a hepatoportoenterostomy, as described by Kasai. The purpose of this procedure is to promote bile flow into the intestine. The procedure is based on Kasai's observation that the fibrous tissue at the porta hepatis invests microscopically patent biliary ductules that, in turn, communicate with the intrahepatic ductal system (Fig. 39-26). Transecting this fibrous tissue at the portal plate, which is invariably encountered cephalad to the bifurcating portal vein, opens these channels and establishes bile flow into a surgically constructed intestinal conduit, usually a Roux-en-Y limb of jejunum (Fig. 39-27). Some authors believe that an intussuscepted antireflux valve is useful in preventing retrograde bile reflux, although the data suggest that it does not influence outcome. A liver biopsy is performed at the time of surgery to determine the degree of hepatic fibrosis that is present. The diameter of bile ducts at the portal plate is predictive of the likelihood of long-term success of biliary drainage through the portoenterostomy. Numerous studies also suggest that the likelihood of surgical success is inversely related to the age at the time of portoenterostomy. Infants treated before 60 days of age are more likely to achieve successful and long-term biliary drainage than are older infants. Although the outlook is less favorable for patients after the twelfth week, it is reasonable to proceed with surgery even beyond this

point, because the alternative is certain liver failure. It is noteworthy that a significant number of patients have had favorable outcomes after undergoing portoenterostomy despite advanced age at the time of diagnosis.

Schematic illustration of the Kasai portoenterostomy for biliary atresia. An isolated limb of jejunum is brought to the porta hepatis and anastomosed to the transected ducts at the liver plate.

Bile drainage is anticipated when the operation is carried out early; however, bile flow does not necessarily imply cure. Approximately one third of patients remain symptom free after portoenterostomy; the remainder require liver transplantation due to progressive liver failure. Independent risk factors that predict failure of the procedure include bridging liver fibrosis at the time of surgery and postoperative cholangitic episodes. A recent review of the data of the Japanese Biliary Atresia Registry, which includes the results for 1381 patients, showed that the 10-year survival rate was 53% without transplantation and 66.7% with transplantation. A common postoperative complication is cholangitis. There is no effective strategy to completely eliminate this complication, and the effectiveness of long-term prophylactic antibiotics has not been fully resolved. In 2002, the National Institutes of Health–supported multicenter Biliary Atresia Research Consortium (BARC) was established to investigate the etiology of biliary atresia and to identify factors that affect outcome after portoenterostomy. BARC has previously reported that rapid normalization of serum bilirubin levels and weight gain are predictive of survival with the native liver. In a prospective randomized controlled trial, BARC is currently analyzing the efficacy of corticosteroids in promoting sustained bile flow after hepatoportoenterostomy.

Choledochal Cyst

CLASSIFICATION

The term *choledochal cyst* refers to a spectrum of congenital biliary tract disorders that were previously grouped under the name *idiopathic dilatation of the common bile duct*. Based on the classification system proposed by Alonso-Lej, five types of

choledochal cyst are described. Type I cysts are characterized by fusiform dilatation of the bile duct. This type is the most common and is found in 80 to 90% of cases. Type II choledochal cysts appear as an isolated diverticulum protruding from the wall of the common bile duct. The cyst may be joined to the common bile duct by a narrow stalk. Type III choledochal cysts arise from the intraduodenal portion of the common bile duct and are also known as *choledochoceles*. Type IVA cysts consist of multiple dilations of the intrahepatic and extrahepatic bile ducts. Type IVB choledochal cysts are multiple dilations involving only the extrahepatic bile ducts. Type V cysts (Caroli's disease) consist of multiple dilations limited to the intrahepatic bile ducts.

Choledochal cyst is most appropriately considered the predominant feature in a constellation of pathologic abnormalities that can occur within the pancreatobiliary system. Frequently associated with choledochal cyst is an anomalous junction of the pancreatic and common bile ducts. The etiology of choledochal cyst is controversial. Babbitt proposed an abnormal pancreatic and biliary duct junction, with the formation of a "common channel" into which pancreatic enzymes are secreted. This process results in weakening of the bile duct wall by gradual enzymatic destruction, which leads to dilatation, inflammation, and finally cyst formation. Not all patients with choledochal cyst demonstrate an anatomic common channel, which raises questions regarding the accuracy of this model.

CLINICAL PRESENTATION

Choledochal cyst is more common in females than in males (4:1). Typically these cysts present in children beyond the toddler age group. The classic symptom triad consists of abdominal pain, mass, and jaundice. However, this complex is actually encountered in fewer than half of patients. The more usual presentation is that of episodic abdominal pain, often recurring over the course of months or years and generally associated with only minimal jaundice that may escape detection. If the disorder is left undiagnosed, patients may develop cholangitis or pancreatitis. Cholangitis may lead to the development of cirrhosis and portal hypertension. Choledochal cyst can present in the newborn period, with symptoms very similar to those of biliary atresia. Often neonates have an abdominal mass at presentation.

DIAGNOSIS

Choledochal cyst is frequently diagnosed in the fetus during screening prenatal ultrasonography. In the older child or adolescent, abdominal ultrasonography may reveal a cystic structure arising from the biliary tree. CT will confirm the diagnosis. These studies show the dimensions of the cyst and define its relationship to the vascular structures in the porta hepatis, as well as the intrahepatic ductal configuration. Endoscopic retrograde cholangiopancreatography is reserved for cases in which confusion remains regarding the diagnosis after evaluation by less invasive imaging modalities. Magnetic resonance cholangiopancreatography may provide a more detailed depiction of the anatomy of the cyst and its relationship to the bifurcation of the hepatic ducts and to the pancreatic duct.

TREATMENT

The cyst wall is composed of fibrous tissue and is devoid of mucosal lining. As a result, the treatment of choledochal cyst is surgical excision followed by biliary-enteric reconstruction. There is no role for internal drainage by cystenterostomy, which leaves the cyst wall intact and leads to the inevitable development of cholangitis. Rarely, choledochal cyst can lead to the development of a biliary tract malignancy. This provides a further rationale for complete cyst excision.

Resection of the cyst requires circumferential dissection. The posterior plane between the cyst and portal vein must be carefully dissected to accomplish removal. The pancreatic duct, which may enter the distal cyst, is vulnerable to injury during

distal cyst excision but can be prevented by avoiding entry into the pancreatic parenchyma. In cases in which the degree of pericystic inflammation is dense, it may be unsafe to attempt complete cyst removal. In this instance, it is reasonable to dissect within the posterior wall of the cyst, which allows the inner lining of the back wall to be dissected free from the outer layer that directly overlies the portal vascular structures. The lateral and anterior cyst, as well as the internal aspect of the back wall, is removed, but the outer posterior wall remains behind. Cyst excision is accomplished, and the proximal bile duct is anastomosed to the intestinal tract, typically via a Roux-en-Y limb of jejunum. More recently, laparoscopically assisted resections of choledochal cysts have been described. In these cases, the end-to-side jejunojejunostomy is performed extracorporeally, but the remainder of the procedure is completed using minimally invasive techniques.

The prognosis for children who have undergone complete excision of choledochal cyst is excellent. Complications include anastomotic stricture, cholangitis, and intrahepatic stone formation. These complications may develop a long time after surgery has been completed.

DEFORMITIES OF THE ABDOMINAL WALL

Embryology of the Abdominal Wall

The abdominal wall is formed by four separate embryologic folds—cephalic, caudal, and right and left lateral folds—each of which is composed of somatic and splanchnic layers. Each of the folds develops toward the anterior center portion of the coelomic cavity, joining to form a large umbilical ring that surrounds the two umbilical arteries, the vein, and the yolk sac or omphalomesenteric duct. These structures are covered by an outer layer of amnion, and the entire unit composes the umbilical cord. Between the fifth and tenth weeks of fetal development the intestinal tract undergoes rapid growth outside the abdominal cavity within the proximal portion of the umbilical cord. As development is completed, the intestine gradually returns to the abdominal cavity. Contraction of the umbilical ring completes the process of abdominal wall formation.

Failure of the cephalic fold to close results in sternal defects such as congenital absence of the sternum. Failure of the caudal fold to close results in exstrophy of the bladder and, in more extreme cases, exstrophy of the cloaca. Interruption of central migration of the lateral folds results in omphalocele. Gastroschisis, originally thought to be a variant of omphalocele, probably results from a fetal accident in the form of intrauterine rupture of a hernia of the umbilical cord.

Umbilical Hernia

Failure of the umbilical ring to close results in a central defect in the linea alba. The resulting umbilical hernia is covered by normal umbilical skin and subcutaneous tissue, but the fascial defect allows protrusion of abdominal contents. Hernias less than a centimeter in size at the time of birth usually will close spontaneously by 4 years of life. Sometimes the hernia is large enough that the protrusion is disfiguring and disturbing to both the child and the family. In such circumstances early repair may be advisable (Fig. 39-28).

Umbilical hernia in a 1-year-old female.

Umbilical hernias are generally asymptomatic protrusions of the abdominal wall. They are generally noted by parents or physicians on physical examination, and these patients are referred for a surgical opinion due to concern for possible incarceration. Although incarceration is rarely seen in an umbilical hernia, it can happen. Children present with abdominal pain, bilious emesis, and a tender, hard mass protruding from the umbilicus. This constellation of symptoms mandates immediate exploration and repair of the hernia. In these cases, a knuckle of ischemic or necrotic bowel may be found that requires resection. More commonly, the child is asymptomatic and treatment is governed by the size of the defect, the age of the patient, and the concerns of the child and family regarding the cosmetic appearance of the abdomen. When the defect is small and spontaneous closure is likely, most surgeons will delay surgical correction until 4 or 5 years of age. If closure does not occur by this time, it is reasonable to repair the hernia. If a younger child has an extremely large hernia, or if the family or child is bothered by the cosmetic appearance, then repair is indicated.

Repair of uncomplicated umbilical hernia is performed under general anesthesia as an outpatient procedure. A small curved incision that fits into the skin crease of the umbilicus is made, and the sac is dissected free from the overlying skin. The fascial defect is repaired with permanent or long-lasting absorbable, interrupted sutures that are placed in a transverse plane. The cosmetic appearance of the umbilicus is restored by tacking the undersurface of the umbilical skin to the reapproximated fascia. The skin is closed using subcuticular sutures. The postoperative recovery is typically uneventful, and recurrence is rare.

Patent Urachus

During the development of the coelomic cavity, there is free communication between the urinary bladder and the abdominal wall through the urachus, which exits adjacent to the omphalomesenteric duct. Persistence of this tract results in a communication between the bladder and the umbilicus. The first sign of a patent urachus is moisture or urine flow from the umbilicus. Recurrent urinary tract infection can result. The urachus may be partially obliterated, with a remnant remaining beneath the umbilicus in the extraperitoneal position as an isolated cyst that may be identified by ultrasonography. Such a cyst usually presents as an inflammatory mass inferior to the umbilicus. Initial treatment is drainage of the infected cyst followed by cyst excision as a separate procedure once the inflammation has resolved.

In the child with a persistently draining umbilicus, a diagnosis of patent urachus should be considered. The differential diagnosis includes an umbilical granuloma, which generally responds to local application of silver nitrate. The diagnosis of patent urachus is confirmed by umbilical exploration. The urachal tract is excised and the bladder is closed. A patent vitelline duct may also present with umbilical drainage. In this circumstance, there is a communication with the small intestine, often at the site of Meckel's diverticulum. Treatment includes umbilical exploration with resection of the involved bowel (Fig. 39-29).

Patent vitelline duct. Note the communication between the umbilicus and the small bowel at the site of a Meckel's diverticulum.

Omphalocele

PRESENTATION

Omphalocele refers to a congenital defect of the abdominal wall in which the bowel and solid viscera are covered by peritoneum and amniotic membrane (Fig. 39-30). The umbilical cord inserts into the sac. The abdominal wall defect measures ≥ 4 cm in diameter. Omphalocele has an incidence of approximately 1 in 5000 live births and occurs in association with special syndromes such as exstrophy of the cloaca (vesicointestinal fissure), the Beckwith-Wiedemann constellation of

anomalies (macroglossia, macrosomia, hypoglycemia, visceromegaly, and omphalocele) and the Cantrell pentalogy (lower thoracic wall malformations such as cleft sternum, ectopia cordis, epigastric omphalocele, anterior midline diaphragmatic hernia, and cardiac anomalies). The defect may be very small or large enough that it contains most of the abdominal viscera. There is a 60 to 70% incidence of associated anomalies, especially cardiac anomalies (20 to 40% of cases) and chromosomal abnormalities. Chromosomal anomalies are more common in children with smaller defects. Omphalocele is associated with prematurity (10 to 50% of cases) and intrauterine growth restriction (20% of cases).

Giant omphalocele in a newborn male.

TREATMENT

Immediate treatment of an infant with omphalocele consists of attending to the vital signs and maintaining body temperature. The omphalocele should be covered with saline-soaked gauze and the trunk should be wrapped circumferentially. No pressure should be placed on the omphalocele sac in an effort to reduce its contents, because this maneuver may increase the risk of rupture of the sac or may interfere with abdominal venous return. Prophylactic antibiotics should be administered in case of rupture. The subsequent treatment and outcome are determined by the size of the omphalocele. In general, small- to medium-sized defects have a significantly better prognosis than extremely large defects in which the liver is present. In these cases, not only is the management of the abdominal wall defect a significant challenge, but these patients often have concomitant pulmonary insufficiency that can lead to significant morbidity and mortality.

Whenever possible, a primary repair of the omphalocele should be undertaken. This involves resection of the omphalocele membrane and closure of the fascia. A layer of prosthetic material may be required to achieve closure. In infants with a giant omphalocele (defect >7 cm in diameter, liver present within the sac), the defect cannot be closed primarily because there is simply no room to reduce the viscera into the abdominal cavity (see Fig. 39-30). Other infants may have associated congenital anomalies that complicate surgical repair. Under these circumstances, a nonoperative approach can be used. The omphalocele sac can be treated with desiccating substances such as povidone-iodine (Betadine), silver sulfadiazine (Silvadene), or sulfasalazine. Typically 2 to 3 months are required before re-epithelialization occurs. In the past, mercury compounds were used, but their use has been discontinued because of associated systemic toxicity. After epithelialization has occurred, attempts should be made to achieve closure of the anterior abdominal wall. Such procedures typically require extensive measures to achieve skin closure, including the use of biosynthetic materials. It is noteworthy that the abdominal vasculature is typically easily mobilized, due to the absence of adhesions to the sac. In cases of giant omphalocele, prolonged hospitalization is typical.

Gastroschisis

PRESENTATION

Gastroschisis is a congenital anomaly characterized by a defect in the anterior abdominal wall through which the intestinal contents freely protrude. Unlike with omphalocele, there is no overlying sac and the size of the defect is much smaller (<4 cm). The abdominal wall defect is located at the junction of the umbilicus and normal skin and is almost always to the right of the umbilicus (Fig. 39-31). The umbilicus becomes partly detached, which allows free communication with the abdominal cavity. The appearance of the bowel provides some information with respect to the in utero timing of the defect. The intestine may be normal in appearance, which suggests that the rupture occurred relatively late during the pregnancy. More commonly, however, the intestine is thick, edematous, discolored, and covered with exudate, which implies a more longstanding process.

Fig. 39-31.

Gastroschisis in a newborn. Note the location of the umbilical cord as well as the edematous, thickened bowel.

Unlike in infants born with omphalocele, in infants with gastroschisis the associated anomalies consist mostly of intestinal atresia. This defect can readily be diagnosed on prenatal ultrasonography (Fig. 39-32). There is no advantage to performing a cesarian section rather than a vaginal delivery. The delayed onset of intestinal function in children with gastroschisis has led some to postulate an injurious effect of amniotic fluid on the exposed bowel. This has led to consideration in some centers of early delivery to minimize intestinal damage and improve outcome. In a decade-long retrospective review, early delivery did not affect the thickness of bowel peel, but infants delivered before 36 weeks had a significantly longer length of hospital stay and time to enteral feeds. Based on these findings, fetal well-being should be the primary determinant of delivery for gastroschisis, as opposed to considerations regarding possible injurious effects of prolonged gestation on the bowel.

Prenatal ultrasonographic scan showing gastroschisis in a fetus at 30 weeks' gestational age. Arrows point to the bowel outside within the amniotic fluid.

TREATMENT

All infants born with gastroschisis require urgent surgical treatment. Of equal importance, these infants require vigorous fluid resuscitation on the order of 160 to 190 mL/kg per day to replace significant evaporative fluid losses. In many instances, the intestine can be returned to the abdominal cavity, and a primary surgical closure of the abdominal wall is performed. Techniques that facilitate primary closure include mechanical stretching of the abdominal wall, thorough orogastric suctioning with foregut decompression, and rectal irrigation and evacuation of all the meconium. Care must be taken to prevent increased abdominal pressure during the reduction, which would lead to compression of the inferior vena cava and respiratory embarrassment, and result in abdominal compartment syndrome. To avoid this complication, it is helpful to

monitor the bladder or airway pressure during reduction. In infants whose intestine has become thickened and edematous, it may be impossible to reduce the bowel into the peritoneal cavity in the immediately postnatal period. Under such circumstances, a plastic spring-loaded silo can be placed onto the bowel and secured beneath the fascia. The silo covers the bowel and allows for graduated reduction on a daily basis as the edema in the bowel wall decreases (Fig. 39-33). Surgical closure can usually be accomplished within approximately 1 week. A piece of prosthetic material may be required to bring the edges of the fascia together. If an atresia is noted at the time of closure, it is prudent to reduce the bowel at the first operation, then return after several weeks once the edema has resolved to correct the atresia. Intestinal function does not typically return for several weeks in patients with gastroschisis. This is especially true if the bowel is thickened and edematous. As a result, these patients require central line placement and institution of TPN to grow.

Use of a silo in an infant with gastroschisis to allow the bowel wall edema to resolve so as to facilitate closure of the abdominal wall.

Prune-Belly Syndrome

CLINICAL PRESENTATION

Prune-belly syndrome is a disorder that is characterized by a constellation of symptoms including extremely lax lower abdominal musculature, dilated urinary tract including the bladder, and bilateral undescended testes (Fig. 39-34). The term *prune-belly syndrome* appropriately describes the wrinkled appearance of the anterior abdominal wall that characterizes

these patients. Prune-belly syndrome is also known as *Eagle-Barrett syndrome* and the *triad syndrome* because of its three major manifestations. The incidence is significantly higher in males. Patients manifest a variety of comorbidities. The most significant is pulmonary hypoplasia, which can lead to death in the most severe cases. Skeletal abnormalities include dislocation or dysplasia of the hip and pectus excavatum.

Fig. 39-34.

Prune-belly (Eagle-Barrett) syndrome. Notice the flaccid abdomen.

The major genitourinary manifestation in prune-belly syndrome is ureteral dilatation. The ureters are typically long and tortuous, and become more dilated distally. Ureteric obstruction is rarely present. The dilatation is thought to be caused by decreased smooth muscle and increased collagen in the ureters. Approximately 80% of affected individuals have some degree of vesicoureteral reflux, which can predispose to urinary tract infection. Despite the marked dilatation of the urinary tract, most children with prune-belly syndrome have adequate renal parenchyma for growth and development. Factors associated with the development of long-term renal failure include the presence of abnormal kidneys on ultrasonographic or renal scan and persistent pyelonephritis.

TREATMENT

Despite the ureteric dilatation, ureteric surgery currently has no role unless an area of obstruction develops. The testes are invariably intra-abdominal, and bilateral orchidopexy can be performed in conjunction with abdominal wall reconstruction at 6 to 12 months of age. Even with orchidopexy, fertility in a male with prune-belly syndrome is unlikely because spermatogenesis over time is insufficient. Deficiencies in the production of prostatic fluid and a predisposition to retrograde ejaculation contribute to infertility. Abdominal wall repair is accomplished through an abdominoplasty, which typically requires a transverse incision in the lower abdomen extending into the flanks.

Inguinal Hernia

An understanding of the management of pediatric inguinal hernias is a central component of modern pediatric surgical practice. Inguinal hernia repair represents one of the most common operations performed in children. The presence of an inguinal hernia in a child is an indication for surgical repair. The operation is termed a *herniorrhaphy* because it involves closing off the patent processus vaginalis. This is to be contrasted with the hernioplasty that is performed in adults, which requires a reconstruction of the inguinal floor.

EMBRYOLOGY

To understand how to diagnose and treat inguinal hernias in children, one must understand their embryologic origin. It is very useful to describe these events to the parents, who often are under the misconception that the hernia was somehow caused by their inability to console their crying child or the child's high activity level. Inguinal hernia results from a failure of closure of the processus vaginalis, a finger-like projection of the peritoneum that accompanies the testicle as it descends into the scrotum. Closure of the processus vaginalis normally occurs a few months before birth. This explains the high incidence of inguinal hernias in premature infants. When the processus vaginalis remains completely patent, a communication persists between the peritoneal cavity and the groin, resulting in a hernia. Partial closure can result in entrapped fluid, which leads to the presence of a hydrocele. A *communicating hydrocele* is a hydrocele that is in communication with the peritoneal cavity and can therefore be thought of as a hernia. When the classification system that is typically applied to adult hernias is used, all congenital hernias in children are by definition indirect inguinal hernias. Children also present with direct inguinal and femoral hernias, although these are much less common.

CLINICAL MANIFESTATION

Inguinal hernias occur more commonly in males than in females (10:1) and are more common on the right side than the left. Infants are at high risk for incarceration of an inguinal hernia because of the narrow inguinal ring. Patients most commonly present with a groin bulge that is noticed by the parents as they change the infant's diapers (Fig. 39-35). Older children may notice the bulge themselves. On examination, the cord on the affected side will be thicker, and pressure on the lower abdomen usually will display the hernia on the affected side. The presence of an incarcerated hernia is indicated by a firm bulge that does not spontaneously resolve and may be associated with fussiness and irritability in the child. The infant with a strangulated inguinal hernia will have an edematous, tender bulge in the groin, occasionally with overlying skin changes. The child will eventually develop intestinal obstruction, peritonitis, and systemic toxicity.

Right inguinal hernia in a 4-month-old male. Arrows point to the bulge in the right groin.

Usually an incarcerated hernia can be reduced. Occasionally this may require light sedation. Gentle pressure is applied on the sac from below in the direction of the internal inguinal ring. After reduction of the incarcerated hernia, the child may be admitted for observation, and herniorrhaphy is performed within the next 24 hours to prevent recurrent incarceration. Alternatively, the child may be scheduled for surgery at the next available time slot. If the hernia cannot be reduced, or if evidence of strangulation is present, emergency operation is necessary. This may require a laparotomy and bowel resection.

When the diagnosis of inguinal hernia is made in an otherwise normal child, operative repair should be planned. Spontaneous resolution does not occur, and therefore a nonoperative approach cannot ever be justified. An inguinal hernia in a female infant or child frequently contains an ovary rather than intestine. Although the gonad usually can be reduced into the abdomen by gentle pressure, it often prolapses in and out until surgical repair is carried out. In some patients, the ovary and fallopian tube constitute one wall of the hernial sac (sliding hernia), and in these patients the ovary can be reduced effectively only at the time of operation. If the ovary is irreducible, prompt hernia repair is indicated to prevent ovarian torsion or strangulation.

When a hydrocele is diagnosed in infancy and there is no evidence of a hernia, observation is the proper therapy until the child is >12 months of age. If the hydrocele has not disappeared by 12 months, invariably there is a patent processus vaginalis, and operative hydrocelectomy with excision of the processus vaginalis is indicated. When the first signs of a hydrocele are seen after 12 months of age, the patient should undergo elective hydrocelectomy, which in a child is always performed through a groin incision. Aspiration of hydroceles is discouraged, because almost all without a patent processus vaginalis will resorb spontaneously, and those with a communication to the peritoneum will recur and require operative repair eventually.

SURGICAL REPAIR

The repair of a pediatric inguinal hernia can be extremely challenging, particularly in the premature child with incarceration. A small incision is made in a skin crease in the groin directly over the internal inguinal ring. Scarpa's fascia is seen and

divided. The external oblique muscle is dissected free from overlying tissue, and the location of the external ring is confirmed. The external oblique aponeurosis is then opened along the direction of the external ring. The undersurface of the external oblique is then cleared from surrounding tissue. The cremasteric fibers are separated from the cord structures and hernia sac, and these are then elevated into the wound. Care is taken not to grasp the vas deferens. The hernia sac is then dissected up to the internal ring and doubly suture ligated. The distal part of the hernia sac is opened widely to drain any hydrocele fluid. When the hernia is very large and the patient very small, tightening of the internal inguinal ring or even formal repair of the inguinal floor may be necessary, although the overwhelming majority of children do not require any treatment beyond high ligation of the hernia sac.

Controversy exists regarding the need for exploration of an asymptomatic opposite side in a child with an inguinal hernia. Several reports indicate that frequency of a patent processus vaginalis on the side opposite the obvious hernia is approximately 30%, although this figure decreases with increasing age of the child. Management options include never exploring the opposite side or exploring only under certain conditions, such as in premature infants or in patients in whom incarceration is present. The opposite side may be readily examined laparoscopically. To do so, a blunt 3-mm trocar is placed into the hernia sac of the affected side. The abdominal cavity is insufflated, and a 2.7-mm 70-degree camera is placed through the trocar to visualize the opposite side. The status of the processus vaginalis on the opposite side can be determined. However, the presence of a patent processus vaginalis by laparoscopy does not always imply the presence of a hernia.

Several authors have now reported a completely laparoscopic approach to the management of inguinal hernias in children. This technique requires insufflation through the umbilicus and the placement of an extraperitoneal suture to ligate the hernia sac. Proponents of this procedure emphasize the fact that no groin incision is required and that the chance of injuring cord structures is decreased. The long-term results of laparoscopic treatment remain to be established.

Inguinal hernias in children recur in <1% of patients, and recurrences usually result from missed hernia sacs at the first procedure, a direct hernia, or a missed femoral hernia. In all children, local anesthetic should be administered either by caudal injection or by direct injection into the wound. In preterm infants spinal anesthesia carries a lower risk of postoperative apnea than general anesthesia.

GENITALIA

Undescended Testis

EMBRYOLOGY

The term *undescended testicle* (cryptorchidism) refers to the interruption of the normal descent of the testis into the scrotum. The testicle may reside in the retroperineum, in the internal inguinal ring, in the inguinal canal, or even at the external ring. The testicle begins as a thickening on the urogenital ridge in the fifth to sixth week of embryologic life. In the seventh and eighth months the testicle descends along the inguinal canal into the upper scrotum, and with its progress the processus vaginalis is formed and pulled along with the migrating testicle. At birth, approximately 95% of infants have the testicles normally positioned in the scrotum.

A distinction should be made between an undescended testicle and an ectopic testicle. An ectopic testis, by definition, is one that has passed through the external ring in the normal pathway and then has come to rest in an abnormal location either overlying the rectus abdominis or external oblique muscle, overlying the soft tissue of the medial thigh, or behind the

scrotum in the perineum. A congenitally absent testicle results from failure of normal development or an intrauterine accident leading to loss of blood supply to the developing testicle.

CLINICAL PRESENTATION

The incidence of undescended testes is approximately 30% in preterm infants and 1 to 3% in term infants. For diagnosis, the child should be examined in the supine position, where visual inspection may reveal a hypoplastic or poorly rugated scrotum. Usually a unilateral undescended testicle can be palpated in the inguinal canal or in the upper scrotum. Occasionally, the testicle will be difficult or impossible to palpate, which indicates either an abdominal testicle or congenital absence of the gonad. If the testicle is not palpable in the supine position, the child should be examined with his legs crossed while seated. This maneuver diminishes the cremasteric reflex and facilitates detection of the location of the testicle.

It is now established that cryptorchid testes show an increased predisposition to malignant degeneration. In addition, fertility is decreased when the testicle is not in the scrotum. For these reasons, surgical placement of the testicle in the scrotum (orchidopexy) is indicated. This procedure does improve the fertility potential, although it is never normal. Similarly, the testicle is still at risk of malignant change, although its location in the scrotum facilitates potentially earlier detection of a testicular malignancy. Other reasons to consider orchidopexy include the risk of trauma to a testicle located at the pubic tubercle, increased incidence of torsion, and the psychologic impact of an empty scrotum in a developing male. The reason for malignant degeneration has not been established, but the evidence points to an inherent abnormality of the testicle that predisposes it to incomplete descent and malignancy rather than malignancy as a result of an abnormal environment.

TREATMENT

Males with bilateral undescended testicles are often infertile. When the testicle is not within the scrotum, it is subjected to a higher temperature, which results in decreased spermatogenesis. Mengel and coworkers studied 515 undescended testicles by histologic analysis and demonstrated a decreasing presence of spermatogonia after 2 years of age. Consequently it is now recommended that an undescended testicle be surgically repositioned by 2 years of age. Nevertheless, the incidence of infertility is approximately two times higher in men who underwent unilateral orchidopexy than in men with normal testicular descent.

The administration of chorionic gonadotropin occasionally may be effective in patients with bilateral undescended testes, which suggests that these patients are more likely to have a hormone insufficiency than children with unilateral undescended testicle. If there is no testicular descent after a month of endocrine therapy, operative correction should be undertaken. A child with unilateral cryptorchidism should undergo surgical correction of the problem. The operation is typically performed through a combined groin and scrotal incision. The cord vessels are fully mobilized, and the testicle is placed in a dartos pouch within the scrotum. An inguinal hernia often accompanies an undescended testis. This should be repaired at the time of orchidopexy.

Patients with a nonpalpable testicle present a challenge in management. The current approach involves laparoscopy to identify the location of the testicle. If the spermatic cord is found to traverse the internal ring or the testis is found at the ring and can be delivered into the scrotum, a groin incision is made and an orchidopexy is performed. If an abdominal testis is identified that is too far away to reach the scrotum, a two-stage Fowler-Stephens approach is used. In the first stage, the testicular vessels can be clipped via laparotomy or laparoscopically. This promotes neovasculogenesis along the vas deferens. Several months later, the second stage is performed during which the intra-abdominal testis is mobilized along with a swath of peritoneum with collateralized blood supply along the vas. This may be done laparoscopically as well. Preservation of the

gubernacular attachments with their collaterals to the testicle confers improved testicular survival after orchidopexy in >90% of cases. It is nonetheless preferable to preserve the testicular vessels whenever possible and complete mobilization of the testicle with its vessels intact. Some surgeons advocate aggressive mobilization of testicular vessels up to the renal hilum if the intra-abdominal testis is within 1 or 2 cm of the internal ring. Other surgeons feel that the staged approach to orchidopexy is superior. To date, no large-scale trial has been performed to answer this question. In either case, meticulous mobilization of the intra-abdominal testis is critical for its survival and successful orchidopexy.

Vaginal Anomalies

Surgical diseases of the vagina in children are either congenital or acquired. Congenital anomalies include a spectrum of disorders that range from simple defects (imperforate hymen) to more complex forms of vaginal atresia, including distal atresia, proximal atresia, and, the most severe, complete atresia. These defects are produced by abnormal development of the müllerian ducts and/or urogenital sinus. The diagnosis is made most often by physical examination. Secretions into the obstructed vagina produce hydrocolpos, which may present as a large, painful abdominal mass. The anatomy may be defined using ultrasonography. Pelvic MRI provides the most thorough and accurate assessment of the pelvic structures. Treatment is dependent on the extent of the defect. For an imperforate hymen, division of the hymen is curative. More complex forms of vaginal atresia require mobilization of the vaginal remnants and creation of an anastomosis at the perineum. Laparoscopy can be extremely useful in mobilizing the vagina, in draining hydrocolpos, and in evaluating the internal genitalia. Complete vaginal atresia requires the construction of skin flaps or the creation of a neovagina using a segment of colon.

The most common acquired disorder of the vagina is the straddle injury. This often occurs as young girls fall on blunt objects that cause a direct injury to the perineum. Typical manifestations include vaginal bleeding and inability to void. Unless the injury is extremely superficial, patients should be examined in the operating room where the lighting is optimal and sedation can be administered. Vaginal lacerations are repaired using absorbable sutures, and the proximity to the urethra should be carefully assessed. Before hospital discharge, the patient must be able to void spontaneously. In all cases of vaginal trauma, it is essential that the patient be assessed for the presence of sexual abuse. In cases in which abuse is suspected, early contact with the sexual abuse or child protection service is necessary, so that the appropriate microbiologic and photographic evidence can be obtained.

Ovarian Cysts and Tumors

PATHOLOGIC CLASSIFICATION

Ovarian cysts and tumors may be classified as non-neoplastic or neoplastic. Nonneoplastic lesions include cysts (simple, follicular, inclusion, paraovarian, or corpus luteum), endometriosis, and inflammatory lesions. Neoplastic lesions are categorized based on the three primordia that contribute to the ovary: mesenchymal components of the urogenital ridge, germinal epithelium overlying the urogenital ridge, and germ cells migrating from the yolk sac. The most common variety is germ cell tumors. Germ cell tumors are classified based on the degree of differentiation and the cellular components involved. The least differentiated tumors are the dysgerminomas, which share features similar to those of seminomas in males. Although these are malignant tumors, they are extremely sensitive to radiation and chemotherapy. The most common lesions are the teratomas, which may be mature, immature, or malignant. The degree of differentiation of the neural elements of the tumor determines the degree of immaturity. The sex cord stromal tumors arise from the mesenchymal components of the urogenital ridge. These include granulosa-theca cell tumors and Sertoli-Leydig cell tumors. These tumors often produce hormones that result in precocious puberty or hirsutism, respectively. Epithelial tumors, although rare, do

occur in children. These include serous and mucinous cystadenomas.

CLINICAL PRESENTATION

Children with ovarian lesions usually present with abdominal pain. Other signs and symptoms include a palpable abdominal mass, evidence of urinary obstruction, symptoms of bowel obstruction, and endocrine imbalance. The surgical approach depends on the appearance of the mass at operation (i.e., whether it is benign appearing or is suspicious for malignancy). In the case of a simple ovarian cyst, surgery depends on the size of the cyst and the severity of symptoms it causes. In general, large cysts (over 4 to 5 cm) should be resected, because they are unlikely to resolve, may be at risk of torsion, and may mask an underlying malignancy. Resection may be performed laparoscopically, and ovarian tissue should be spared in all cases.

Surgical Management

If an ovarian lesion appears malignant, levels of tumor markers, including alpha-fetoprotein (teratomas), lactate dehydrogenase (dysgerminomas), beta human chorionic gonadotrophin (choriocarcinomas), and cancer antigen 125 (epithelial tumors), should be measured. Although the diagnostic sensitivity of these markers is variable, they provide information for postoperative follow-up and indicate the response to therapy. When a malignancy is suspected, the patient should undergo a formal cancer operation. This procedure is performed through either a midline incision or a Pfannenstiel approach. Ascites fluid and peritoneal washings should be collected for cytologic study. The liver and diaphragm are inspected carefully for metastatic disease. An omentectomy is performed if there is any evidence of tumor present. Pelvic and para-aortic lymph nodes are biopsied, and the primary tumor is resected completely. Finally, the contralateral ovary is carefully inspected and, if a lesion is seen, it is biopsied. Dysgerminomas and epithelial tumors are bilateral in up to 15% of cases. It is occasionally possible to preserve the ipsilateral fallopian tube. More radical procedures are not indicated.

OVARIAN CYSTS IN THE NEWBORN

An increasing number of ovarian cysts are being detected by prenatal ultrasonography. In the past, surgical excision was recommended for all cysts >5 cm in diameter because of the perceived risk of ovarian torsion. It has now become apparent from serial ultrasonographic examinations that many of these lesions will resolve spontaneously. Therefore, asymptomatic, simple cysts may be observed, and surgery can be performed only when the cysts fail to decrease in size or become symptomatic. Typically, resolution occurs by approximately 6 months of age. A laparoscopic approach is preferable when simple cysts must be removed. By contrast, complex cysts of any size require surgical intervention at presentation.

Ambiguous Genitalia

EMBRYOLOGY

Normal sexual differentiation occurs in the sixth fetal week. In every fetus, wolffian (male) and müllerian (female) ducts are present until the onset of sexual differentiation. Normal sexual differentiation is directed by the sex-determining region of the Y chromosome (SRY). This is located on the distal end of the short arm of the Y chromosome. SRY provides a genetic switch that initiates gonadal differentiation in the mammalian urogenital ridge. Secretion of müllerian inhibiting substance (MIS) by the Sertoli cells of the seminiferous tubules results in regression of the müllerian duct, the anlage of the uterus, fallopian tubes, and upper vagina. The result of MIS secretion therefore is a phenotypic male. In the absence of SRY in the Y chromosome, MIS is not produced, and the müllerian duct derivatives are preserved. Thus, the female phenotype prevails.

For the male phenotype to develop, the embryo must have a Y chromosome, the SRY must be normal without point mutations or deletions, testosterone and MIS must be produced by the differentiated gonad, and the tissues must respond to these hormones. Any disruption of the orderly steps in sexual differentiation may be reflected clinically as variants of the intersex syndromes, which are currently referred to as disorders of sex development (DSDs).

DSDs may be classified as (a) ovotesticular DSD (with both ovarian and testicular gonadal tissue present; previously known as *true hermaphroditism*); (b) 46,XY DSD, characterized by undervirilization or undermasculinization of an XY male (only testicular tissue present; previously known as *male pseudohermaphroditism*); (c) 46,XX DSD, characterized by overvirilization or masculinization of an XX female (ovarian tissue only; female pseudohermaphroditism); and (d) 46,XY complete gonadal dysgenesis (usually underdeveloped or imperfectly formed gonads).

OVOTESTICULAR DISORDER OF SEX DEVELOPMENT (TRUE HERMAPHRODITISM)

Ovotesticular DSD is the rarest form of ambiguous genitalia. Patients have both normal male and normal female gonads, with an ovary on one side and a testis on the other. Occasionally, an ovotestis is present on one or both sides. The majority of these patients have a 46,XX karyotype (46,XX testicular DSD). Both the testis and the testicular portion of the ovotestis should be removed.

46,XY DISORDER OF SEX DEVELOPMENT (MALE PSEUDOHERMAPHRODITISM)

The condition of 46,XY DSD occurs in infants with an XY karyotype but deficient masculinization of the external genitalia. Bilateral testes are present, but the duct structures differentiate partly as phenotypically female. The causes of the disorder include inadequate testosterone production due to biosynthetic error, inability to convert testosterone to dihydrotestosterone due to 5 α -reductase deficiency, or deficiencies in androgen receptors. The latter disorder is termed *testicular feminization syndrome*. Occasionally, the diagnosis in these children is made during routine inguinal herniorrhaphy in a phenotypic female, at which time testes are found. The testes should be resected due to the risk of malignant degeneration, although this should be done only after a full discussion with the family has occurred.

46,XX DISORDER OF SEX DEVELOPMENT (FEMALE PSEUDOHERMAPHRODITISM)

The syndrome of 46,XX DSD is characterized by overvirilization or masculinization of an XX female. The most common cause of this female condition is congenital adrenal hyperplasia. These children have a 46,XX karyotype but have been exposed to excessive androgens in utero. Common enzyme deficiencies include 21-hydroxylase deficiency, 11 β -hydroxylase deficiency, and 3 β -hydroxysteroid dehydrogenase deficiency. These deficiencies lead to overproduction of intermediary steroid hormones, which results in masculinization of the external genitalia of the XX fetus. These patients are unable to synthesize cortisol. In 90% of cases, deficiency of 21-hydroxylase causes adrenocorticotrophic hormone to stimulate the secretion of excessive quantities of adrenal androgen, which masculinizes the developing female (Fig. 39-36). These infants are prone to salt loss and require cortisol replacement. Those with mineralocorticoid deficiency also require fludrocortisone replacement.

Fig. 39-36.

Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Ambiguous genitalia manifest as enlarged clitoris and labioscrotal folds in an infant with adrenogenital syndrome.

MIXED GONADAL DYSGENESIS

Mixed gonadal dysgenesis is characterized by dysgenetic gonads and retained müllerian structures. The typical karyotype is mosaic, usually 45XO,46XY. The incidence of malignant tumors in the dysgenetic gonads, most commonly gonadoblastoma, is high. Therefore, they should be removed.

MANAGEMENT

In the differential diagnosis of patients with DSD, the following diagnostic steps are necessary: (a) evaluation of the genetic background and family history; (b) assessment of the anatomic structures by physical examination and/or ultrasonography; (c) chromosome analysis; (d) determination of biochemical factors in serum and urine to evaluate for the presence of an enzyme defect; and (e) laparoscopy for gonadal biopsy. Treatment should include correction of electrolyte and volume losses in cases of congenital adrenal hyperplasia and replacement of hormone deficiency. Surgical assignment of gender should never be done at the first operation. Although historically female gender had been assigned, there is abundant and convincing evidence that raising a genotypic male as a female has devastating consequences, not only anatomically but also psychosocially. This is particularly relevant given the role of prenatal and postnatal hormones on gender imprinting and identity. In general, surgical reconstruction should be performed after a full genetic work-up and with the involvement of pediatric endocrinologists, pediatric plastic surgeons, and ethicists with expertise in gender issues. Discussion with the family also plays an important role. This approach reduces the anxiety associated with these disorders and helps to ensure the normal physical and emotional development of these patients.

PEDIATRIC MALIGNANCY

Cancer is the second leading cause of death in children after trauma and accounts for approximately 11% of all pediatric deaths in the United States. Several features distinguish pediatric from adult cancers, including the presence of tumors that are predominantly seen in children, such as neuroblastomas and germ cell tumors, and the favorable response to chemotherapy observed for many pediatric solid malignancies, even in the presence of metastases.

Wilms' Tumor

CLINICAL PRESENTATION

Wilms' tumor is the most common primary malignant tumor of the kidney in children. Approximately 500 new cases are seen annually in the United States, and most are diagnosed in children between 1 and 5 years of age with the peak incidence at age 3. Advances in the care of patients with Wilms' tumor have resulted in an overall cure rate of roughly 90%, even in the presence of metastatic spread. The tumor usually develops in otherwise healthy children as an asymptomatic mass in the flank or upper abdomen. Frequently, the mass is discovered by a parent while bathing or dressing the child. Other symptoms include hypertension, hematuria, obstipation, and weight loss. Occasionally the mass is discovered after blunt abdominal trauma.

GENETICS OF WILMS' TUMOR

Wilms' tumor can arise from both germline and somatic mutations, and can occur in the presence or absence of a family history. Nearly 97% of Wilms' tumors are sporadic in that they occur in the absence of a heritable or congenital cause or risk factor. When a heritable risk factor is identified, the affected children often present at an earlier age and the disease is frequently bilateral. Most of these tumors are associated with germline mutations. It is well established that there is a genetic predisposition to Wilms' tumor in the WAGR syndrome, which consists of Wilms' tumor, aniridia, genitourinary abnormalities, and mental retardation. In addition, there is an increased incidence of Wilms' tumor in certain overgrowth conditions, particularly Beckwith-Wiedemann syndrome and hemihypertrophy. WAGR syndrome has been shown to result from the deletion of one copy each of the Wilms' tumor gene *WT1* and the adjacent aniridia gene *PAX6* on chromosome band 11p13. Beckwith-Wiedemann syndrome is an overgrowth syndrome that is characterized by visceromegaly, macroglossia, and hyperinsulinemic hypoglycemia. It arises from mutations at the 11p15.5 locus. There is evidence to suggest that analysis of the methylation status of several genes in the 11p15 locus could predict the individual risk for the development of Wilms' tumor. Importantly, however, most patients with Wilms' tumor do not have mutations at these genetic loci.

SURGICAL TREATMENT

Before operation, all patients suspected of having Wilms' tumor should undergo abdominal and chest CT. These studies characterize the mass, identify the presence of metastases, and provide information on the opposite kidney (Fig. 39-37). CT scanning also reveals the presence of nephrogenic rests, which are precursor lesions to Wilms' tumor. Abdominal ultrasonography should be performed to evaluate for the presence of renal vein or vena caval extension.

Fig. 39-37.

Wilms' tumor of the right kidney (arrow) in a 3-year-old girl.

The management of patients with Wilms' tumor has been carefully analyzed within the context of large studies involving thousands of patients. These studies have been coordinated by the National Wilms Tumor Study Group (NWTSG) in North America and by the International Society of Paediatric Oncology (SIOP), mainly in European countries. Significant differences in the approach to patients with Wilms' tumor have been highlighted by these studies. The NWTSG supports a strategy of surgery followed by chemotherapy in most instances, whereas the SIOP approach is to shrink the tumor using preoperative chemotherapy. In some circumstances preoperative chemotherapy is supported by both groups, including in cases of bilateral involvement or inferior vena cava involvement that extends above the hepatic veins and involvement of a solitary kidney by Wilms' tumor. The NWTSG proponents argue that preoperative therapy in other instances results in a loss of important staging information and therefore places patients at higher risk for recurrence or, alternatively, may lead to overly aggressive treatment in some cases and greater morbidity. However, the overall survival rates are no different for patients treated using the NWTSG and SIOP approaches.

The goal of surgery is complete removal of the tumor. It is crucial to avoid tumor rupture or injury to contiguous organs. A sampling of regional lymph nodes should be included, and all suspicious nodes should be excised or biopsied. Typically a transverse abdominal incision is made, and a transperitoneal approach is used. The opposite side is carefully inspected to ensure that no disease is present. Although historically this involved the complete mobilization of the contralateral kidney, current evidence indicates that preoperative high-resolution CT scanning is sufficiently accurate to detect clinically significant lesions if they are present. Provided only unilateral disease is present, a radical nephroureterectomy is then performed with control of the renal pedicle as an initial step. If there is spread above the hepatic veins, an intrathoracic approach may be required. If bilateral disease is encountered, chemotherapy is administered, followed by a nephron-sparing procedure. Biopsy may be required if the patient does not respond to the initial chemotherapy.

CHEMOTHERAPY

After nephroureterectomy for Wilms' tumor, the need for chemotherapy and/or radiation therapy is determined by the

histologic features and clinical stage of the tumor. Essentially, patients who have disease confined to one kidney that is completely excised surgically receive a short course of chemotherapy, and for this group a 97% 4-year survival is expected, with tumor relapse rare after that time. Patients who have more advanced disease or tumors with unfavorable histologic features receive more intensive chemotherapy and radiation therapy. Even in patients with stage IV disease, cure rates of 80% are achieved. The survival rates are worse in the small percentage of patients whose tumors are considered to be of unfavorable histologic type.

Neuroblastoma

CLINICAL PRESENTATION

Neuroblastoma is the third most common pediatric malignancy and accounts for approximately 10% of all childhood cancers. The overwhelming majority of patients have advanced disease at the time of presentation, and unlike in patients with Wilms' tumor, the overall survival rate is <30%. Over 80% of cases present before the age of 4 years, and the peak incidence is 2 years of age. Neuroblastomas arise from the neural crest cells and show different levels of differentiation. The tumor originates most frequently in the adrenal glands, posterior mediastinum, neck, or pelvis but can arise in any sympathetic ganglion. The clinical presentation depends on the site of the primary and the presence of metastases.

Two thirds of these tumors are first noted as an asymptomatic abdominal mass. The tumor may cross the midline, and a majority of patients already show signs of metastatic disease. Occasionally, children may experience pain from the tumor mass or from bony metastases. Proptosis and periorbital ecchymosis may occur due to the presence of retrobulbar metastasis. Because neuroblastomas originate in paraspinal ganglia, they may invade through neural foramina and compress the spinal cord, causing muscle weakness or sensory changes. Rarely, children may have severe watery diarrhea due to the secretion of vasoactive intestinal peptide by the tumor or show paraneoplastic neurologic findings, including cerebellar ataxia or opsoclonus/myoclonus.

DIAGNOSTIC EVALUATION

Because these tumors derive from the sympathetic nervous system, catecholamines and their metabolites are produced at increased levels. Elevated levels of serum catecholamines (dopamine, norepinephrine) or the urine catecholamine metabolites vanillylmandelic acid and homovanillic acid are seen. Measurement of vanillylmandelic acid and homovanillic acid in serum and urine aids in making the diagnosis and in monitoring for treatment adequacy and recurrence. The minimum criterion for a diagnosis of neuroblastoma is the presence of one of the following: (a) an unequivocal pathologic diagnosis made from tumor tissue by light microscopy (with or without immunohistologic analysis, electron microscopy, or increased levels of serum catecholamines or urinary catecholamine metabolites); or (b) the combination of bone marrow aspirate or biopsy specimen containing unequivocal tumor cells and increased levels of serum catecholamines or urinary catecholamine metabolites as described earlier.

The patient should be evaluated by abdominal CT, which may show displacement and occasionally obstruction of the ureter of an intact kidney (Fig. 39-38). Before the institution of therapy, a complete staging work-up should be performed. This includes radiograph of the chest, bone marrow biopsy, and radionuclide scans to search for metastases. Any abnormality on chest radiograph should be followed up with CT of the chest.

Abdominal neuroblastoma arising from the right retroperitoneum (*arrow*).

PROGNOSTIC INDICATORS

A number of biologic variables have been studied in children with neuroblastoma. An open biopsy is often required to provide sufficient tissue for analysis. The presence of hyperdiploid tumor DNA is associated with a favorable prognosis, whereas *N-myc* amplification is associated with a poor prognosis regardless of patient age. The Shimada classification describes tumors as having either favorable or unfavorable histologic features based on the degree of differentiation, the mitosis-karyorrhexis index, and the presence or absence of schwannian stroma. In general, children of any age with localized neuroblastoma and infants <1 year of age with advanced disease and favorable disease characteristics have a high likelihood of disease-free survival. By contrast, older children with advanced disease have a significantly decreased chance for cure even with intensive therapy. For example, aggressive multiagent chemotherapy has resulted in a 2-year survival rate of approximately 20% in older children with stage IV disease. Neuroblastoma in the adolescent has a worse long-term prognosis regardless of stage or site and, in many cases, a more prolonged course.

SURGERY

The goal of surgery is complete resection. However, this is often not possible due to the extensive locoregional spread of the tumor at the time of presentation. Under these circumstances, a biopsy is performed and preoperative chemotherapy is provided based on the stage of the tumor. After neoadjuvant treatment has been administered, surgical resection is performed. The principal goal of surgery is to obtain at least 95% resection, without compromising major structures. Abdominal tumors are approached through a transverse incision. Thoracic tumors may be approached through a posterolateral thoracotomy or through a thoracoscopic approach. An intraspinal component may be present. In all cases of intrathoracic neuroblastoma, particularly those at the thoracic inlet, it is important to be aware of the possibility that Horner's syndrome (anhidrosis, ptosis, meiosis) may develop. This typically resolves, although it may take many months to do so.

NEUROBLASTOMA IN INFANTS

Spontaneous regression of neuroblastoma has been well described in infants, especially in those with stage 4S disease. Regression generally occurs only in tumors with a near triploid number of chromosomes that also lack *N-myc* amplification and loss of chromosome arm 1p. Recent studies indicate that in infants with asymptomatic, small, low-stage neuroblastoma detected by screening, tumors may spontaneously regress. These patients may be observed safely without surgical intervention or tissue diagnosis.

Rhabdomyosarcoma

Rhabdomyosarcoma is a primitive soft tissue tumor that arises from mesenchymal tissues. The most common sites of origin are the head and neck (36%), extremities (19%), genitourinary tract (21%), and trunk (9%), although the tumor can arise virtually anywhere. The clinical presentation of the tumor depends on the site of origin. The diagnosis is confirmed by the findings of incisional or excisional biopsy after evaluation by MRI, CT of the affected area and the chest, and bone marrow biopsy. The tumor grows locally into surrounding structures and metastasizes widely to lung, regional lymph nodes, liver, brain, and bone marrow. The staging system for rhabdomyosarcoma is based on the tumor, nodes, and metastasis (TNM) system as established by the Soft Tissue Sarcoma Committee of the Children's Oncology Group. It is shown in Table 39-3. Surgery is an important component of the staging strategy and involves biopsy of the lesion and evaluation of lymphatics. Primary resection should be undertaken when complete excision can be performed without causing disability. If this is not possible, the lesion is biopsied and intensive chemotherapy is administered. It is important to plan the biopsy so that it does not interfere with subsequent resection. After the tumor has decreased in size, resection of gross residual disease should be performed. Radiation therapy is effective in achieving local control when microscopic or gross residual disease exists after initial treatment. Patients with completely resected tumors of embryonal histologic type do well without radiation therapy, but radiation therapy benefits patients with group I tumors of alveolar or undifferentiated histologic type.

Table 39-3 Staging of Rhabdomyosarcoma	
Stage 1	Localized disease involving the orbit or head and neck (excluding parameningeal sites), or genitourinary region (excluding bladder/prostate sites), or biliary tract (favorable sites).
Stage 2	Localized disease of any other primary site not included in the stage 1 category (unfavorable sites). Primary tumors must be ≤5 cm in diameter, and there must be no clinical regional lymph node involvement by tumor.
Stage 3	Localized disease of any other primary site. These patients differ from stage 2 patients by having primary tumors >5 cm and/or regional node involvement.
Stage 4	Metastatic disease at diagnosis.

Children's Cancer Study Group. Pediatric Oncology Group. *Cancer* 80:1165, 1997.

PROGNOSIS

The prognosis for rhabdomyosarcoma is related to the site of origin, resectability, presence of metastases, number of metastatic sites, and histopathologic features. Primary sites associated with more favorable prognoses include the orbit and nonparameningeal head and neck, paratestis and vagina (nonbladder, nonprostate genitourinary), and the biliary tract. Patients with tumors <5 cm in size have better survival than children with larger tumors, and children with metastatic disease at diagnosis have the poorest prognosis. Tumor histologic type influences prognosis; the embryonal variant is a

favorable type, whereas the alveolar type has an unfavorable prognosis.

Teratoma

Teratomas are tumors composed of tissue from all three embryonic germ layers. They may be benign or malignant, may arise in any part of the body, and are usually found in midline structures. Thoracic teratomas usually present as an anterior mediastinal mass. Ovarian teratomas present as an abdominal mass, often with symptoms of torsion, bleeding, or rupture. Retroperitoneal teratomas may present as a flank or abdominal mass.

Mature teratomas usually contain well-differentiated tissues and are benign, whereas immature teratomas contain varying amounts of immature neuroepithelium or blastemal tissues. Immature teratomas can be graded from 1 to 3 based on the amount of immature neuroglial tissue present. Tumors of higher grade are more likely to have foci of yolk sac tumor. Malignant germ cell tumors usually contain frankly neoplastic tissues of germ cell origin (i.e., yolk sac carcinoma, embryonal carcinoma, germinoma, and choriocarcinoma). Yolk sac carcinomas produce alpha-fetoprotein and choriocarcinomas produce β human chorionic gonadotrophin, so that elevations of these substances in the serum can serve as tumor markers. Germinomas can also produce elevation of serum beta human chorionic gonadotrophin, but not to the levels associated with choriocarcinoma.

SACROCOCCYGEAL TERATOMA

Sacroccocygeal teratoma usually presents as a large mass extending from the sacrum in the newborn period. Diagnosis may be established by prenatal ultrasonography. In fetuses with evidence of hydrops and a large sacroccocygeal teratoma, prognosis is poor; thus prenatal intervention has been advocated in such patients. The mass may be as small as a few centimeters in diameter or as massive as the size of the infant (Fig. 39-39). The tumor has been classified based on the location and degree of intrapelvic extension. Lesions that grow predominantly into the presacral space often present later in childhood. The differential diagnosis consists of neural tumors, lipoma, and myelomeningoceles.

Sacroccygeal teratoma in a 2-day-old boy.

Most tumors are identified at birth and are benign. Malignant yolk sac tumor histology occurs in a minority of these tumors. Complete resection of the tumor as early as possible is essential. The rectum and genital structures are often distorted by the tumor but usually can be preserved in the course of resection. Perioperative complications of hypothermia and hemorrhage can occur with massive tumors and may prove lethal. These are of particular concern in small, preterm infants with large tumors. The cure rate is excellent if the tumor is excised completely. The majority of patients who develop recurrent disease can be treated successfully with subsequent platinum-based chemotherapy.

Liver Tumors

More than two thirds of all liver tumors in children are malignant. There are two major histologic subgroups: hepatoblastoma and hepatocellular carcinoma. The age of onset of liver cancer in children is related to the histologic type of the tumor. Hepatoblastoma is the most common malignancy of the liver in children, with most of these tumors diagnosed before 4 years of age. Hepatocellular carcinoma is the next most common, with a peak incidence between 10 and 15 years of age. Malignant mesenchymomas and sarcomas are much less common and constitute the remainder of the malignancies. The finding of a liver mass does not necessarily imply that a malignancy is present. Nearly 50% of all masses are benign; hemangiomas are the most common lesion.

Most children with a liver tumor have an abdominal mass that is usually painless and that is discovered by the parents while changing the child's clothes or while bathing the child. Patients are rarely jaundiced but may show anorexia and weight loss. Most liver function test results are normal. Alpha-fetoprotein levels are increased in 90% of children with hepatoblastomas but are elevated much less commonly in children with other liver malignancies. Radiographic evaluation of these children

should include an abdominal CT scan to identify the lesion and to determine the degree of local invasiveness (Fig. 39-40). For lesions that appear malignant, a biopsy should be performed unless the lesion can be completely resected easily. Hepatoblastoma is most often unifocal, whereas hepatocellular carcinoma is often extensively invasive or multicentric. If a hepatoblastoma is completely removed, the majority of patients survive; however, only a minority of patients have lesions amenable to complete resection at diagnosis.

Fig. 39-40.

Computed tomographic scan of the abdomen showing hepatocellular carcinoma (*arrows*) in a 12-year-old boy.

A staging system based on postsurgical extent of tumor and surgical resectability is shown in Table 39-4. The overall survival rate for children with hepatoblastoma is 70%, in contrast to only 25% for those with hepatocellular carcinoma. Children diagnosed with stage I and II hepatoblastoma have a cure rate of >90% compared with 60% for those with stage III tumors and approximately 20% for those with stage IV disease. Among children diagnosed with hepatocellular carcinoma, those with stage I tumors have a good outcome, whereas those with stage III or IV tumors usually do not survive. The fibrolamellar variant of hepatocellular carcinoma may have a better prognosis.

Table 39-4 Staging of Pediatric Liver Cancer	
Stage I	No metastases, tumor completely resected
Stage II	No metastases, tumor grossly resected with microscopic residual disease (i.e., positive margins); or tumor rupture or tumor spill at the time of surgery
Stage III	No distant metastases, tumor unresectable or resected with gross residual tumor, or positive lymph nodes
Stage IV	Distant metastases regardless of the extent of liver involvement

SURGERY

The abdominal CT scan usually indicates the resectability of the lesion, although occasionally this can be determined only at the time of exploration. Complete surgical resection of the tumor is the primary goal and is essential for cure. For tumors that are unresectable, preoperative chemotherapy should be administered to reduce the size of the tumor and improve the possibility for complete removal. Chemotherapy is more successful for hepatoblastoma than for hepatocellular carcinoma. Areas of locally invasive disease, such as the diaphragm, should be resected at the time of surgery. For unresectable tumors, liver transplantation may be offered to select patients. The fibrolamellar variant of hepatocellular carcinoma may have a better outcome with liver transplantation than other hepatocellular carcinomas.

TRAUMA IN CHILDREN

Injury is the leading cause of death among children >1 year of age. In fact, trauma is responsible for almost half of all pediatric deaths—more than cancer, congenital anomalies, pneumonia, heart disease, homicide, and meningitis combined. Death from unintentional injuries accounts for 65% of all injury-related deaths in children <19 years. Motor vehicle collisions are the leading cause of death in individuals aged 1 to 19 years, followed by homicide or suicide (predominantly with firearms) and drowning. Each year, approximately 20,000 children and teenagers die as a result of injury in the United States. For every child who dies from an injury, it is calculated that 40 others are hospitalized and 1120 are treated in emergency departments. An estimated 50,000 children acquire permanent disabilities each year, most of which are the result of head injuries. Thus, pediatric trauma continues to be one of the major threats to the health and well-being of children.

Specific considerations apply to trauma in children that influence management and outcome. These relate to the mechanisms of injury, the anatomic variations in children compared with adults, and the physiologic responses of children.

Mechanisms of Injury

Most pediatric trauma is blunt. Penetrating injuries are seen in the setting of gun violence, falls onto sharp objects, or penetration by glass after falling through windows. Age and gender significantly influence the patterns of injury. Male children <16 years are exposed to contact sports and drive motor vehicles. As a result, they have a different pattern of injury than younger children, characterized by higher injury severity scores. In the infant and toddler age group, falls are a frequent cause of severe injury. Injuries in the home are extremely common. These include falls, near-drownings, caustic ingestion, and nonaccidental injuries.

Initial Management

The goals of managing the pediatric trauma patient are similar to those of managing the adult trauma patient and conform to the Advanced Trauma Life Support guidelines as established by the American College of Surgeons Committee on Trauma. Airway control is the first priority. In a child, respiratory embarrassment can proceed quickly to cardiac arrest. One must be aware of the anatomic differences between the airway of the child and that of the adult. The child has a shorter neck, smaller and more anterior larynx, floppy epiglottis, short trachea, and large tongue. The child's fifth digit can provide an estimate of the required size of the endotracheal tube. Alternatively, the formula $(\text{age} + 16)/4$ may be used. Uncuffed endotracheal tubes should be used in children <8 years of age to minimize tracheal trauma. After the airway is evaluated, breathing is

assessed. Gastric distention from aerophagia can severely compromise respirations. A nasogastric tube should therefore be placed early during the resuscitation. Pneumothorax or hemothorax should be treated promptly. When evaluating the circulation, one should recognize that tachycardia is usually the earliest measurable response to hypovolemia. Other signs of impending hypovolemic shock in children include changes in mentation, delayed capillary refill, skin pallor, and hypothermia. IV access should be rapidly secured once the patient arrives in the trauma bay. The first approach should be to use the antecubital fossae. If this is not possible, a cutdown to the saphenous at the groin can be performed quickly and safely. Intraosseous cannulation can provide temporary access in infants until IV access is established. The use of percutaneous neck lines should generally be avoided. Blood is drawn for cross-matching and measurement of liver enzyme, lipase, and amylase levels and hematologic profile after the IV lines are placed.

In patients who show signs of volume depletion, a 20-mL/kg bolus of saline or lactated Ringer's solution should be given promptly. If the patient does not respond to three boluses, blood should be transfused (10 mL/kg). The source of bleeding should be established. Common sites include the chest, abdomen, pelvis, extremity fractures, or large scalp wounds. These should be carefully sought. Care is taken to avoid hypothermia by infusing warmed fluids and by using external warming devices.

Evaluation of Injury

Radiographs of the cervical spine, chest, and abdomen with pelvis should be obtained for all patients. All extremities that are suspicious for fracture should also be evaluated by radiography. This is preferable to performing routine CT scanning of the neck in the child, because radiographs provide sufficient anatomic detail in children to diagnose clinically significant cervical spine injuries while subjecting the child to significantly less radiation than CT scans. Screening blood tests that include levels of aspartate aminotransferase, alanine aminotransferase, amylase, and lipase are useful for the evaluation of liver and pancreatic injuries. Significant elevations in the levels of these enzymes require further evaluation by CT scanning. The child with significant abdominal tenderness and a mechanism of injury that could cause intra-abdominal injury should undergo abdominal CT scanning with IV and oral contrast in all cases. Diagnostic peritoneal lavage has a limited role as a screening test in children. However, occasionally it can be useful for a child who is brought emergently to the operating room for management of significant intracranial hemorrhage. At the time of craniotomy, diagnostic peritoneal lavage can be performed concurrently to detect abdominal bleeding. Although focused abdominal ultrasonography is extremely useful in the evaluation of adult abdominal trauma, it has not been widely accepted in the management of pediatric blunt abdominal trauma. In part this relates to the widespread use of nonoperative treatment for most solid organ injuries, which would result in a positive finding on abdominal ultrasonographic scan.

Injuries to the Central Nervous System

The central nervous system (CNS) is the most commonly injured system, and CNS trauma is the leading cause of death among injured children. In the toddler age group, nonaccidental trauma is the most common cause of serious head injury. Findings suggestive of abuse include the presence of retinal hemorrhage on funduscopic evaluation and intracranial hemorrhage without evidence of external trauma (indicative of a shaking injury) as well as fractures at different stages of healing on skeletal survey. In older children, CNS injury occurs most commonly after falls and bicycle and motor vehicle collisions. The initial head CT scan often underestimates the extent of injury in children. Criteria for performing head CT include any loss of consciousness or amnesia for the trauma and inability to assess CNS status, as in the intubated patient. Patients with mild, isolated head injury (Glasgow Coma Scale score of 14 or 15) and negative results on CT scans can be

discharged if their neurologic status is normal after 6 hours of observation. Young children and those in whom there is multisystem involvement should be admitted to the hospital for overnight observation. Any change in the neurologic status warrants neurosurgical evaluation and repeat CT scanning. In patients with severe head injury (Glasgow Coma Scale score of ≤ 8), urgent neurosurgical consultation is required. These patients are evaluated to determine whether intracranial pressure monitoring or craniotomy is necessary.

Thoracic Injuries

The pediatric thorax is pliable due to incomplete calcification of the ribs and cartilages. As a result, blunt chest injury commonly results in pulmonary contusion, although rib fractures are infrequent. Diagnosis is made by chest radiograph, and severe hypoxia requiring mechanical ventilation may be present. Pulmonary contusion usually resolves with careful ventilator management and judicious volume resuscitation. Children who have sustained massive blunt thoracic injury may develop traumatic asphyxia. This is characterized by cervical and facial petechial hemorrhages or cyanosis associated with vascular engorgement and subconjunctival hemorrhage. Management includes ventilation and treatment of coexisting CNS or abdominal injuries. Penetrating thoracic injuries may result in damage to the lung or major disruption of the bronchi or great vessels.

Abdominal Injuries

In children, the small rib cage and minimal muscular coverage of the abdomen can result in significant injury after seemingly minor trauma. The liver and spleen in particular are relatively unprotected and are often injured after direct abdominal trauma. Duodenal injuries are usually the result of blunt trauma, which may arise from child abuse or injury from a bicycle handlebar. Duodenal hematomas usually resolve without surgery. Small intestine injury usually occurs in the jejunum in the area of fixation by the ligament of Treitz. These injuries are generally caused by rapid deceleration when a lap belt is worn. There may be a hematoma on the anterior abdominal wall caused by the lap belt, the so-called seat belt sign (Fig. 39-41A). This should alert the caregiver to the possibility of an underlying small bowel injury (Fig. 39-41B) as well as to a potential lumbar spine injury (Chance fracture).

Photographs of a patient who sustained a lap belt injury. **A.** Arrowheads denote bruising across the abdomen from the lap belt. **B.** At laparotomy, a perforation of the small bowel was identified.

The spleen is injured relatively commonly in blunt abdominal trauma in children. The extent of injury to the spleen is graded (Table 39-5), and management is governed by the injury grade. Current treatment involves a nonoperative approach in most cases, even for grade IV injuries, assuming the patient is hemodynamically stable. This approach avoids surgery in most cases. All patients should be placed in a monitored unit, and type-specific blood should be available for transfusion. When nonoperative management is successful, as it is in most cases, an extended period of bedrest is prescribed. This optimizes the chance for healing and minimizes the likelihood of reinjury. A typical guideline is to keep the child on extremely restricted activity for 2 weeks longer than the grade of spleen injury (i.e., a child with a grade IV spleen injury is prescribed 6 weeks of restricted activity). When the child has an ongoing fluid requirement or when a blood transfusion is necessary, exploration should not be delayed. At surgery, the spleen can often be salvaged. If a splenectomy is performed, prophylactic antibiotics

and immunizations should be administered to protect against overwhelming postsplenectomy sepsis.

Table 39-5 Grading of Splenic Injuries	
Grade I	Subcapsular hematoma, <10% surface area capsular tear, <1 cm in depth
Grade II	Subcapsular hematoma, nonexpanding, 10–50% surface area; intraparenchymal hematoma, nonexpanding, <2 cm in diameter; capsular tear, active bleeding, 1–3 cm, does not involve trabecular vessel
Grade III	Subcapsular hematoma, >50% surface area or expanding; intraparenchymal hematoma, >2 cm or expanding; laceration >3 cm in depth or involving trabecular vessels
Grade IV	Ruptured intraparenchymal hematoma with active bleeding; laceration involving segmental or hilar vessels producing major devascularization (>25% of spleen)
Grade V	Shattered spleen; hilar vascular injury that devascularizes spleen

The liver is also commonly injured in blunt abdominal trauma. A grading system is used to characterize hepatic injuries (Table 39-6), and nonoperative management is usually successful (Fig. 39-42). Recent studies have shown that associated injuries are more significant predictors of outcome in children with liver injuries than the actual injury grade. Criteria for surgery are similar to those for splenic injury and primarily involve hemodynamic instability. The intraoperative considerations in the management of massive hepatic injury are similar in children and adults.

Table 39-6 Liver Injury Grading System	
Grade I	Capsular tear <1 cm in depth
Grade II	Capsular tear 1–3 cm in depth, <10 cm in length
Grade III	Capsular tear >3 cm in depth
Grade IV	Parenchymal disruption 25–75% of hepatic lobe or one to three Couinaud's segments
Grade V	Parenchymal disruption >75% of hepatic lobe or more than three Couinaud's segments within a single lobe; injury to retrohepatic vena cava

Abdominal computed tomographic scan of a child showing a grade III liver laceration (*arrows*).

Renal contusions may occur in significant blunt abdominal trauma. Nonoperative management is usually successful, unless the patient's condition is unstable due to active renal bleeding. The presence of a normal contralateral kidney should be confirmed at the time of surgery.

FETAL INTERVENTION

One of the most exciting developments in the field of pediatric surgery has been the emergence of fetal surgery. In general, performance of a fetal intervention may be justified when a defect is present that would cause devastating consequences to the infant if left uncorrected. For the overwhelming majority of congenital anomalies, postnatal surgery is the preferred modality. However, in specific circumstances, fetal surgery may offer the best possibility for a successful outcome. The decision to perform a fetal intervention requires careful patient selection as well as the availability of a multidisciplinary center that is dedicated to the surgical care of the fetus and the mother. Patient selection is dependent in part on highly accurate prenatal imaging, which includes ultrasonography and MRI. Performance of a fetal surgical procedure may be associated with significant risks to both the mother and the fetus. From the maternal viewpoint, open fetal surgery may lead to uterine bleeding due to the uterine relaxation required during the procedure. The long-term effects on subsequent pregnancies remain to be established. For the fetus, in utero surgery carries the risk of premature labor and amniotic fluid leak. As a result, these procedures are performed only when the expected benefit of fetal intervention outweighs the risk to the fetus of standard postnatal care. Currently, open fetal intervention may be efficacious in certain cases of large congenital lung lesions with hydrops, large teratomas with hydrops, twin-twin transfusion syndrome, some types of congenital lower urinary tract obstruction, and myelomeningocele. This list of diagnoses that potentially may benefit from a fetal intervention is significantly shorter than that of a decade ago, due in part to improvements in the outcomes of several diseases that are managed in the postnatal period and also to the recognition of the relative lack of benefit of fetal surgery for many conditions.

Fetal Surgery for Lower Urinary Tract Obstruction

Lower urinary tract obstruction refers to a group of diseases characterized by obstruction of the distal urinary system. Common causes include the presence of posterior urethral valves and urethral atresia, as well as other anomalies of the urethra and bladder. The pathologic effects of lower urinary tract obstruction lie in the resultant massive bladder distention that occurs, which can lead to reflux hydronephrosis. This may result in oligohydramnios and cause limb contractures, facial anomalies (Potter facies), and pulmonary hypoplasia. Carefully selected patients with lower urinary tract obstruction may benefit from vesicoamniotic shunting. With relief of the obstruction and improvement in renal function, fetal growth and lung development may be preserved.

Fetal Surgery for Congenital Diaphragmatic Hernia

Given the high mortality associated with the most severe cases of congenital diaphragmatic hernia (CDH), tremendous efforts have been made to determine whether fetal intervention could improve the outcome of this disease. In 1990, Harrison and colleagues reported the first open fetal repair of CDH. The high morbidity associated with the open technique led to the development of fetal tracheal occlusion as a therapeutic approach. This was based on the observation that tracheal occlusion could lead to increased lung growth and reduction of the intrathoracic viscera in animal models. Tracheal occlusion can be achieved in utero by the placement of clips that are removed at the time of delivery. Despite initial enthusiasm for this approach, a recent randomized trial that compared fetal tracheal occlusion with standard postnatal care for left-sided CDH showed no improvement in survival for patients treated with tracheal occlusion.

Fetal Surgery for Myelomeningocele

Myelomeningocele refers to a spectrum of anomalies in which portions of the spinal cord are not covered by the spinal column. This leaves the neural tissue exposed to the injurious effects of the amniotic fluid as well as to trauma from contact with the uterine wall. Nerve damage ensues, resulting in varying degrees of lower extremity paralysis as well as bowel and bladder dysfunction. Initial observations indicated that the amount of injury increased throughout the pregnancy, which provided the rationale for fetal intervention. The current in utero approach for the fetus with myelomeningocele focuses on obtaining coverage of the exposed spinal cord. The efficacy of in utero treatment compared with postnatal repair remains to be determined.

Ex Utero Intrapartum Therapy Procedure

The ex utero intrapartum therapy (EXIT) procedure is used in circumstances in which airway obstruction is predicted at the time of delivery due to the presence of a large neck mass, such as a cystic hygroma or teratoma (Fig. 39-43), or to congenital tracheal stenosis. The success of the procedure depends on the maintenance of uteroplacental perfusion for a sufficient duration to secure the airway. To achieve this, deep uterine relaxation is obtained during a cesarian section under general anesthesia. Uterine perfusion with warmed saline also promotes relaxation and blood flow to the placenta. On average, between 20 and 30 minutes of placental perfusion can be achieved. The fetal airway is secured either by placement of an orotracheal tube or performance of a tracheostomy. Once the airway is secured, the cord is cut, and a definitive procedure may be performed to relieve the obstruction in the postnatal period. In general, infants with cystic neck masses such as lymphangiomas have a more favorable response to an EXIT procedure than infants with solid tumors such as teratomas; this is particularly true for premature infants.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 40. Urology >

KEY POINTS

1. In the surgical treatment of invasive bladder cancer, a thorough lymph node dissection is essential.
2. Patients with testicular cancer without radiographic evidence of metastasis often harbor microscopic deposits of disease and require either adjuvant treatment or very close surveillance.
3. Nephrectomy is the mainstay of treatment for localized renal cell carcinoma, and it also provides a survival benefit in the setting of metastatic disease.
4. The vast majority of renal trauma can be treated conservatively, with early surgical intervention reserved for persistent bleeding or renal vascular injuries.
5. Distal ureteral injuries should only be treated with bladder reimplantation because of the high failure rate of distal uretero-ureterostomies.
6. Extraperitoneal bladder ruptures can be treated conservatively but intraperitoneal ruptures typically require surgical repair.
7. Nearly all episodes of acute urinary retention can be treated with conservative measures such as decreasing narcotic usage and increasing ambulation.
8. Testicular torsion is an emergency where successful testicular salvage is inversely related to the delay in repair, so cases with a high degree of clinical suspicion should not wait for a radiologic diagnosis.
9. Fournier's gangrene is a potentially lethal condition that requires aggressive débridement and close follow-up due to the frequent need for repeat débridement.
10. Most small ureteral calculi will pass spontaneously, but larger stones (>6 mm) are better treated with ureteral stenting and lithotripsy.

ANATOMY

The anatomic structures that fall under the purview of genitourinary surgery are the kidneys, adrenals, ureters, bladder, prostate, seminal vesicles, urethra, vas deferens, and testes. They are situated mainly outside the peritoneum, but urologic surgery frequently involves intraperitoneal approaches to the kidney, bladder, and retroperitoneal lymph nodes. Furthermore, urologists must be familiar with the techniques of intestinal surgery for the purposes of urinary diversion and bladder augmentation.

Kidney and Adrenal

The kidneys are paired retroperitoneal organs that are invested in a fibro-fatty layer: Gerota's fascia. Posterolaterally, the kidneys are bordered by the quadratus lumborum and posteromedially by the psoas muscle. Anteriorly they are confined by

the posterior layer of the peritoneum. On the left, the spleen lies superolaterally, separated from the kidney and Gerota's fascia by the peritoneum. On the right, the liver is situated superiorly and anteriorly and also is separated by the peritoneum. The second portion of the duodenum is in close proximity to the right renal vessels and, during right renal surgery, it must be reflected anteromedially (Kocherized) to achieve vascular control. The renal arteries, in the typical configuration, are single vessels extending from the aorta that branch into several segmental arteries before entering the renal sinus. The right renal artery passes posterior to the vena cava and is significantly longer than the left renal artery. Occasionally, the kidney is supplied by a second renal artery, typically to the lower pole. Within the kidney, there is essentially no anastomotic arterial flow, so the kidneys are prone to infarction when branch vessels are interrupted. The renal veins, which course anteriorly to the renal arteries, drain to the vena cava. The left renal vein passes anteriorly to the aorta and is much longer than the right renal vein. The left vein is in continuity with the left gonadal vein, the left inferior adrenal vein, and a lumbar vein. These veins provide adequate drainage for the left kidney in the event that drainage to the vena cava is interrupted. The right renal vein has no such collateral venous drainage.

The collecting system of the kidney is composed of several major and minor calyces that coalesce into the renal pelvis. The renal pelvis can have either a mainly intrarenal or extrarenal position. The renal pelvis tapers into the ureteropelvic junction (UPJ) where it joins with the ureter.

The adrenal glands lie superomedially to the kidneys within Gerota's fascia. There is a layer of Gerota's fascia between the adrenal and the kidney. However, in the presence of a tumor or inflammatory process, the adrenal can become very adherent to the kidney, and separation can be difficult. The arterial supply of the adrenals derives from the aorta and small branches from the renal arteries. The venous drainage on the left is mainly through the inferior phrenic vein and through the left renal vein via the inferior adrenal vein. On the right, the adrenal is drained by a very short (<1 cm) vein to the vena cava. It can be avulsed by moderate traction and can be the source of troublesome bleeding.

Ureter

The ureters are muscular structures that course anterior to the psoas muscles from the renal pelvis to the bladder. The blood supply of the proximal ureter derives from the aorta and renal artery and comes mainly from the medial direction. However, once it crosses the iliac vessels at the pelvic brim near where the iliac vessels bifurcate, it derives its blood supply laterally from branches from the iliac arteries. The blood supply has implications for managing ureteral injuries. Mobilizing the distal ureter for anastomosis requires releasing its lateral attachments, which results in ischemia, so for this reason, distal ureteral injuries are typically managed by bringing the proximal ureter to the bladder.

The ureters course along the pelvic sidewall and pass under the uterine arteries in women, making them vulnerable to injury during hysterectomy. They enter the bladder at the lateral aspect of the base. They course through the bladder musculature at an oblique angle and open into the bladder at the ureteral orifices that are relatively close to the bladder outlet.

Bladder and Prostate

The urinary bladder is situated in the retropubic space in an extraperitoneal position. A portion of the bladder dome is adjacent to the peritoneum, so ruptures at this point can result in intraperitoneal urine leakage. The anatomic relations of the bladder are dependent on the degree of filling. A very distended bladder can project above the umbilicus. At physiologic volumes (200 to 400 mL), the bladder projects modestly into the abdomen. The sigmoid colon lies superolaterally and may become adherent or fistulize to the bladder secondary to diverticulitis. The rectum lies posterior to the bladder in males, whereas the vagina and uterus are posterior in females.

In males, the prostate is in continuity with the bladder neck, and the urethra courses through it. The prostate has a significant component of smooth muscle and can provide urinary continence even in the absence of the external striated sphincter. The puboprostatic ligaments connect the prostate to the pubic symphysis, and pelvic fractures often result in proximal urethral injuries due to the traction that these ligaments provide. Between the prostate and the rectum lies Denonvilliers' fascia, which is the main anatomic barrier that prevents prostate cancer from regularly penetrating into the rectum. Just beyond the apex of the prostate is the external (voluntary) sphincter, which is part of the genitourinary diaphragm.

Penis

The penis is composed of three main bodies, along with fascia, neurovascular structures, and skin. The corpora cavernosum are the paired, cylinder-like structures that are the main erectile bodies of the penis. Proximally, they lie along the medial aspects of the inferior pubic rami in the perineum. Distally, they fuse along their medial aspects and form the pendulous penis. The corpora cavernosum consist of a tough outer layer called the *tunica albuginea*, and spongy, sinusoidal tissue inside that fills with blood to result in erection. The two corpora cavernosum have numerous vascular interconnections, so they function as one compartment. The cavernosal arteries, which are branches of the penile artery, course through the center of the corporal sinusoidal tissue. The sinusoidal tissue is innervated by the cavernosal nerves, which are autonomic nerves that originate in the hypogastric plexus and play a critical role in erection. Before entering the penis, the cavernosal nerves travel immediately adjacent to the prostate, which explains why they often are damaged at radical prostatectomy. On the underside of the penis lies the corpus spongiosum, which surrounds the urethra. The spongiosum does not have the same tunical layers as the corpora cavernosum, so it does not exhibit the same firmness during erection. The tip of the penis, called the glans, is in continuity with the corpus spongiosum.

Surrounding all three bodies of the penis are the outer dartos fascia and the inner Buck's fascia. The dorsal nerves of the penis, which provide sensation to the penile skin, derive from the pudendal nerves and, along with the dorsal penile arteries, travel along the dorsum of the penis within Buck's fascia. The neurovascular bundle of the penis must be avoided during surgical exploration of the penis for injuries or reconstruction.

Scrotum and Testes

The scrotum is a capacious structure that contains the testes and epididymes. Because of its dependent position, significant edema can develop when a patient is fluid overloaded and bleeding can result in the accumulation of large hematomas. Beneath the skin, from superficial to deep, are the dartos, external spermatic, cremasteric, and internal spermatic fascias. These layers are not always distinct. Beneath the internal fascia are the parietal and visceral layers of the tunica vaginalis, between which hydroceles form. The visceral layer of the tunica vaginalis is adherent to the testis. The testis' noncompliant outer layer is the tunica albuginea. Inside the tunica are the seminiferous tubules. The blood supply enters the testis at the superior pole by way of the spermatic cord. In addition to the vas deferens, the cord carries three separate sources of arterial blood flow—the testicular artery that branches from the aorta below the renal artery, the cremasteric artery, and the deferential artery. Interruption of one of the arteries during vasectomy or inguinal surgery will not result in ischemia to the testis. Venous drainage parallels the arterial inflow except that the left gonadal vein drains into the renal vein rather than the vena cava. Dilation of spermatic veins is called a *varicocele* and may be palpable when a patient is standing. They are not considered pathologic unless they cause discomfort or affect fertility, which they sometimes do.

UROLOGIC MALIGNANCIES

Bladder Cancer

The most common form of bladder cancer in the United States is transitional cell carcinoma (TCC). Tobacco use, followed by occupational exposure to various carcinogenic materials such as automobile exhaust or industrial solvents are the most frequent risk factors, though many with the disease have no identifiable risks.¹ Other forms of bladder cancer, such as adenocarcinoma and squamous cell carcinoma, occur in distinct patient populations. Patients with chronic irritation from catheters, bladder stones, or schistosomiasis infection are at risk for the squamous cell variant while those with urachal remnants or bladder exstrophy have an increased risk of adenocarcinoma.

Bladder cancer can be categorized into invasive and noninvasive types. Management of TCC varies greatly, depending on the depth of invasion. A complete transurethral resection of the bladder tumor, which allows staging of the tumor, is the first step. The tumor is completely removed, if possible, along with a sampling of the muscular bladder wall underlying the tumor, because the large majority of bladder tumors grow in an exophytic pattern projecting into the bladder lumen. In females, a bimanual examination can help determine if there is fixation of the bladder to adjacent structures. Radiologic imaging of most bladder tumors is of limited benefit in determining the presence or size/stage of a bladder tumor. However, in the presence of a known bladder tumor, unilateral or bilateral hydronephrosis is an ominous sign of locally advanced disease.² Computed tomography (CT) scans do provide valuable information regarding metastatic involvement of pelvic lymph nodes, liver, or lung. For patients that have disease invading into bladder muscle (T2), immediate cystectomy with extended lymph node dissection offers the best chance of survival, although current long-term cure for those presenting with clinically localized disease is still only achieved in 50 to 60% of patients.³ The addition of neoadjuvant or adjuvant chemotherapy in those without discernible metastatic spread is gaining increasing acceptance and does provide an increase in survival.⁴ Patients with limited lymph node involvement may be cured with surgery alone, but those with extensive lymph node involvement have a dismal prognosis.

Patients have multiple reconstructive options, including continent and noncontinent urinary diversions. The orthotopic neobladder has emerged as a popular urinary diversion for patients without urethral involvement. This diversion type involves the detubularization of a segment of bowel, typically distal ileum, which is then refashioned into a pouch that is anastomosed to the proximal urethral. Detubularization decreases intrapouch filling pressure, which improves urinary storage capacity. The external sphincter is still intact, and voiding is achieved through sphincteric relaxation and a Valsalva's maneuver. The most common noncontinent diversion is the ileal conduit, whereby a segment of distal ileum is isolated with one end brought out through the abdominal wall as a urostomy. Ileal conduits are preferred for renal insufficiency because urine is not "stored" and therefore has less time in contact with the absorptive surface of the ileal segment. Conduits are also used when the bladder is unresectable, but urinary diversion is necessary due to intractable bleeding or severe voiding pain. Each segment of bowel that is used offers its own advantages and inherent complications.

Patients with nonmuscle invasive TCC (confined to the bladder mucosa or submucosa) can be managed with transurethral resection alone. However, patients are at risk for recurrence and progression to muscle-invasive disease. Tumor grade is extremely important in assessing the risk of disease progression. Those patients with high-grade disease or recurrent tumors can be treated with intravesical agents such as bacille Calmette-Guérin or mitomycin C. These agents decrease risk of progression and recurrence, by induction of an effective immunologic antitumor response in the case of bacille Calmette-Guérin and through direct cytotoxicity for mitomycin C. Those patients at high risk of progression that fail conservative

therapy should be offered cystectomy. As upper tract recurrence is fairly common, surveillance must be performed with retrograde pyelograms or CT urograms.

SURGICAL APPROACHES AND COMPLICATIONS

The typical surgical approach for cystectomy is a lower midline incision from just above the umbilicus to the pubic symphysis. This allows adequate exposure of the pelvic contents, iliac vessels, and lower abdominal cavity. The peritoneum between the median umbilical ligaments (urachal remnant) also is taken with the specimen. In men, the prostate is removed with the bladder. In women, the uterus, ovaries (in postmenopausal women), and anterior wall of the vagina are removed with the bladder. The vagina may be spared, depending on the location and extent of the tumor, but significantly more operative bleeding results. Robotic approaches for cystectomy are increasingly used, but the lymph node dissection and urinary diversion is still usually finished through an open incision. The benefit of the robotic portion is decreased blood loss during the pelvic dissection (due to pneumoperitoneum), and the shortening of the time that the abdomen is open.

Complications of bladder cancer surgery involve perforation during transurethral resection of the bladder tumor, which requires catheter drainage for several days if small or open repair if large and intraperitoneal, which is rare. Cystectomy and urinary diversion may result in ileus, bowel obstruction, intestinal anastomotic leak, urine leak, or rectal injury. A urine leak from the ureteroenteric anastomosis is a common cause of ileus, but may also result in intra-abdominal urinoma or abscess formation if drainage is ineffective. Deep venous thrombosis is common after cystectomy⁵ due to the advanced age of most patients, proximity of the iliac veins to the resection and lymph node dissection, and the presence of malignancy.

Testicular Cancer

Testicular cancer is the most common solid malignancy in men ages 15 to 35 years of age.⁶ Most men are diagnosed with an asymptomatic enlarging mass (Fig. 40-1). A major risk for the development of testicular cancer is cryptorchidism. Although the debate continues over whether early surgical intervention to bring an undescended testis into the scrotum alters the future risk of cancer, it is accepted that doing so allows much easier monitoring for the development of a testicular mass.

Testicular cancer. Patients often present with advanced disease in spite of scrotal enlargement for several months.

Most neoplasms arise from the germ cells, though nongerm cell tumors arise from Leydig's or Sertoli's cells. The nongerm cell tumors are rare and generally follow a more benign course. Germ cell cancers are categorically divided into seminomatous and nonseminomatous forms that follow different treatment algorithms.

All solid testicular masses observed on physical examination and documented on ultrasound are malignant until proven otherwise, because the vast majority are cancerous. Initial studies must include tumor markers, including alpha-fetoprotein and beta human chorionic gonadotrophin. Elevated tumor markers are found almost exclusively in nonseminomatous germ cell tumor, though occasionally seminomas will cause a modest rise in beta human chorionic gonadotrophin. Chest and abdominal imaging must be performed to evaluate for evidence of metastasis. The most common site of spread is the retroperitoneal lymph nodes extending from the common iliac vessels to the renal vessels, and abdominal imaging should be performed in all patients. There is no role for percutaneous biopsy of testicular masses due to the risk of seeding the scrotal wall and changing the natural retroperitoneal lymphatic drainage of the testicle, because the testes have a remarkably predictable pattern of lymphatic drainage. In cases where metastatic disease to the testicle is suspected, an open testicular biopsy by delivery of the testicle through the inguinal canal is recommended. Lymphoma may involve one or both testes, but evidence of the disease usually is present elsewhere in the body, although relapses may be isolated to the testes.

Even in the absence of enlarged lymph nodes (stage I), micrometastatic disease is often present, so adjuvant surgery or chemotherapy is offered. However, watchful waiting protocols have been gaining in popularity. Retroperitoneal lymph node dissection (RPLND) is potentially curative in the setting of limited lymph node involvement and has been the preferred

adjuvant treatment of those with stage I disease; some advocate its use in stage IIa and IIb disease. Pure seminoma is exquisitely radiosensitive and stage I, IIa, and IIb disease can be treated with external beam radiation to the retroperitoneal nodes. Both forms of germ cell tumors with disseminated disease or large bulky lymph nodes are best treated with chemotherapy. However, teratoma frequently is a component of retroperitoneal lymph node metastasis, and it is not responsive to chemotherapy or radiation and can demonstrate aggressive malignant degeneration. Postchemotherapy RPLND for residual masses can be challenging. Large bulky metastases may encase the great vessels, and vascular graft placement after resection occasionally is required.

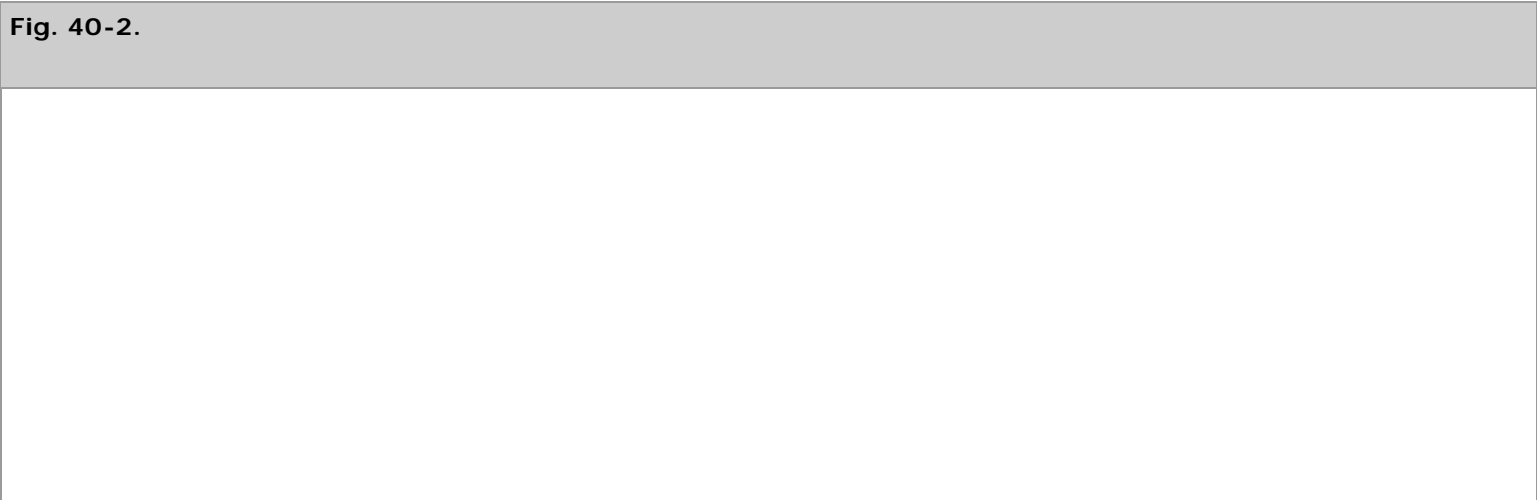

SURGICAL APPROACH AND COMPLICATIONS

For orchiectomy, an inguinal incision is made over the external ring and carried laterally over the position of the internal ring. It is important to not violate the scrotal skin during orchiectomy due to the concern, mostly theoretical, of altering the lymphatic drainage of the testis. For RPLND, a midline incision usually is made from the xiphoid process to the pubic symphysis, although some use a thoracoabdominal approach. Laparoscopic approaches are used with increasing regularity.

Complications of testicular cancer surgery include scrotal hematoma formation, which can be prevented by meticulous hemostasis. Complications after RPLND include bowel obstruction; excessive bleeding, particularly from retrocaval lumbar veins; and chylous ascites. Patients who undergo a full, bilateral RPLND often suffer from anejaculation due to the interruption of the descending postganglionic sympathetic nerve fibers that are involved in seminal emission. For this reason, right and left templates have been developed that limit dissection and preserve some of these nerves with a low risk of leaving residual microscopic cancer.⁷

Kidney Cancer

Renal cell carcinoma (RCC) is a malignancy of the renal epithelium that can arise from any component of the nephron (Fig. 40-2). In 2008, there is estimated to be 54,000 new cases in the United States, with roughly 13,000 deaths.⁸ With the widespread use of imaging for many medical complaints, a stage migration has led an increased incidence of small renal masses.⁹ Various histologic subtypes include clear-cell, papillary (types I and II), chromophobe, collecting duct, and unclassified forms. Collecting duct and unclassified forms have dismal prognosis and very little response to systemic therapy. Benign lesions, which are more commonly found when small tumors are removed, include oncocytomas and angiomyolipomas. Renal tumors are usually solid, but they also can be cystic. Simple cysts are very common and are not malignant, but more complex cysts may be malignant. The Bosniak classification system, based on septations, calcifications, and enhancement, is used to assess the likelihood of malignancy (Table 40-1).¹⁰

Complex renal cyst. A right kidney with a Bosniak type 3 renal cyst. Note the enhancing septum (*arrow*). This cyst was removed and found to be a high-grade papillary renal cell carcinoma.

Table 40-1 Bosniak Renal Cyst Computed Tomography Classification

Category	Description	Risk of Malignancy/Management
I	Thin-walled cyst with water density with no septations or calcifications.	0%/nonsurgical
II	Thin-walled cyst with few hairline septa that may contain fine or very limited thick calcifications. Also includes homogeneously hyperdense cysts <3 cm.	0%/nonsurgical
II F (follow)	Multiple hairline or slightly thickened septa without measurable enhancement. May contain nodular calcification. Also includes hyperdense cysts >3 cm.	~5%/should be followed for progression
III	Irregular or smooth thickened walls or septa with measurable enhancement.	~50%/surgical
IV	Same as III, but with enhancing solid components.	~100%/surgical

Most cases of RCC are sporadic, but many hereditary forms have been described. These syndromes frequently involve a germline mutation in a tumor-suppressor gene. Von Hippel-Lindau disease is associated with multiple tumors including clear-cell RCC (Fig. 40-3). The involved gene, *vhl*, also frequently is mutated or hypermethylated in sporadic RCC.¹¹ Other rare forms include Birt-Hogg-Dubé syndrome, where patients get oncocytomas or chromophobe tumors. Patients with hereditary papillary RCC and hereditary leiomyomatosis develop papillary RCC.

von Hippel-Lindau disease. A computed tomography image of a patient with von Hippel-Lindau disease and bilateral kidney tumors that are predominantly intrarenal. Note the numerous cysts in the head of the pancreas (*arrow*).

The most common sites of metastasis are the retroperitoneal lymph nodes and lungs, but liver, bone, and brain also are common sites of spread. Up to 20 to 30% of patients may present with metastatic disease, in which case, surgical debulking can improve survival, as shown in randomized controlled trials.^{12,13} Patients with all but the smallest renal masses should undergo testing for the presence of metastatic disease including chest CT, bone scan, and liver function tests.

Patients with localized disease may be cured with either partial or radical nephrectomy (Fig. 40-4). The oncologic efficacy of partial nephrectomy (nephron sparing) appears to be similar to that of radical nephrectomy. However, those patients with larger tumors or with a more central tumor location may be at increased risk for surgical complications. Nephron-sparing surgery should be considered in all patients, if feasible, as those patients undergoing a radical nephrectomy are at risk for future chronic kidney disease.¹⁴ The lack of harm from nephrectomy due to malignancy has been extrapolated from the fact that kidney donors do not routinely develop renal insufficiency. However, kidney donors are a highly selected group, and patients with renal tumors are typically older and have more comorbidities. Additionally, the risk of contralateral RCC is 2 to 3% in most series,¹⁵ and a partial nephrectomy may prevent the future need for dialysis in case of a contralateral kidney tumor.

Fig. 40-4.

Partial nephrectomy. A kidney after partial resection for a small renal mass. Note the visible collecting system in the base of the defect (*arrow*).

Minimally invasive techniques for renal surgery have greatly changed the field of kidney cancer. Laparoscopic radical nephrectomy allows more rapid convalescence and decreased narcotic requirements. Laparoscopic partial nephrectomy is challenging and is performed only in experienced hands due to its associated high rate of complications. Ablative techniques such as cryoablation and radiofrequency ablation have been gaining in popularity, but long-term results from these techniques are currently lacking due to their recent development. Observation also may be a viable option for small renal masses, especially in patients with multiple comorbidities or advanced age. Most small renal masses are low grade with a slow growth rate, and patients very rarely progress to metastatic disease after limited follow-up of 2 to 3 years.¹⁶

Up to 10% of RCC invades the lumen of the renal vein or vena cava. The degree of venous extension directly impacts the surgical approach. Patients with thrombus below the level of the liver can be managed with cross-clamping above and below the thrombus and extraction from a cavotomy at the insertion of the renal vein (Fig. 40-5A). Usually, the thrombus is not adherent to the vessel wall. However, cross-clamping the vena cava above the hepatic veins can drastically reduce cardiac preload, and therefore, bypass techniques often are necessary. For thrombus above the hepatic veins, a multidisciplinary approach with either venovenous or cardiopulmonary bypass is necessary. In cases of invasion of the wall of the vena cava or atrium, deep hypothermic circulatory arrest may be used to give a completely bloodless field. Tumor thrombus embolization to the pulmonary artery is a rare but known complication during these cases and is associated with a high mortality (Fig. 40-5B). For cases of extensive tumor thrombus, intraoperative transesophageal echocardiography should be considered for monitoring and assessment of possible thrombus embolization. If a thrombus embolization occurs, a sternotomy/cardiopulmonary bypass with extraction of the thrombus may be life saving.

Fig. 40-5.

Inferior vena cava thrombus. **A.** A multidetector computed tomographic image displaying a tumor thrombus extending above the diaphragm (*arrow*) arising from a right renal mass. **B.** An en bloc removal of a different right renal mass with a tumor thrombus that extended to the pulmonary artery. This patient is alive 6 years after surgery.

Patients undergoing resection of localized renal masses are at substantial risk of future recurrence. Many predictive features have been recognized, but the most widely accepted prognostic findings are tumor stage, grade, and size, each of which exerts an independent effect on recurrence. Surveillance strategies after nephrectomy typically involve abdominal and chest imaging at 6- to 12-month intervals for 5 to 10 years, depending on the level of risk as determined by the original lesion.¹⁷ Isolated solitary recurrences, either local or distant, can be resected with long-term disease-free rates approaching 50%.¹⁸

SURGICAL APPROACH AND COMPLICATIONS

Nephrectomy, either partial or radical, can be performed through a number of surgical approaches. Flank incisions over the eleventh or twelfth ribs from the anterior axillary line to the lateral border of the rectus muscle provide access to the kidney without entering the peritoneum. However, entry into the pleura is not uncommon. If small, the pleurotomy usually can be closed without need for a chest tube. The anterior subcostal approach also is used for nephrectomy. There is no risk for pleural entry, but this incision is transperitoneal so ileus is somewhat more likely. Laparoscopic nephrectomy is now commonplace, while laparoscopic partial nephrectomy is used less frequently. For large tumors, particularly on the right side where the liver makes exposure of the tumor more difficult, a thoracoabdominal approach is very helpful. In these cases, the flank incision is made over the tenth rib and carried further posterior and anterior than a typical flank incision. The chest and abdominal cavities are intentionally entered for maximum exposure, and the diaphragm is partially divided in a circumferential fashion, which allows cephalad retraction of the liver. A chest tube is used postoperatively. The adrenal gland

is no longer routinely removed unless the tumor is adherent to it. The benefit of lymph node dissection when the nodes are not clinically involved is uncertain.

Complications of radical nephrectomy include bleeding, pneumothorax, splenic injury, liver injury, and pancreatic tail injury. Partial nephrectomy has the added risks of delayed bleeding and urine leak. Ileus is not commonplace when the peritoneal cavity is not entered.

Prostate Cancer

Prostate cancer is the most common nonskin malignancy in men, with an incidence of approximately 250,000 to 300,000 per year. Yearly screening consisting of digital rectal exam and serum prostate-specific antigen (PSA) testing starting at age 50 years old is recommended by several organizations, such as the American Cancer Society and the American Urological Association. Patients of African American descent or those with a family history of prostate cancer should be considered for screening starting at 45 years of age. Men with abnormal digital rectal exams or PSA elevation have an indication for prostate biopsy to determine the presence of the disease. With the advent of PSA screening, prostate cancer has experienced a stage migration, with most cases now discovered locally confined within the prostate. The majority of patients with prostate cancer will not die of the disease by 10 to 15 years, whether it is treated at diagnosis or not. However, those undergoing initial treatment have improved cancer-specific survival.¹⁹

Prostate cancer is graded according to the Gleason scoring system.²⁰ A primary and secondary score are assigned based on the most common and second most common histologic pattern. Grades run from 1 for the most differentiated to 5 for the least. The grades are added to give the Gleason score. In current practice, scores below 6 are almost never assigned. Gleason score, preoperative PSA level, and digital rectal exam are used to estimate the likelihood of whether the cancer is localized, locally advanced, or metastatic. Prostate cancer with high Gleason scores (8 to 10) or a high PSA level (>20) is much more likely to have spread, often at a micrometastatic level. After definitive treatment, an increasing PSA is indicative of recurrent cancer.

The most common site of spread of prostate cancer is the pelvic lymph nodes and bone. For patients with intermediate or high-risk disease based on clinical stage, grade on biopsy, and PSA level, staging includes bone scan and CT imaging to evaluate the pelvic lymph nodes. Multiple treatment options are available for men with localized disease, including radical prostatectomy (retropubic, perineal, or robotic/laparoscopic approaches), brachytherapy, and external beam radiation therapy. For low-risk disease, the efficacy of each treatment modality is thought to be similar. For low-risk disease, radical prostatectomy can be performed with unilateral or bilateral cavernosal nerve-sparing to limit postoperative erectile dysfunction (ED). For high-risk disease, either non-nerve-sparing surgery or external beam radiation therapy plus androgen deprivation may be performed. The associated morbidity of each treatment differs, and it is important to discuss the side effects with patients. Irritative voiding and bowel symptoms are common after radiation therapy, with ED being a late side effect. Radical prostatectomy is associated with early incontinence and ED (depending on nerve-sparing). Incontinence improves significantly with time, with <1% of men in experienced hands suffering severe long-term problems with urinary control. Likewise, ED improves with time. The large majority of younger men (<55 years of age) regain erectile function, often with the aid of oral medications, if both cavernosal nerves were spared.²¹ Older men or those with 0 or 1 nerve spared have lower rates of erectile function.

Expectant management may be a useful strategy in men with anticipated survival of <10 years, low Gleason score (≤ 6), early-stage disease (cT1c), and small volume disease as determined by biopsy. Patients should be watched closely with

digital rectal exam, PSA testing, and repeat biopsy at 1 year to assess the possible progression of disease. Patients, however, should be counseled that randomized controlled trials of surgery vs. observation have been shown to improve survival and lessen the risk of developing of metastatic disease.¹⁹ Once prostate cancer has spread, it is no longer curable. Medications that lower serum testosterone or that block the androgen receptor are able to control the disease, often for years, but the cancer inevitably becomes resistant to this treatment. Nevertheless, patients with noncurable prostate cancer can live many years, and a large number die of causes other than prostate cancer.

SURGICAL APPROACH AND COMPLICATIONS

The approach for a retropubic prostatectomy uses a lower midline incision from the pubic symphysis to approximately 5 cm below the umbilicus. The peritoneum is not entered. Lymph nodes are removed between the external iliac and obturator vessels bilaterally, although it may be omitted in cases where the probability of involvement is very low. Some regularly perform a wider dissection that may improve staging, although any therapeutic benefit is uncertain. The cavernosal nerves lay immediately posterolateral to the prostatic capsule. They may be spared if the cancer is not likely to penetrate the capsule on that side, which is a function of preoperative parameters such as biopsy results, PSA, and clinical examination. Perineal prostatectomy involves a transverse incision between the scrotum and anus. Benefits include reduced blood loss and faster convalescence, but this approach does not allow lymph node dissection and nerve-sparing is more difficult. Robotic prostatectomy has superseded laparoscopic prostatectomy due to the lower learning curve and increased agility. Benefits are lower blood loss and faster convalescence. Some claim faster return of continence and lower ED rates, but these findings have not yet been widely demonstrated.

Complications of prostatectomy depend on approach. Retropubic approaches may result in urine leaks, lymphocele, and very rarely, rectal or ureteral injury. The perineal approach has a somewhat higher rate of rectal injury. Robotic prostatectomy uses a transperitoneal approach that can occasionally result in ileus, particularly in cases of a urine leak from the vesicourethral anastomosis. All approaches carry a small risk of urinary incontinence and a more substantial risk of ED.

TRAUMA

Kidney

Renal injuries are more common during blunt trauma, accounting for 90% of injuries to the kidney. Any patient with a major deceleration injury, shock, or gross hematuria should undergo radiographic imaging of the kidneys. All patients with penetrating injuries to the flank or abdomen must undergo imaging unless unstable and requiring immediate exploration.

Renal injuries are classified by extent of damage (Table 40-2). Blunt traumatic injuries usually can be managed conservatively, while penetrating renal injuries usually require exploration. Urinary extravasation alone does not require exploration, but reimaging is necessary and, if persistent leakage is present, a stent or nephrostomy tube is indicated. All grade V vascular injuries should be considered for immediate exploration, as a delay of several hours greatly decreases the risk of renal salvage. High-grade renal injuries are associated with significant bleeding, but patients who are stable and without a pulsatile or expanding hematoma can be observed. Even in expert hands, the risk of renal loss at surgery is significant and must be considered before opening the retroperitoneum, and most grade IV injuries can be managed nonoperatively (Fig. 40-6).²² Patients typically are placed on restricted activity until hematuria resolves. Table 40-3 lists indications for assessing surgical intervention in renal trauma patients.

Table 40-2 American Association for the Surgery of Trauma Renal Injury Scale

Grade	Injury Type	Description
1	Contusion	Microscopic or gross hematuria with normal imaging
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
2	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
		<1 cm in depth without urinary extravasation
3	Laceration	>1 cm in depth without collecting system rupture or urinary extravasation
4	Laceration	Parenchymal laceration through cortex, medulla, and collecting system
4	Vascular	Main renal artery or vein injury with contained hemorrhage
5	Laceration	Completely shattered kidney
5	Laceration	Avulsion of renal hilum leading to devascularized kidney

Blunt renal trauma after a bicycle accident. **A.** A computed tomography image of a left kidney with several deep lacerations into the collecting system and a large perirenal hematoma. Delayed images showed urinary extravasation. This patient was managed nonoperatively. **B.** Computed tomographic image at 45 days showing significant improvement in the appearance of the kidney.

Table 40-3 Indications for Surgical Intervention for Renal Trauma

Absolute indications

1. Persistent, life-threatening hemorrhage from probable renal injury
2. Renal pedicle avulsion (grade V injury)
3. Expanding, pulsatile, or uncontained retroperitoneal hematoma

Relative indications

1. Large laceration of the renal pelvis or avulsion of the ureteropelvic junction
2. Coexisting bowel or pancreatic injuries
3. Persistent urinary leakage, postinjury urinoma, or perinephric abscess with failed percutaneous or endoscopic management
4. Abnormal intraoperative one-shot IV urogram
5. Devitalized parenchymal segment with associated urine leak
6. Complete renal artery thrombosis of both kidneys or of a solitary kidney when renal perfusion appears preserved
7. Renal vascular injuries after failed angiographic management
8. Renovascular hypertension

Source: Adapted with permission from Santucci RA, Wessells H, Bartsch G, et al: Evaluation and management of renal injuries: Consensus statement of the renal trauma subcommittee. *BJU Int* 93:937, 2004.

If immediate operative exploration for other injuries is required, renal injury staging can be performed while in the operating

room. If concern exists over renal injury or the presence of a retroperitoneal hematoma, a single-shot, 10-minute delayed IV pyelogram (IVP) (2 mL/kg contrast) is useful at assessing the presence of two functional kidneys and extent of injury. If the IVP is abnormal or the hematoma is pulsatile, renal exploration should be performed.

Renal exploration should begin once the renal hilum is controlled. Although rarely necessary, temporary control of the renal hilum may decrease the need for nephrectomy when a significant injury is found on exploration. Complete exposure is necessary to evaluate the extent of injury. All nonviable tissue should be débrided and segmental and intralobar arteries ligated with 4-0 chromic or polydioxanone sutures. If the collecting system is injured, it should be repaired at this time. A stent and percutaneous drain should be considered to prevent urinoma formation. A partial vascular injury to the renal vein or artery can be repaired with 5-0 or 6-0 Prolene sutures. A complete injury may require débridement, and if an end-to-end anastomosis cannot be performed, a vascular graft may be required.

Ureter

The retroperitoneal location of the ureter protects it from external trauma, and blunt injury is rare but can occur with rapid deceleration injuries. Penetrating trauma may occur but a high index of clinical suspicion is required to make the appropriate diagnosis. Any penetrating trauma involving the retroperitoneum should undergo evaluation with intraoperative inspection, IVP, or CT urogram. A retrograde pyelogram is the most sensitive test for ureteral injury, and a stent can be placed if a partial transection is observed. The ureter also is frequently injured intraoperatively, most commonly from open and laparoscopic surgical procedures including hysterectomy, low-anterior colonic resections, or aortic surgery. Endoscopic procedures such as ureteroscopy also can lead to ureteral injury such as perforation and avulsion.

Surgical repair depends on location and extent of injury. A suture in place briefly may be removed usually without consequence. Partial injuries can be primarily repaired, although all devitalized tissue must be débrided to avoid delayed tissue breakdown and urinoma formation. Ureteral stents should be placed in this situation to facilitate healing without stricture. Lower ureteral injuries (below the iliac vessels) are best treated with ureteral reimplant, as the blood supply can be tenuous, and strictures are more common with a distal uretero-ureterostomy. Midureteral level injuries can be treated with a uretero-ureterostomy if a spatulated, tension-free repair can be achieved. For longer defects, the bladder can be mobilized and brought up to the psoas muscle (psoas hitch). For additional length, a tubularized flap of bladder (Boari flap) can be created and anastomosed to the remaining ureter. Renal mobilization with nephropexy by anchoring to the psoas muscle can provide additional length. Autotransplantation, transuretero-ureterostomy, and ileal ureter are rarely needed during an acute setting.

Bladder

Bladder injury can occur from penetrating and blunt trauma. The diagnosis should be entertained for any lower abdominal or pelvic trauma. Intraperitoneal ruptures are less common than retroperitoneal ruptures but may be seen in the setting of a full bladder before injury. Bladder injuries often are associated with pelvic fractures and may frequently occur in conjunction with urethral injuries. Nearly all patients present with gross hematuria, although occasionally microscopic hematuria is present. A delayed presentation can be associated with intoxication, but it also may occur as a result of iatrogenic injury. These patients often have electrolyte abnormalities such as metabolic derangements, azotemia, and leukocytosis from urine absorption. Patients clinically present with fevers or a prolonged ileus.

Radiographic evaluation begins with either a fluoroscopic or CT cystogram. It is vital to avoid underfilling, as it may lead to a false negative study. A preset amount can be instilled based on age calculations, which is typically approximately 300 to 400

mL in adults. The bladder can be filled under gravity by raising the Foley catheter to 15 cm above the pubic ramus. The contrast material should be allowed to fill to the natural capacity of the bladder. It is important to have a postdrainage film to assess for persistent contrast which may indicate a rupture.

Extraperitoneal bladder injuries can typically be managed with catheter drainage for 7 to 10 days. If intraoperative exploration is to occur for other injuries, repair can be performed at that time. For patients with pelvic injuries that require an open operation with placement of metal hardware, repair of the bladder rupture should be performed if possible. Intraperitoneal bladder injuries should be explored immediately and repaired. However, for cases of a missed intraperitoneal injury, patients often do well with catheter drainage only. For large ruptures after repair, a suprapubic tube is recommended, but a large urethral catheter is sufficient for smaller injuries. All injuries, especially those managed nonoperatively, should be followed up by a cystogram to document healing before catheter removal.

Urethra

Urethral injuries can be divided by anterior (penile and bulbar urethra) and posterior (membranous and prostatic) location. Any patient with blunt pelvic trauma, blood present at the urethral meatus, hematuria, inability to void, or perineal hematoma should be considered to have a urethral injury until proven otherwise. Urethral injuries should be anticipated with pubic ramus fractures and occur in 10% of unilateral and 20% of bilateral injuries.²³

Staging is performed by retrograde urethrography. This study can be easily performed in the trauma suite with the patient in an oblique position and a 12F catheter placed in the urethral meatus. With the penis placed on traction, 30 mL of contrast is instilled while an X-ray is obtained during filling. The addition of fluoroscopy is a valuable addition to the procedure but can be omitted if not available. A partial or complete disruption can be diagnosed based on extravasation or filling of the proximal urethra. Patients with partial urethral injuries can have an attempt at catheter placement. Those with complete disruptions should have a placement of suprapubic tube.

Anterior injuries often are related to blunt straddle injuries and penetrating trauma. Blunt anterior urethral injury can be managed in multiple ways and only small series are available in the literature to compare methods. Immediate surgical repair is not recommended in the acute setting with the exception of low velocity penetrating injuries. If the patient is stable with minimal hematoma formation, repair should be considered. In this setting of a 1- to 2-cm defect, the urethra can be débrided, spatulated, and anastomosed in an end-to-end, watertight fashion. Large defects should have treatment deferred, as grafts or flaps may be required for repair and the success may diminish with infections. For most cases, catheter drainage is recommended. Many advocate avoiding a placement of a urethral catheter, as it may convert a partial tear to a complete dissection. However, a single gentle passage performed by a urologist is safe. For a complete disruption, the placement of a suprapubic tube is recommended; however, a stricture at the site of injury may ensue.

Posterior urethral injuries usually result from pelvic crush injuries and shearing forces causing a prostatomembranous disruption. The patient's other injuries dictate urologic management. Initial open surgical exploration of the urethral injury should be avoided due to altered anatomy, risk of bleeding, and high likelihood of incontinence and ED from injury of adjacent nerves. Patients can be managed with suprapubic tube and delayed repair or with delayed primary realignment. Primary endoscopic realignment, when possible, leads to decreased rates of strictures without increasing adverse outcomes.^{24,25}

Urethral strictures can be caused by trauma or inflammatory conditions. They should be staged with either a retrograde urethrography or voiding cystourethrogram (VCUG). Patients with short defects may be amenable to dilatation or cystoscopic

urethrotomy. Depending on location, length, and severity, open repairs may be required. Long defects may require grafting to avoid significant penile shortening. Young patients should be considered for open surgical management to definitely repair the stricture due to the tendency of strictures to recur when treated with simple dilation.

Testes

Testicular injury most commonly occurs with blunt injuries when the testicle is forcibly compressed against the thigh or pubic bone with enough force to rupture the tunica albuginea. For patients with scrotal trauma, ultrasound is the preferred modality for staging the extent of injury. Ultrasound can evaluate the testicular blood flow, the presence of testicular contusions, intratesticular hematomas, hematoceles, or a disrupted tunica albuginea. The presence of a hematocele should increase suspicion for testicular rupture because ultrasound may not detect the tunical defect in this setting.²⁶

The goal of surgery is to salvage as much parenchyma as possible and to avoid delayed complications such as ischemic atrophy or abscess formation. A large hematocele, if not evacuated, could lead to ischemic atrophy, and drainage should be considered. A ruptured tunica albuginea can be repaired primarily and nonviable parenchyma may need to be débrided. For penetrating trauma, immediate exploration is recommended for accurate staging and repair. Frequently, these injuries result in major devascularization and nonviable tissue (especially gunshot wounds). Although salvage may be possible, an orchiectomy usually is required.

Penis

Penile fractures are rare injuries that involve a traumatic rupture of the tunica albuginea, usually occurring during sexual intercourse. The engorged penile corporal bodies can rupture if sufficient force is generated against the partner's pubic symphysis or perineum (Fig. 40-7). Men may notice an immediate audible "pop" and experience rapid penile detumescence. Immediate swelling develops. If Buck's fascia is disrupted, swelling and ecchymosis can be noted throughout the perineum ("butterfly sign"). At presentation, a classic "eggplant" appearance of the penis is often, although not always, seen. Exploration by a circumcising incision and repair of the defect offers the best chance at avoiding permanent ED and penile deformity while also minimizing the risk of infection.²⁷ A retrograde urethrogram should be performed to rule out urethral injury at the time of surgery. Alternatively, the urethra can be manually occluded intraoperatively at the penoscrotal junction and a dilute methylene blue solution injected under pressure into the urethral meatus with a catheter-tip syringe. Leakage should be visualized if there is a urethral disruption. If present, the urethra should be repaired, taking care not to significantly narrow the lumen. A Foley catheter is left in place for several days after surgery. Any penetrating injury to the penis must undergo exploration to repair any injuries to the corporal bodies or the urethra.

Penile fracture. **A.** A patient with a penile fracture that was suspected based on history and examination. Note the lack of skin discoloration that is often present. **B.** Intraoperative finding of bilateral corporal body ruptures (*arrows*) along the ventral penile surface. The urethra, which is between the surgeon's fingers, surprisingly escaped injury.

EMERGENCIES

Acute Urinary Retention

Acute urinary retention (AUR) can happen in men or women and results from a variety of causes, although it most commonly occurs in men with benign prostatic hyperplasia (BPH). Other chronic causes of poor bladder emptying, such as diabetic neuropathy, urethral stricture, multiple sclerosis, or Parkinson's disease, can result in episodes of complete urinary retention, often when the bladder becomes overdistended. This frequently occurs in the hospital setting when patients have limited mobility and are receiving medications that decrease bladder contractility, including opiates or anticholinergics. Constipation, a common side effect of those medications, can itself worsen urinary retention. Significant hematuria can result in the formation of blood clots, which may block the urethra and cause retention.

Although some patients receiving large doses of narcotics or those with chronically decompensated bladders may not experience discomfort, most patients with AUR have significant pain. If the urinary retention has lasted several days (often accompanied by overflow incontinence), patients may be in renal failure. Treatment should be the placement of a urethral catheter as quickly as possible. However, BPH or urethral strictures often make the placement of a catheter difficult. For men with BPH, a coude (French for *curved*) catheter is helpful in negotiating past the angulation in the prostatic urethra (Fig. 40-8A). The curved portion (which is angled in line with the balloon port) is maintained at the 12 o'clock position as it is passed through the urethra (Fig. 40-8B). A common mistake is to use a smaller catheter to bypass the enlarged prostate. However, a larger (18F to 20F) catheter is less flexible and is more likely to push into the bladder rather than curl in the prostatic urethra. Smaller catheters are useful for bypassing a urethral stricture. A urethral stricture should be suspected when the catheter meets resistance closer to the meatus, as many strictures occur in the distal urethra, which is narrower than the proximal portion. Using a 12F or 14F catheter often will allow the passage of the catheter into the bladder. If catheter placement is not successful, a suprapubic tube should be placed approximately two finger breadths above the pubic symphysis. Aspiration with a finder needle should be used first to localize the bladder and avoid intra-abdominal contents, although bowel injury is unlikely with a distended bladder filling the pelvis. If hematuria is the cause of retention, continuous bladder irrigation often is necessary to prevent clot formation. This is done through a large three-way catheter that has an additional port for fluid inflow. Fluid is infused by gravity only because the use of higher pressure could result in bladder rupture if outflow is occluded.

Coude catheter. **A.** A schematic drawing of a lateral view of the prostatic urethra showing the upward angulation at the bladder neck, which a coude catheter is helpful in negotiating. **B.** The tip of a coude catheter. Note the curved tip, which should always point to 12 o'clock when inserted.

A urinalysis should be checked because a poorly emptying bladder is prone to infection. Renal function also should be assessed for those in AUR by checking the creatinine level. An elevated creatinine level suggests that AUR has resulted in renal dysfunction, and these patients are at risk for postobstructive diuresis. These patients must be closely watched for excessive urine output, often caused by an osmotic diuresis due to retained nitrogenous waste products or a temporary renal concentrating defect. Fluid and electrolytes must be replaced if the urine output exceeds 200 mL/h, especially if hemodynamic instability or electrolyte imbalances are seen. Fluid replacement typically is 0.5 mL of 0.45 normal saline for

every 1 mL of urine output above 200 mL in 1 hour, although sodium and potassium supplementation requirements depend on the electrolyte status of the patient.

Once the bladder is adequately drained, the cause of AUR should be addressed. For men with suspected BPH, an alpha blocker such as tamsulosin should be started. Finasteride or dutasteride, which shrink the prostate, work over several months and will not provide significant benefit in the short term. Narcotics should be tapered as tolerated, and constipation should be treated. Acute spinal cord compression, which is accompanied by saddle paresthesias, is a neurologic emergency that requires neurosurgical or orthopedic consultation. In most cases, except severe neurologic injuries, patients will be able to resume voiding, and the catheter can be removed after 1 to 2 days. Postvoid residuals should be checked with a portable ultrasound device or by "straight" catheterization to determine the residual amount of urine left after the patient tries to empty their bladder. The inability to void or a postvoid residual over 150 to 200 mL is concerning for the development of another episode of AUR. Patients may be given the option of an indwelling catheter for another few days with a subsequent voiding trial, or learning the self intermittent catheterization technique, whereby, after predetermined intervals (4 to 6 hours) or after voiding attempts, the patient passes a catheter into their bladder and empties. This is the preferred method, as it reduces the likelihood of infections from indwelling catheters and may improve bladder functionality. However, most patients are resistant to this approach.

Testicular Torsion

The differential diagnosis of acute scrotal pain includes testicular torsion. This usually occurs in neonates or adolescent males but may be observed in other age groups. The blood supply to the testicle is compromised due to twisting of the spermatic cord within the tunica vaginalis resulting in ischemia to the epididymis and the testis. In newborns, an extravaginal torsion also can occur with twisting of the tunica vaginalis and spermatic cord together. Risk factors for torsion include undescended testis, testicular tumor, and a "bell-clapper" deformity with poor gubernacular fixation of the testicles to the scrotal wall.

Clinical history is vital for diagnosis. Patients describe a sudden onset of pain at a distinct point in time, with subsequent swelling. Physical examination may demonstrate a swollen, asymmetric scrotum with a tender, high-riding testicle. Children normally have a brisk cremasteric reflex that usually is lost in the setting of torsion. The diagnosis is made by clinical history and examination, but can be supported by a Doppler ultrasound which typically shows decreased intratesticular blood flow relative to the contralateral testis. If an ultrasound is not promptly available, timely surgical exploration should ensue if there is reasonable suspicion of torsion. However, besides ruling out other pathologies, an ultrasound can rule out an associated testicular neoplasm that would necessitate tumor serum marker evaluation and an inguinal, rather than a scrotal, incision.

Immediate surgical exploration can salvage an ischemic testes. More than 80% of testes can be salvaged if surgery is performed within 6 hours, which decreases to 20% or less as time progresses beyond 12 hours.²⁸ At the time of surgery, the contralateral testes also must be explored and fixed to the dartos fascia due to the possibility that the same anatomic defect allowing torsion exists on the contralateral side. Midline or bilateral transverse scrotal incisions are made. Once the testis is detorsed, it should be assessed for viability after being given time for normal blood flow to resume. The testes are fixed to the dartos fascia with a small, nonabsorbable suture on their medial and lateral aspects, taking care to ensure that the spermatic cord is not twisted before doing so. An orchiectomy should be performed to avoid later risk of abscess formation only if the testis is clearly necrotic because overall testicular function may be improved with testicular preservation in cases of moderately delayed (15 hours) presentation.²⁹

Fournier's Gangrene

Fournier's gangrene is a necrotizing fasciitis of the male genitalia and perineum that can be rapidly progressing and fatal if not treated promptly (Fig. 40-9A). Mortality has been reported as high as 30 to 40%.³⁰ Risk factors for Fournier's include urethral strictures, perirectal abscesses, poor perineal hygiene, diabetes, cancer, HIV, and other immunocompromised states.³¹ The infection spreads along the dartos, Scarpa's, and Colles' fascias. Clinical signs include fevers, perineal and scrotal pain, and associated indurated tissue. Cellulitis, eschars, necrosis, flaking skin, and crepitus may all be observed. The diagnosis is made on largely clinical suspicion, and significantly less on laboratory or radiographic findings. Classically, the patient describes pain out of proportion to the physical findings.

Fournier's gangrene. **A.** Necrotic scrotal skin from Fournier's gangrene. **B.** Débridement of gangrenous tissue. Note the extensive débridement, which is commonly required. The right testicle required removal in this case (the left is wrapped in gauze), but typically the testes are not involved with the necrotic process.

Prompt débridement of nonviable tissue and broad-spectrum antibiotics is necessary to prevent further spread (Fig. 40-9B). If there is damage to the external sphincter, patients may require a colostomy.³¹ As the testes have a separate blood supply, they are usually not threatened and do not need to be removed. They may be tucked subcutaneously into the thigh ("thigh pouch") to ease postoperative management. Patients may frequently require return trips to the operating room for further débridement. Tight glucose control and adequate nutrition are necessary to facilitate wound healing. The large tissue defect should be initially treated with frequent dressing changes. Reconstructive strategies involving skin grafting are needed when large tissue defects result from extensive tissue damage.

Priapism

Priapism is a persistent erection for greater than 4 hours unrelated to sexual stimulation. Priapism is divided into two types, based on the underlying pathophysiology. The most common type—low flow/ischemic priapism—is a medical emergency. On examination, the penis is very tender and both cavernosal bodies will be rigid while the glans will be flaccid. Decreased venous outflow with persistent inflow results in increased intracorporal pressure and tumescence, which is the normal process of erection. Diminished arterial inflow due to elevated intrapenile pressure usually is brief under normal circumstances. Priapism is essentially a compartment syndrome.³² With prolonged erection (priapism), the sustained decrease in arterial inflow ultimately causes tissue hypoxia, acidosis, and edema and results in long-term fibrosis and impotence, and sometimes

frank necrosis. Risk factors include sickle cell disease or trait, malignancy, medications, cocaine abuse, certain antidepressants, and total parenteral nutrition.^{33–35} If a cause is not identified, a hematologic work-up is necessary to rule out malignancy or blood dyscrasias.

The management of priapism is rapid detumescence with the goal of preservation of future erectile function. The ability to achieve normal erections is directly related to length of the episode of priapism.³² Low-flow priapism can be confirmed with a penile blood gas of the cavernosal bodies demonstrating hypoxic, acidotic blood. Initial management can include oral agents such as pseudoephedrine or baclofen, but more aggressive measures usually are necessary to achieve rapid detumescence. Insertion of a large gauge needle (18 gauge) into the lateral aspect of one corporal body allows thorough aspiration and irrigation of both corporal bodies because of widely communicating channels. Injection of phenylephrine (up to 200 mg in 20 mL normal saline) into the corporal bodies may be required. For those with sickle cell disease, hydration and oxygen administration should be performed first, as that is sometimes successful in this group.³⁶

A surgical shunt is sometimes necessary to resolve the episode. Distal shunts should be performed first, as they can be done quickly in the emergency room with a True-Cut needle (Winter shunt). If this fails, an operative distal shunt can be performed (Al-Ghorab). Proximal shunts such as Grayhack's (corporal-saphenous vein) or Quackel's (proximal cavernosum-spongiosum) shunts may be required in refractory cases.

The other form, high flow/traumatic priapism, is rare and is related to penile or perineal trauma resulting in a cavernous artery–corporal body fistula. This form is not painful as it is not related to ischemia and can be managed conservatively. Many cases will resolve with time; those that do not can undergo selective arterial embolization.³⁷

Paraphimosis

Foreskin emergencies occur in uncircumcised men. Paraphimosis is a common problem that represents a true medical emergency. When foreskin is retracted for prolonged periods, constriction of the glans penis may ensue. This is particularly likely in hospitalized patients who are confined to bed or who have altered mentation. Edema often forms in the genitals of supine patients due to the dependent position of that area. Patients with diminished consciousness will not be aware of the penile pain from paraphimosis, which may delay recognition of the problem until too late. Delay can be catastrophic as penile necrosis may occur due to ischemia.³⁸ Penile blocks, pain medication, and sedation are sometimes necessary before manual reduction. It is useful to apply firm pressure to the edematous distal penis for several minutes. Although painful, this reduction in penile edema can be the key to success. With the fingers pulling the constricting band distally, the thumbs can push the glans penis back into normal location. If the foreskin cannot be manually reduced, surgical intervention is required.

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a life-threatening infection that results from complicated pyelonephritis by gas-producing organisms. It is an acute necrotizing infection of the kidney that occurs predominantly in diabetic patients.³⁹ Patients frequently present with sepsis and ketoacidosis. *Escherichia coli* appears to be the most frequent organism responsible for this infection.⁴⁰

Patients require supportive care, IV antibiotics, and relief of any urinary tract obstruction. Emphysematous pyelonephritis can be subdivided based on extent of infection. Those with gas confined to the parenchyma frequently can be managed conservatively with placement of a nephrostomy tube to allow drainage of purulent material. Patients with extensive involvement of the perirenal tissue may not respond to conservative management, and strong consideration should be given

to expeditious nephrectomy, particularly if the patient is displaying signs of sepsis.

INFECTIONS

Cystitis

Cystitis is an infection in the bladder with common symptoms of dysuria, and urinary frequency and urgency. Urinary culture (10^5 colony-forming units) is necessary to make a definitive diagnosis, although lower thresholds are meaningful if clinical suspicion is high. Urinalysis can assist with the diagnosis, as leukocyte esterase is a marker of inflammation, and nitrites are formed from bacterial reduction of nitrates. Risk factors include female gender, urinary instrumentation, urinary obstruction, diabetes, and neurologic bladder dysfunction.

An uncomplicated episode of cystitis requires a 3-day course of antibiotics. Those with complicated cystitis require 7 days of antibiotics and possible imaging studies. Asymptomatic bacteruria does not necessarily need to be treated except if found in a pregnant women, before a planned urinary tract surgery, or with associated urinary tract obstruction. Patients undergoing nonurologic surgery also should be considered for treatment, especially those involving cardiac valves or orthopedic hardware.

Pyelonephritis

Pyelonephritis is a bacterial infection of the kidney that usually manifests itself by fevers and flank tenderness. It is frequently attributed to ascending bacteria along the path of the ureters and rarely due to hematogenous bacterial spread. Patients typically present with flank pain and fevers. However, very young or elderly patients may not demonstrate these symptoms but rather irritability, poor appetite, or altered mental status. Urinary tract imaging is not required unless urinary obstruction or stones are suspected or if the patient is not responding to antibiotics. Patients who are not septic and can tolerate fluids can be discharged home on a 2-week course of oral antibiotics. Otherwise, they should be hospitalized for IV antibiotics. Fevers from pyelonephritis may take 24 to 48 hours to subside in the setting of effective antibiotic therapy. Pyelonephritis can result in renal scarring that is accelerated in the setting of urinary obstruction. Emphysematous pyelonephritis can be a life-threatening condition with a mortality of up to 30% (see Emphysematous Pyelonephritis in the Emergencies section).

Occasionally, pyelonephritis can develop into an abscess that can be located within the renal parenchyma (renal abscess) or between the capsule and Gerota's fascia (perinephric abscess). Any patient that is not properly responding to antibiotic therapy after 72 hours should undergo imaging with CT scan to rule out an abscess or obstruction. Treatment consists of broad-spectrum IV antibiotics and percutaneous drainage.

Prostatitis

Acute prostatitis is a bacterial infection in the prostate gland, most commonly by urinary pathogens. Patients present with fevers, dysuria, and perineal or back discomfort. A digital rectal examination may indicate an indurated and tender gland. However, a brisk digital rectal examination should be avoided, as it is extremely uncomfortable for patients and is thought to cause bacteremia. Patients require a 4- to 6-week course of antibiotic therapy, typically a quinolone. Those that continue to have no improvement in 48 hours should be considered for imaging to rule out a prostatic abscess. If present, large abscesses can be managed with transurethral unroofing or percutaneous drainage.

Chronic prostatitis presents with continued lower urinary tract symptoms and pelvic pain. Chronic prostatitis may be bacterial

or nonbacterial, which can be distinguished by culturing pre- and postprostatic massage urine. The bacterial form is a frequent cause of recurrent urinary tract infections in men and can be treated with a prolonged course of antibiotics. Chronic nonbacterial prostatitis does not respond to antibiotics or most other medications. Biofeedback, physical therapy, and other nonprostate-specific treatments may be effective in the treatment of this challenging clinical entity.⁴²

Epididymo-Orchitis

Epididymo-orchitis is typically the result of bacterial infection originating in the urinary tract. However, most men will not show evidence of urinary tract infection. Symptoms are unilateral painful swelling of the epididymis and/or testis, often with fever. The scrotum may be erythematous on the side of involvement. The white blood cell (WBC) count often is elevated. The onset is fairly rapid, but not as sudden as torsion. An ultrasound may provide supporting evidence such as increased blood flow to the epididymis. A reactive hydrocele may be present. Intratesticular infection can result in ischemic orchitis, and reduced testicular blood flow can be seen on ultrasound. Although the clinical history of gradual onset may point to an infectious etiology, scrotal exploration is necessary when blood flow is reduced to rule out torsion unless other signs such as pyuria, elevated WBC count, or fevers are present.

Treatment is with oral antibiotics if the patient is not markedly febrile and is otherwise stable. Hospitalization and parenteral antibiotics are required if the patient has high fevers, significantly elevated WBC, or hemodynamic instability, as sepsis from epididymo-orchitis is possible. Intratesticular abscesses may form, and usually result in orchiectomy. The tunica albuginea of the testis is not compliant, so elevated pressures from intratesticular inflammation can result in ischemic necrosis of the parenchyma.

LOWER URINARY TRACT OBSTRUCTION

Benign Prostatic Hyperplasia

BPH is a clinical diagnosis describing urinary symptoms attributable to obstruction by the prostate, although some patients with BPH have minimally enlarged glands, and some with large prostates have no symptoms. The symptoms of BPH are urinary frequency, urgency, hesitancy, slow stream, and/or nocturia. These symptoms are not specific and may be caused by infection, urethral strictures, or neurologic dysfunction from diabetes, Parkinson's disease, multiple sclerosis, stroke, or spinal cord injury. Besides voiding symptoms, consequences of BPH include gross hematuria, infections due to incomplete emptying, bladder calculi, and AUR. Over time, incomplete emptying may lead to chronic bladder overdistension that can result in a defunctionalized bladder, sometimes permanently.

Medical treatment of BPH is usually the first step. Alpha blockers act on alpha receptors in the smooth muscle of the prostate and decrease its tone. 5 α -Reductase inhibitors, which block the conversion of testosterone to the more potent dihydrotestosterone, shrink the prostate over several months. Both are used either singly or in combination as medical therapy for BPH. If medications are ineffective at alleviating urinary symptoms or other consequences of BPH, surgical intervention is indicated. Transurethral resection of the prostate is the mainstay of endoscopic surgical BPH treatment. It is extremely effective at improving flow and decreasing residual urine. Complications are rare but include incontinence and excessive fluid absorption of the hypotonic irrigating solution used during resection, resulting in the transurethral resection syndrome. It is due to hyponatremia and fluid overload, and although rare, can result in death. Mental status changes and pulmonary edema are managed by diuresis and sodium supplementation with hypertonic saline in severe cases. Because of these rare, but potentially dangerous side effects, laser vaporization of the prostate has grown popular. It is associated with very limited fluid absorption, and saline can be used because there is no electrocautery. There also is less bleeding. Urinary

outcomes appear to be similar to transurethral resection of the prostate.⁴³ When the prostate is very enlarged (>100 g), endoscopic management is less effective and open surgical procedures can be used. Suprapubic (simple) prostatectomy involves enucleation of the majority of the prostate, but the capsule is left so there is minimal effect on continence and erectile function.

Urethral Stricture

The voiding symptoms of urethral stricture are very similar to BPH. Strictures may result from scarring due to infectious urethritis, prior instrumentation, trauma, or cancer. Urethral carcinoma is very rare, particularly in males, so most strictures are due to benign causes. Diagnosis is by retrograde urethrogram or cystoscopy. They may be treated with dilation or transurethral incision, but they have a tendency to recur after treatment. Open surgical excision is preferred for long or recalcitrant strictures, and long-term success rates are excellent.⁴⁴

UPPER URINARY TRACT OBSTRUCTION

The hallmark of partial or complete upper urinary tract obstruction is hydroureteronephrosis (HN), with the ureteral dilation extending to the level of the obstruction (Fig. 40-10). HN may be seen on CT imaging or ultrasound, and it may range from very mild to severe, with associated parenchymal thinning in chronic cases. In the acute setting, the degree of HN does not necessarily correlate with the degree of obstruction, as it may take time for severe HN to develop. The obstruction may be intrinsic, as with calculi or ureteral tumors, or due to extrinsic compression due to varied causes, such as an intra-abdominal tumor, iliac aneurysm, or gravid uterus. Serum creatinine may be elevated, but the contralateral kidney will compensate so serum chemistries may not indicate renal impairment. Normal renal function makes intervention less urgent, but even partial obstruction may result in permanent loss of function on the affected side if not alleviated within several weeks.⁴⁵ Complete occlusion can cause permanent dysfunction within 2 weeks.⁴⁶

Hydronephrosis and ureteral calculus. **A.** Left hydronephrosis from distal obstruction (*arrow*). **B.** A 4-mm calculus at the ureterovesical junction (*arrow*).

Treatment of ureteral obstruction is by endoscopic placement of a ureteral stent, which is a temporary plastic tube with curls on each end to prevent migration. Stents allow flow both through the lumen and around it. When chronic stenting is required, it must be changed every 3 months to prevent severe encrustation with urinary sediments. Stents commonly become colonized with bacteria, but symptomatic infections are less common.⁴⁷ Once a stent is in place, mild residual HN often will persist due to ureteral aperistalsis and urinary reflux, but unless severe, does not represent residual obstruction.

When stent placement is unsuccessful or fails to provide adequate drainage due to severe extrinsic compression, a percutaneous nephrostomy (PCN) should be placed. This is the preferred approach when a patient is unstable because it requires less anesthesia and provides more rapid and reliable decompression of the renal collecting system.

Urolithiasis

Urolithiasis, or urinary calculus disease, may affect up to 10% of the population over the course of a lifetime.⁴⁸ Calculi are crystalline aggregates of one or more components, most commonly calcium oxalate. They also may contain calcium phosphate, magnesium ammonium phosphate (struvite), uric acid, or cystine. Calcium and struvite-containing stones often are visible on plain radiographs, but CT scans will demonstrate all calculi except those composed of crystalline-excreted indinavir, an antiretroviral medication.⁴⁹ For this reason noncontrast CT scans have become the study of choice to evaluate for urolithiasis.

Several underlying causes exist for the formation of urinary calculi. Hypercalciuria due to hyperparathyroidism, sarcoidosis, "renal leaks," or idiopathic overabsorption can lead to calcium-containing stones. Patients often will develop calculi after gastric bypass, which has been attributed to increased oxalate excretion in the urine.⁵⁰ After bypass, dietary calcium is bound by unabsorbed dietary fats (saponification), preventing it from binding dietary oxalate, thereby making oxalate more available for intestinal absorption. Patients with gout are at risk for uric acid stones due to increased urinary uric acid and decreased urine pH, which diminishes uric acid solubility.

Urinary calculi may occur anywhere in the urinary tract. They usually are asymptomatic in the renal pelvis or bladder, but they are a very common cause of symptomatic ureteral obstruction. The obstruction may be partial or complete. Smaller stones (up to 6 mm) may cause severe symptoms, such as flank pain and nausea, but typically pass without intervention beyond supportive care.⁵¹ Alpha blockers, which relax the distal ureter, may be given to reduce renal colic.⁵² Calculi ≥ 7 mm are more likely to become impacted or to have a prolonged passage through the ureter. For this reason, intervention at the time of presentation is preferred for larger stones (except cases where the calculus is in the very distal ureter) due to the likelihood of repeat emergency room visits for severe symptoms.

Several methods for treating urinary calculi are available, depending on location. Obstructing stones often are temporized with stent placement, which allows proximal collecting system decompression. When urinary infection coexists with an obstructing stone, a stent can be placed, but a PCN is preferable if the patient demonstrates any instability. Definitive treatment of renal or ureteral calculi (lithotripsy) is through ureteroscopy, percutaneous nephrostolithotomy (PCNL), or extracorporeal shock wave lithotripsy (ESWL). Ureteroscopy is performed with a flexible or semirigid device that is passed to the level of the calculus. Under direct visualization, a laser fiber is passed through the scope, and energy is delivered to fragment the calculus. Fragments are extracted, although they usually will pass spontaneously. PCNL is performed through a percutaneous tract into the kidney, where a larger scope and various energy sources (laser, ultrasound) are used to fragment large renal calculi. This approach is well suited to staghorn calculi. ESWL is completely noninvasive and uses a device that delivers convergent shock-wave energy to the calculus under fluoroscopic guidance.

Complications of lithotripsy are specific to the technique used. Ureteroscopy may occasionally lead to strictures due to scarring from trauma to the ureter. If performed in the setting of infection, endoscopic irrigation can force bacteria into the renal parenchyma and result in sepsis. PCNL can cause significant bleeding, and if the tract used to access the kidney traverses the lower aspect of the pleura, large amounts of irrigating fluid can result in a significant hydrothorax. ESWL can occasionally cause renal hematomas, and splenic rupture has been seen after the treatment of a left-sided stone.^{53,54}

Patients with recurrent stones benefit from stone composition analysis and metabolic work-up to determine the underlying cause if not apparent from the clinical history. Better hydration is useful for all etiologies. Patients with calcium-containing stones do not benefit from a reduction in dietary calcium unless they have absorptive hypercalciuria, which most do not. In fact, patients with higher dietary calcium have, on average, fewer episodes of urolithiasis.⁵⁵

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a process resulting in encasement of the ureters, along with the great vessels, in a dense fibrotic mass. Many patients present in acute renal failure, and imaging demonstrates medially displaced ureters with a homogeneous, plaque-like mass in the retroperitoneum. The cause may occasionally be a neoplastic process such as histiocytosis or lymphoma—which must be ruled out—but most are idiopathic.⁵⁶ Many medications such as the ergot derivative methysergide, methyldopa, and beta blockers have been implicated as precipitating factors for the inflammatory process.⁵⁷

Bilateral ureteral stent or PCN placement provides temporary relief of the obstruction. Corticosteroids may be given to reverse the inflammatory process, but surgical ureterolysis still usually is required to free the ureters from retroperitoneal encasement. They are brought into the peritoneum and wrapped in omentum to prevent re-entrapment.

PEDIATRIC UROLOGY

Ureteropelvic Junction Obstruction

UPJ obstruction is the most common cause of hydronephrosis found on prenatal ultrasound. UPJ obstruction also is commonly observed in children and young adults. Intrinsic and extrinsic causes of UPJ obstruction exist and can be determined by presentation. Intrinsic UPJ obstruction occurs in neonates due to an adynamic or stenotic segment of proximal ureter. This impairs flow of urine into the ureter, particularly during times of high flow, and causes dilatation of the collecting system. Over time, elevated renal pelvic pressures and recurrent infections can injure renal parenchyma. Abnormal lower pole renal arteries may be a secondary cause of UPJ obstruction by kinking the proximal ureter. Nuclear scans (mercaptoacetyltriglycine or ^{99m}Tc diethylene-triamine-penta-acetic acid) have replaced the IVP as the diagnostic modality of choice. Delayed clearance of contrast or radiotracer implies obstruction. Invasive pressure-flow examinations (Whitaker test) rarely are performed.

Not every case of UPJ obstruction requires operative intervention. Many children with hydronephrosis due to an apparent UPJ obstruction are not highly obstructed and will improve with time. However, patients with infections or impaired renal function require repair to improve drainage. Open pyeloplasty is considered the gold standard approach, especially in infants. In older children or adults, laparoscopic or robotic approaches for pyeloplasty can speed convalescence and diminish postoperative pain. An endoscopic approach, endopyelotomy, is also an option in older children and adults. Surgery involves ureteroscopy and a full-thickness lateral incision into the affected ureteral segment with a laser or knife taking care not to injure the renal hilar vessels.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is the second most common cause of hydronephrosis after UPJ obstruction. Up to two thirds of infants presenting with urinary tract infections may be found with VUR.⁵⁸ The majority of cases occur in females. Primary reflux is a congenital anomaly caused by insufficient intramural tunneling of the distal ureter, although bladder outlet obstruction may cause unilateral or bilateral secondary reflux when the ureters are anatomically normal. The primary danger of VUR is the development of recurrent episodes of pyelonephritis, which can cause cumulative renal damage through scarring.

Neonates with hydronephrosis detected on prenatal ultrasound or infants or children experiencing a urinary tract infection should be evaluated for VUR with a VCUG. VUR is graded according to the International Classification System. Spontaneous resolution of VUR, which is the norm, is a function of the grade of VUR.⁵⁹ The large majority of low-grade (1 to 2) reflux will spontaneously resolve, while 30 to 50% of grades III and IV reflux and 9% of grade V reflux will resolve.^{59,60} The initial management of VUR is controversial, particularly for moderate degrees. Surgical repair with ureteral reimplantation is effective, but may be overtreatment for those destined to resolve spontaneously. However, conservative management, consisting of antibiotic prophylaxis, may result in breakthrough infections with resistant organisms. A newer endoscopic technique, the submucosal injection of bulking agents at the ureteral orifice, is making this debate less important. It is a minimally invasive technique that may, in some patients, obviate the need for open surgical repair or long-term suppressive antibiotics. Submucosal bulking is not effective in every case, and patients with severe reflux may still need reimplantation.

Ureterocele

A ureterocele is a cystic dilation of the terminal ureter thought to result from a persistent membrane between the ureteral bud and the urogenital sinus. Most patients will have associated genitourinary anomalies such as duplicated collecting

systems or an ectopic ureteral location. Patients frequently present during childhood and can present in multiple ways depending on size and degree of obstruction. Patients may have hydronephrosis and pyelonephritis. A large, prolapsing ureterocele can cause bladder outlet obstruction, and rarely, a large ureterocele can present as an intralabial mass in a newborn child. Diagnosis can be confirmed with cystoscopy, VCUG, or IVP.

Patients with a functioning renal moiety can undergo endoscopic incision of the ureterocele; however, VUR is common postoperatively. A ureterocele in a nonfunctioning duplicated system may require a heminephrectomy to avoid infections.

Posterior Urethral Valve

Posterior urethral valves can be a particularly damaging cause of bilateral hydronephrosis in a newborn boy. The "valves," which are tissue folds located in the prostatic urethra, cause bladder outlet obstruction. Diagnosis is established with a VCUG, which may show poor bladder emptying and a dilated posterior urethra. A Foley catheter should be placed in the bladder to decompress the urinary system to allow renal function to potentially recover. Treatment involves cystoscopic ablation or resection of the valve. Even after ablation of the valves and elimination of the urethral obstruction, patients with posterior urethral valves are at significant risk of renal failure, depending on the degree of prenatal obstruction.⁶¹ Bladders frequently suffer damage and become partially defunctionalized from prolonged prenatal obstruction, and normal voiding patterns often are not established. The most serious outcome of posterior urethral valves is pulmonary hypoplasia due to intrauterine oligohydramnios, and efforts have been made prenatally to transplacentally decompress the urinary bladder and prevent this dreaded development.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 41. Gynecology >

KEY POINTS

1. The general gynecology examination must incorporate the whole physical examination to adequately diagnosis and treat gynecologic disorders.
2. Gynecologic causes of acute abdomen include: pelvic inflammatory disease and tubo-ovarian abscess, ovarian torsion, ruptured ectopic pregnancy, and septic abortion. Pregnancy must be ruled out early in assessment of reproductive age patients presenting with abdominal or pelvic pain.
3. Pregnancy confers important changes to both the cardiovascular system and the coagulation cascade. Trauma in pregnancy must be managed with these changes in mind.
4. Pelvic floor dysfunction (pelvic organ prolapse, urinary and fecal incontinence) is common; 11% of women will undergo a reconstructive surgical procedure at some point in their lives.
5. It is critical that abnormal lesions of vulva, vagina, and cervix are biopsied for diagnosis before any treatment is planned; postmenopausal bleeding should always be investigated to rule out malignancy. Early-stage cervical cancer is managed surgically whereas chemoradiation is preferred for stages IB and above.
6. Risk-reducing salpingo-oophorectomy should be considered in women with *BRCA1* or *BRCA2* mutations; risk-reducing salpingo-oophorectomy and complete hysterectomy should be considered in women with hereditary nonpolyposis coli cancer.
7. Complete debulking for epithelial ovarian cancer is a critical element in patient response and survival. The preferred primary therapy for optimally debulked advanced-stage ovarian epithelial ovarian cancer in women without significant intra-abdominal adhesions is intraperitoneal chemotherapy.

PATHOPHYSIOLOGY AND MECHANISMS OF DISEASE

The female reproductive tract is a unique component of the body with a multitude of tightly regulated functions. Many of the activities normally ongoing, such as angiogenesis and physiologic invasion, are necessary for the reproductive organs to fulfill their purpose, and are usurped in disease. Immune surveillance is modified by multiple mechanisms under investigation, regulated in a different fashion, to allow implantation, placentation, and development of the fetus. How this potential disruption of the normal immune barriers is involved in pathologic events is incompletely understood. The ongoing rupture, healing, angiogenesis, and regrowth of the ovarian capsule and endometrium during the menstrual cycle uses the same series of biologic and biochemical events that are also active in pathologic events such as endometriosis and endometriomas, mature teratomas, dysgerminomas, and progression to malignancy. Genetic abnormalities, both germline and somatic, that may cause competence and/or promote disease are now being uncovered, especially in the progression to malignancy, in pharmacogenomics, and in surgical risks such as bleeding and clotting. Incorporation of genetic and genomic information in disease diagnosis and assessment is a wave for the near future and may alter how we consider who is at risk, how diseases are diagnosed and followed, and even what drugs or therapies we use for an individual patient. These points will be

incorporated with surgical approaches into discussions of anatomy, diagnostic work-up, infection, surgical and medical aspects of the obstetric patient, pelvic floor dysfunction, and neoplasms.

ANATOMY

The outlet of the bony pelvis is defined by the ischiopubic ramus anteriorly and the coccyx and sacrotuberous ligaments posteriorly.¹ This outlet can be subdivided into anterior and posterior triangles, which share a common base via a line between the ischial tuberosities. The soft tissues of the anterior triangle are layered in a fashion similar to the anterior abdominal wall. The most superficial layer is a skin and adipose layer (vulva) that overlies a fascial layer (perineal membrane) that is, in turn, superficial to a muscular layer (levator ani).

Vulva

The labia majora form the cutaneous boundaries of the lateral vulva and represent the female homologue of the male scrotum (Fig. 41-1). The labia majora are fatty folds covered by hair-bearing skin in the adult. They fuse anteriorly over the anterior prominence of the symphysis pubis, the mons pubis. The deeper portions of the adipose layers are called Colles' fascia and insert onto the inferior margin of the perineal membrane, limiting spread of superficial hematomas inferiorly. Adjacent and medial to the labia majora are the *labia minora*, smaller folds of connective tissue covered laterally by non-hair-bearing skin and medially by vaginal mucosa. The anterior fusion of the labia minora forms the *prepuce and frenulum of the clitoris*; posteriorly, the labia minora fuse to create the *fossa navicularis* and posterior fourchette. The term *vestibule* refers to the area medial to the labia minora bounded by the fossa navicularis and the clitoris. Both the urethra and the vagina open into the vestibule. Skene's glands lie lateral and inferior to the urethral meatus. Cysts, abscesses, and neoplasms may arise in these glands.

External genitalia.

(Reproduced with permission from Rock J, Jones HW: *TeLinde's Operative Gynecology*, 9th ed. Philadelphia, PA: Lippincott, Williams & Wilkins, 2003, Fig. 5-1, p 70.)

Erectile tissues and associated muscles are in the space between the perineal membrane and the vulvar subcutaneous tissues (Fig. 41-2). The clitoris is formed by two crura and is suspended from the pubis. Overlying the crura are ischiocavernosus muscles that run along the inferior surfaces of the ischiopubic rami. Extending medially from the inferior end of the ischiocavernosus muscles are the superficial transverse perinei muscles. These terminate in the midline in the perineal body, caudal and deep to the posterior fourchette. Vestibular bulbs lie just deep to the vestibule and are covered laterally by bulbocavernosus muscles. These originate from the perineal body and insert into the body of the clitoris. At the inferior end of the vestibular bulbs are Bartholin's glands, which connect to the vestibular skin by ducts.

Musculature of the Pelvic Floor

The opening of the pelvis is spanned by the muscles of the pelvic diaphragm (Fig. 41-3). These muscles contract tonically. Most anatomy textbooks fail to give a true picture of the horizontal nature of the pelvic floor musculature (due to embalming artifact). These muscles include, from anterior to posterior, bilaterally, the *pubococcygeus*, *puborectalis*, *iliococcygeus*, and *coccygeus* muscles. The first two of these muscles contribute fibers to the fibromuscular perineal body. The *urogenital hiatus* is bordered laterally by the pubococcygeus muscles and anteriorly by the *symphysis pubis*. It is through this muscular defect that the urethra and vagina pass, and it is the focal point for the study of disorders of pelvic support such as cystocele, rectocele, and uterine prolapse.

Fig. 41-3.

Nerves of the Pelvic Floor

The pudendal nerve arises from S2 to S4, travels laterally, exiting the greater sciatic foramen, hooking around the ischial spine and sacrospinous ligament, and returning via the greater sciatic foramen (Fig. 41-4). It travels through Alcock's canal and becomes the sensory and motor nerve of the perineum. The motor neurons originate in Onuf's nucleus in the sacral spinal cord and serve the tonically contracting urethral and anal sphincter. Direct branches from the S2 to S4 nerves serve the levator ani muscles. During childbirth and other excessive straining, this tethered nerve (along with the levator ani muscles) is subject to stretch injury, and at least partially responsible for many female pelvic floor disorders.

Fig. 41-4.

The nerve supply of the female pelvis.

Internal Genitalia

Figure 41-5 is a view of the internal genitalia as one would approach the pelvis from a midline abdominal incision. The central uterus and uterine cervix are supported by the pelvic floor muscles. They are suspended by the lateral fibrous cardinal, or *Mackenrodt's ligament* and the uterosacral ligaments, which insert into the paracervical fascia medially and into the muscular sidewalls of the pelvis laterally. Posteriorly, the uterosacral ligaments provide support for the vagina and cervix as they course

from the sacrum lateral to the rectum and insert into the paracervical fascia.

Fig. 41-5.

Internal pelvic anatomy, from above.

The bilateral fallopian tubes arise from the upper lateral *cornua* of the uterus and course posterolaterally. Each widens in the distal third, or *ampulla*. The ovaries are attached to the uterine cornu by the *proper ovarian ligaments*. Emanating from the uterine cornu and traveling through the inguinal canal are the round ligaments, eventually attaching to the subcutaneous tissue of the mons pubis. The ovaries are suspended from the lateral pelvis by their vascular pedicles, the *infundibulopelvic ligaments*. The peritoneum enfolding the *adnexa* (tube, round ligament, and ovary) is referred to as the *broad ligament*, although it is no more ligamentous than the peritoneum overlying the ovarian artery and vein.

The peritoneal recesses in the pelvis anterior and posterior to the uterus are referred to as the *anterior* and *posterior cul-de-sacs*. The latter is also called the *pouch* or *cul-de-sac of Douglas*. On transverse section, several avascular, and therefore important, surgical planes can be identified (Fig. 41-6). These include the lateral paravesical and pararectal spaces, and from anterior to posterior, the retropubic or prevesical space of Retzius and the vesicovaginal, rectovaginal, and retrorectal or presacral spaces. The pelvic brim demarcates the obstetric, or true, from the false pelvis contained within the iliac crests.

Fig. 41-6.

The muscles of the pelvic sidewall include the iliacus, the psoas, and the obturator internus muscle (Fig. 41-7). Except for the middle sacral artery originating at the aortic bifurcation, and the ovarian arteries originating from the abdominal aorta, the blood supply to the pelvis arises from the internal iliac arteries. The internal iliac, or hypogastric arteries divide into anterior and posterior branches. The latter supply lumbar and gluteal branches. From the anterior division of the hypogastric arteries arise the obturator, uterine, pudendal, middle rectal, along with superior and middle vesical arteries. The nerves found in the pelvis are the sciatic, obturator, and femoral nerves (see Fig. 41-4). Sympathetic fibers course along the major arteries and parasympathetics form the superior and inferior pelvic plexus. The ureters enter the pelvis as they cross the distal common iliac arteries laterally and then course inferior to the ovarian arteries and veins until crossing under the uterine arteries just lateral to the cervix. After traveling to the cervix, the ureters course downward and medially over the anterior surface of the vagina before entering the base of the bladder.

Fig. 41-7.

DIAGNOSIS

Elements of Gynecologic History

A complete history is a seminal part of any assessment (Table 41-1). Many gynecologic diseases can present with broad constitutional symptoms, occur secondary to other conditions, or be related to medications. A full history should include particular attention to family history, organ system history, including breast, GI, and urinary tract symptoms, and a careful anesthesia and surgical history. The key elements of a focused gynecologic history include the following:

- Age at menarche and menopause
- Present and past menstrual status
- Obstetrical history
- History of pelvic assessments, including cervical smear results
- History of pelvic infections and HIV status if indicated, and
- Prior gynecologic surgery(s).

Table 41-1 Key Elements of the Gynecologic History		
Issue	Elements to Explore	Associated Issues
Menstrual history	Age at menarche, menopause	Identifies abnormal patterns related to endocrine, structural, infectious, and oncologic etiologies
	Bleeding pattern, postmenopausal bleeding, spotting between periods	
	Any medications (Coumadin, heparin, aspirin,	

	herbals, others) or personal or family history that might lead to prolonged bleeding times	
Obstetrical history	Number of pregnancies, dates, type of deliveries, pregnancy loss, abortion, complications	Identifies predisposing pregnancy for gestational trophoblastic disease, possible surgical complications
Infectious diseases	Sexually transmitted diseases and treatment and/or testing for these	Also need to explore history of other GI diseases that may mimic sexually transmitted diseases (Crohn's, diverticulitis)
Contraceptive history	Present contraception if appropriate, prior use, type, and duration	Concurrent pregnancy with procedure or complications of contraceptives
Cytologic screening	Frequency, results (normal, prior abnormal Papanicolaou), any prior surgery or diagnoses, human papillomavirus testing history	Prolonged intervals increase risk of cervical cancer. Relationship to anal, vaginal, vulvar cancers.
Prior gynecologic surgery	Type (laparoscopy, vaginal, abdominal); diagnosis (endometriosis?, ovarian cysts?, tubo-ovarian abscess?); actual pathology if possible.	Assess present history against this background (for example, granulosa cell pathology, is it now recurrent?)
Pain history	Site, location, relationship (with urination, with menses, with intercourse at initiation or deep penetration?, with bowel movements?), referral?	Assesses relationship to other organ systems, and potential involvement of these with process. Common examples presenting as pelvic pain, ureteral stone, endometriosis with bowel involvement, etc.

Gynecologic Examination

Many women use their gynecologist as their primary care physician. When that is the case, it is necessary that a full medical and surgical history be taken and that, in addition to the pelvic examination, a minimum additional examination should include: thyroid, breast, cardiac, and pulmonary examinations. The pelvic examination starts with a full abdominal examination. Inguinal node evaluation is performed before placing the patient's legs in the dorsal lithotomy position (in stirrups). A flexible, focused light source is essential and vaginal instruments including speculums of variable sizes and shapes including pediatric sizes (Graves and Pederson) are required to assure that the patient's anatomy can be fully and comfortably viewed.

The external genitalia are inspected, noting the distribution of pubic hair, the skin color and contour, the Bartholin's and Skene's glands, and perianal area. Abnormalities are documented, and a map with measurements of abnormalities drawn. A warmed lubricated speculum is inserted into the vagina and gently opened to identify the cervix if present, or the vaginal apex if not. If there is a concern that a malignancy is present, careful digital assessment of a vaginal mass and location may be addressed before speculum placement to avoid abrading a vascular lesion and inducing hemorrhage. The speculum would then be inserted just short of the length to the mass to view that area directly before advancing. An uncomplicated speculum examination includes examination of the vaginal sidewalls, assessment of secretions including culture if necessary, and collection of the cervical cytologic specimen. Cervical cytology is performed by use of a brush placed into the cervical os, rotation of the brush, and then placement of the brush into liquid medium or spread and fixed on a glass slide, depending on the evaluation methods in use.

A bimanual examination is performed by placing two fingers in the vaginal canal; one finger may be used if patient has had prior radiation with stenosis or chemo- or other therapy with associated vaginal atrophy (Fig. 41-8). Carefully and sequentially assess the size and shape of the uterus by moving it against the abdominal hand, the adnexa by carefully sweeping the abdominal hand down the side of the uterus. The rectovaginal examination, one finger in the vagina and one in

the rectal vault, is used to further examine and characterize the location, shape, fixation, size, and complexity of the uterus, adnexa, cervix, and anterior and posterior cul de sacs. The rectovaginal exam also allows examination of the uterosacral ligaments from the back of the uterus sweeping lateral to the rectal finger to the sacrum.

Fig. 41-8.

Bimanual abdominovaginal palpation of the uterus.

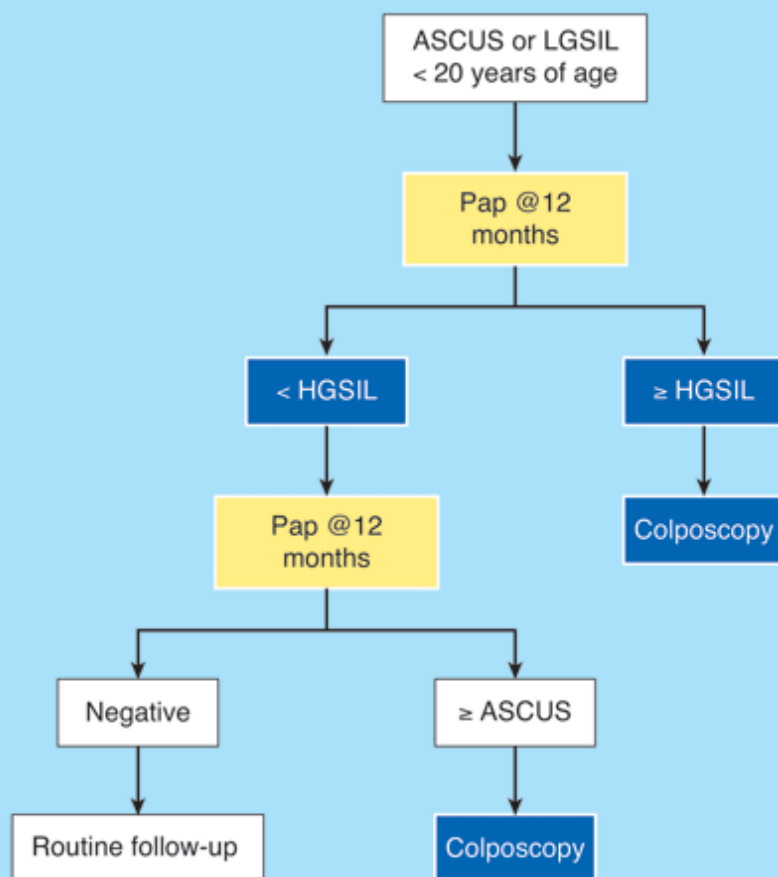

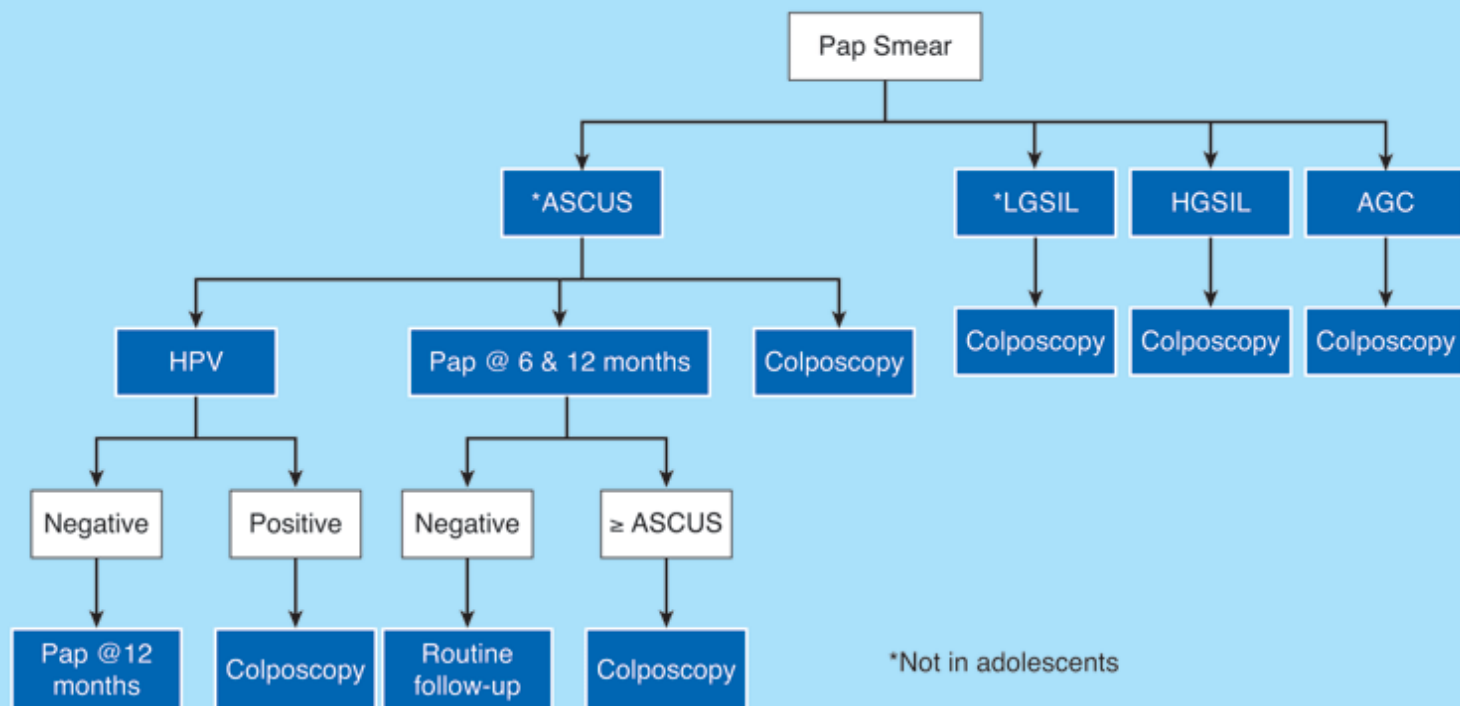

It is critical that presurgical assessment include a full general examination. This is particularly important with potentially oncologic diagnoses or infectious issues to assure that the proposed surgery is both safe and appropriate. Complications such as sites of metastatic cancer or infection, associated bleeding and/or clotting issues and history, and drug exposure, allergies, and current medications must be addressed.

Screening Procedures

CERVICAL CYTOLOGY

The present guidelines for cervical cytology recommend annual evaluation for all sexually active women up to the age of 30 years old. After age 30, cervical cytology may be extended to every 2 to 3 years if cytology has remained negative and/or testing for human papillomavirus (HPV) high-risk types have been negative. This can be achieved with either liquid techniques or the older smear technique, recognizing that the accepted approach is moving to liquid techniques as they allow for reflex testing of HPV high-risk subtypes as appropriate. It is beyond the scope of the chapter to describe in detail the complex patterns that vary by age and prior history for following abnormal cytology findings. These must be addressed before any surgery, other than diagnostic, involving the cervix is planned. The diagnostic approach for abnormal Pap smears is detailed in Fig. 41-9.

Fig. 41-9.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>

Diagnostic approach for cervical dysplasia. AGC = atypical glandular cells; ASCUS = atypical cells of undetermined significance; HGSIL = high-grade squamous intraepithelial lesion; HPV = human papillomavirus; LGSIL = low-grade squamous intraepithelial lesion; Pap = Papanicolaou.

HUMAN PAPILLOMAVIRUS TESTING

If liquid-based cytology is used, HPV testing for high-risk types can be done using the same specimen collected for cervical cytology.² HPV testing is useful to triage atypical cells of undetermined significance cytology results to either colposcopy or observation in patients beyond adolescence. Approximately half of atypical cells of undetermined significance cases will test positive for high-risk HPV subtypes and need colposcopy; those with negative tests can be followed routinely with cervical cytology. HPV testing is indicated in particular for planning intervals of cervical screening after age 30 years old. In these patients, if HPV testing is combined with cytology and both test negative, screening intervals can be spaced to every 3 years. Patients with low-grade squamous intraepithelial lesions have a high likelihood of testing positive, and as such high-risk HPV testing is not cost effective for triage; all should go to colposcopy.

VAGINAL DISCHARGE AND CULTURES

See section on Lower Genital Tract Infections.

BETA HUMAN CHORIONIC GONADOTROPHIN TESTING

Quantitative urinary pregnancy tests for beta human chorionic gonadotrophin (beta-hCG) are standard before any surgery in a woman of reproductive age and potential, regardless of contraception history. In addition, serum beta-hCG testing is appropriate for evaluation of suspected ectopic pregnancy, gestational trophoblastic disease (GTD), or ovarian mass in a young woman. In the case of ectopic pregnancy, serial levels are required when a pregnancy cannot be identified in the uterine cavity. As a general rule, there should be at least a 66% rise in the beta-hCG level over 48 hours if there is a viable intrauterine pregnancy.

Common Office Procedures for Diagnosis

VULVAR BIOPSY

Any abnormal lesion including skin color changes, raised lesions, or ulcerations should be biopsied. Local infiltration of a longer acting anesthetic is followed by punch biopsy appropriate to the lesion. The specimen is elevated with Adson forceps and cut from its base with iris scissors.

VAGINAL BIOPSY

This biopsy follows the same principles as vulvar biopsy but often is difficult to perform because of the angle of the lesion. After injection with local anesthetic, traction of the area with Allis forceps and direct resection of the lesion with a Metzenbaum scissors or cervical biopsy instrument (Schubert, Kevorkian, etc.) can achieve an adequate biopsy.

Cervical biopsy topical 4% lidocaine may be adequate for the many cervical biopsies that can be done without a tenaculum. The maintenance of sharp cervical biopsy forceps is critical to success. A loop electrosurgical excision procedure (LEEP) can be performed if the lesion is more extensive or vascular and allows the ball tip to be used for cautery.

Cauterization of all of the above lesions can be performed with silver nitrate, Monsel's solution, or direct electrical cauterization as required. If not adequate, suture should suffice to provide hemostasis.

ENDOMETRIAL BIOPSY

An endometrial sampling should be performed before planned hysterectomy if there is a history of abnormal bleeding, defined as bleeding between periods, spotting other than midcycle, heavy bleeding, frequent bleeding, or postmenopausal bleeding. A

patient with the potential for pregnancy should have a pregnancy test before the procedure. Topical 4% lidocaine can be applied under direct visualization to the anterior cervix where a tenaculum might be placed, and then in the endocervical canal with a cotton-tipped applicator. A Pipelle is inserted after cervical cleaning and the depth noted; a tenaculum is placed if the cervix is too mobile or the uterus too flexed. The specimen is obtained by pulling on the central end, creating a small amount of suction in the uterine cavity, and moving it within the cavity to access all sides.³ Additional passes may be made if the specimen is not initially adequate.

EVALUATION FOR FISTULAE

Common office procedures to evaluate for the presence of vesicovaginal fistulae include placement of a vaginal tampon before the procedure, and then insertion of sterile milk or sterile dye into the bladder through a transurethral catheter. Evaluation of suspected ureteral fistula is best done with radiologic imaging, and when confirmed, IV injection of dye may allow for direct visualization if the site is not obvious. Rectal fistula can be identified in a similar fashion using a large Foley catheter placed in the distal rectum through which dye may be injected or with the use of an oral charcoal slurry and timed examination. Common areas for fistulae are at the vaginal apex, at the site of a surgical incision, or around the site of a prior episiotomy or perineal repair after a vaginal delivery.

GYNECOLOGIC INFECTIONS

Lower Genital Tract Infections

Vulvovaginal symptoms are extremely common, accounting for >10 million office visits per year in the United States. The causes of vaginal complaints are commonly infectious in origin but they include a number of noninfectious causes, such as chemicals or irritants, hormone deficiency, foreign bodies, systemic diseases, and malignancy. Symptoms are commonly nonspecific and include abnormal vaginal discharge, pruritus, irritation, burning, odor, dyspareunia, bleeding, and ulcers.

CULTURES

The two most important cultures of vaginal secretions are for gonorrhea and chlamydia. A purulent discharge from the cervix should always raise suspicion of these infections even in the absence of pelvic pain or other signs. These cultures are obtained by removing ectocervical discharge or blood and then with a sterile swab obtaining an endocervical swab that is then placed in carrier media for later culture on Thayer-Martin medium, and/or for enzyme linked immunosorbent assay or direct fluorescent antibody testing.

Vaginitis

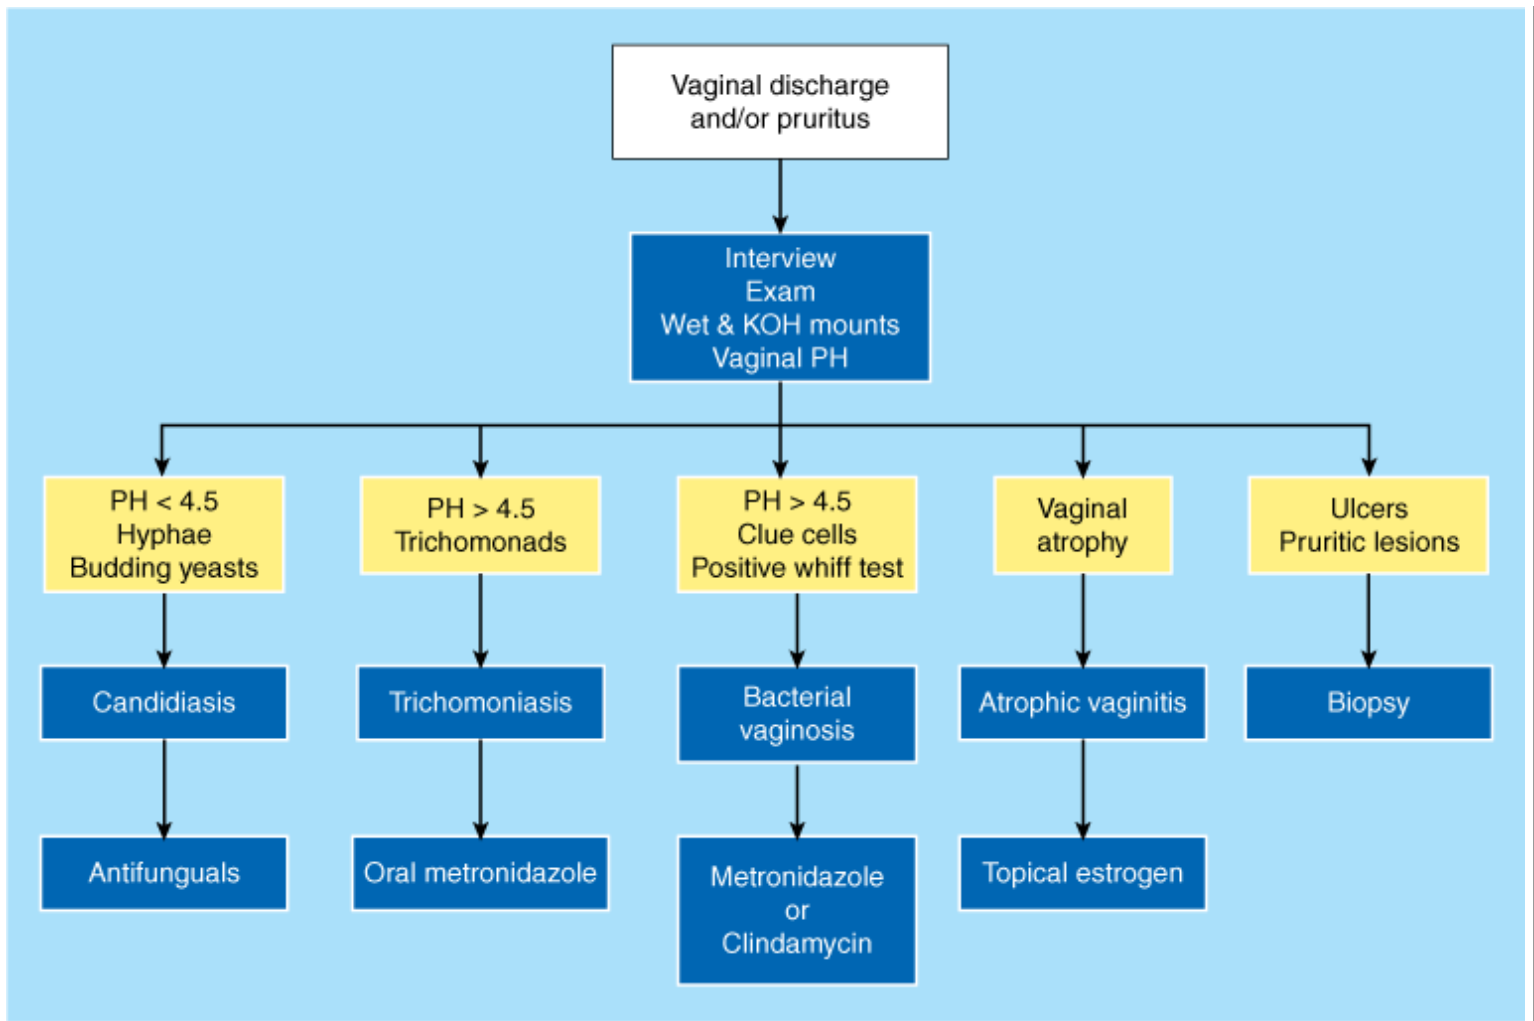

Normal vaginal discharge is white or transparent, thick, and mostly odorless. It increases during pregnancy, with use of estrogen-progestin contraceptives, or at midcycle around the time of ovulation. Complaints of foul odor and abnormal vaginal discharge should be investigated. Candidiasis, bacterial vaginosis (BV), and trichomoniasis account for 90% of cases of vaginitis (Table 41-2). The initial work-up includes pelvic examination, vaginal pH testing, microscopy, and, less commonly, vulvovaginal and cervical cultures.⁴ The pH of the normal vaginal secretions is 3.8 to 4.4, which is hostile to growth of pathogens. pH of 4.9 or greater is indicative of a bacterial or protozoal infection. Vaginal pH is obtained by dipping a pH tape into vaginal secretions collected on the speculum. Microscopy requires preparing wet and potassium hydroxide (KOH) mounts by adding a drop of normal saline or 10% KOH solutions to a specimen of the discharge. Microscopic examination of the wet mount may reveal motile trichomonads indicative of trichomoniasis or the characteristic clue cells of BV. KOH lyses cellular material and allows the clinician to appreciate the presence of mycelia characteristic of candidiasis. Treatment of vaginal

infection before anticipated surgery is appropriate, particularly for BV, which may be associated with a higher risk for vaginal cuff infections. Figure 41-10 summarizes the diagnostic and treatment approach for common causes of vulvovaginitis.

Table 41-2 Features of Common Causes of Vaginitis			
	Bacterial Vaginosis	Vulvovaginal Candidiasis	Trichomoniasis
Pathogen	Anaerobic organisms	<i>Candida albicans</i>	<i>Trichomonas vaginalis</i>
% of Vaginitis	40	30	20
pH	>4.5	<4.5	>4.5
Signs and symptoms	Malodorous, adherent discharge	White discharge, vulvar erythema, pruritus, dyspareunia	Malodorous purulent discharge, vulvovaginal erythema, dyspareunia
Wet mount	Clue cells	Pseudohyphae or budding yeasts in 40% of cases	Motile trichomonads
KOH mount		Pseudohyphae or budding yeasts in 70% of cases	
Amine test	+	–	–
Treatment	Metronidazole 500 mg bid x 7 d or 2 g single dose, metronidazole or clindamycin vaginal cream	Oral fluconazole 150 mg single dose, vaginal antifungal preparations	Metronidazole 2 g single dose and treatment of partner

+ = positive; – = negative; KOH = potassium hydroxide.

Fig. 41-10.

Treatment algorithm for vulvovaginitis. KOH = potassium hydroxide.

BACTERIAL VAGINOSIS

BV is the most common cause of vaginal discharge, accounting for 50% of cases. It results from reduction in concentration of the normally dominant lactobacilli and increase in concentration of anaerobic organisms like *Gardnerella vaginalis*, *Mycoplasma hominis*, *Bacteroides* spp, and others.^{5,6} Patient presentation, symptoms, cause, diagnostics, and interventions are shown in Table 41-2. Diagnosis is made by microscopy and involves recognition of clue cells, which are epithelial cells studded with adherent bacteria causing their margins to be obliterated. The discharge typically produces a fishy odor upon addition of KOH (amine or Whiff test).

VULVOVAGINAL CANDIDIASIS

Vulvovaginal candidiasis is the most common cause of vulvar pruritus. It generally is caused by *Candida albicans* and occasionally by other *Candida* spp. It is common in pregnancy, in diabetics, in patients taking antibiotics, and in the immunocompromised. Seventy-five percent of women will experience one episode, with 40 to 50% having two or more. Diagnosis is confirmed by observation of pseudohyphae or yeasts on microscopy.

TRICHOMONAS VAGINALIS

Trichomonas vaginalis causes primarily a vaginal infection; however, the copious discharge results in a secondary vulvitis. Diagnosis is made with saline wet mount demonstrating motile protozoans.

Genital Ulcer Syndromes

The frequency of the infectious etiologies of genital ulcers varies by geographic location. In the United States, the most common causes of sexually transmitted genital ulcers in young adults are, in descending order of prevalence: herpes simplex virus (HSV), syphilis, and chancroid.⁷ Others infectious causes of genital ulcers include lymphogranuloma venereum and granuloma inguinale. Noninfectious etiologies include Behçet's disease, neoplasms, and trauma. Establishing a diagnosis requires knowledge of the characteristics of genital ulcer syndromes and a rational approach to the evaluation of patients to guide therapy at the time of the initial encounter (Table 41-3). Confirmation of the established diagnosis requires the use of appropriate diagnostic tests.⁸

Table 41-3 Clinical Features of Genital Ulcer Syndromes

	Herpes	Syphilis	Chancroid	Lymphogranuloma Venereum	Granuloma Inguinale (Donovanosis)
Pathogen	HSV type II and, less commonly, HSV type I	<i>Treponema palladium</i>	<i>Haemophilus ducreyi</i>	<i>Chlamydia trachomatis</i> L1–L3	<i>Calymmatobacterium granulomatis</i>
Incubation period	2–7 d	Typically 2–4 wk (can range from 1–12 wk)	1–14 d	3 d–6 wk	1–4 wk (up to 6 mo)
Primary lesion	Vesicle	Papule	Papule or pustule	Papule, pustule, or vesicle	Papule
Number of lesions	Multiple, may coalesce	Usually one	Usually multiple, may coalesce	Usually one	Variable
Diameter (mm)	1–2	5–15	2–20	2–10	Variable
Edges	Erythematous	Sharply demarcated, elevated, round, or oval	Undermined, ragged, irregular	Elevated, round, or oval	Elevated, irregular
Depth	Superficial	Superficial or deep	Excavated	Superficial or deep	Elevated
Base	Serous, erythematous	Smooth, nonpurulent	Purulent	Variable	Red and rough ("beefy")
Induration	None	Firm	Soft	Occasionally firm	Firm
Pain	Common	Unusual	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, tender, often bilateral	Firm, nontender, bilateral	Tender, may suppurate, usually unilateral	Tender, may suppurate, loculated, usually unilateral	Pseudoadenopathy
Treatment	Acyclovir 400 mg PO tid x 7–10 d for primary infection and 400 mg PO tid x 5 d for episodic management	Primary, secondary, and early latent (<1 y): benzathine PCN-G 2.4 million U IM x 1	Azithromycin 1 g PO or ceftriaxone 250 mg IM x 1	Doxycycline 100 mg PO bid x 21 d	Doxycycline 100 mg PO bid x 3 wk until all lesions have healed
			or	Erythromycin base 500 mg PO qid x 21 d	
		Late latent (>1 y)	Ciprofloxacin		

		and latent of unknown duration: benzathine PCN-G 2.4 million units IM qwk x 3	500 mg PO bid x 3 d or Erythromycin base 500 mg PO tid x 7 d		
Suppression	Acyclovir 400 mg PO bid for those with frequent outbreak	—	—	—	—

HSV = herpes simplex virus; PCN-G = penicillin.

Source: Adapted from Stenchever M, Droegemueller W, Herbst A, et al: *Comprehensive Gynecology*, 4th ed. St Louis: Mosby, 2001.

GENITAL HERPES

Herpes is a recurrent, incurable, sexually transmitted disease that has reached epidemic proportions. At least one in five individuals has had genital herpes in the United States. Herpes simplex infection is highly contagious and is caused by HSV-II and, less commonly, by HSV-I. Primary infection is a genital and systemic disease. Patients usually present with multiple painful vesicles that coalesce to form shallow superficial ulcers involving the vulva, vagina, and cervix.⁹ Other possible symptoms include dysuria, fever, malaise, tender inguinal lymphadenopathy, and headaches. Less commonly, the infection can be subclinical and entirely asymptomatic. Once a patient is infected, there is a tendency for outbreaks at various intervals for life. Between outbreaks, the herpes virus resides dormant in the dorsal root ganglia of S2–4. Recurrent genital herpes is a local disease and characteristically less severe than the primary infection and of shorter duration. A common feature of recurrence is as prodromal phase of vulvar burning, tenderness, and pruritus lasting from a few hours up to a few days. Diagnosis is made by simple inspection of the lesions, cytology is helpful (Tzanck smear), and culture is confirmatory. Treatment is outlined in Table 41-3; alternative antiviral medications include famciclovir and valacyclovir. Vaginal delivery is contraindicated in pregnant patients presenting in labor with active genital herpes. Cesarean section is indicated and aims to prevent a potentially devastating neonatal infection.^{10,11}

SYPHILIS

Syphilis is a chronic, systemic, sexually transmitted disease and is the second most common cause of genital ulcers and is caused by *Treponema pallidum*, an anaerobic spirochete.¹² In the United States, >36,000 cases of syphilis were reported in 2006, including 9756 cases of primary and secondary syphilis. The incidence was highest in women 20 to 24 years of age. Clinically, syphilis is divided into primary, secondary, tertiary, and congenital. The primary stage is marked by the appearance of a single ulcer (chancre). The chancre usually is firm, round, painless, may be accompanied by regional adenopathy, and develops at the site of entry of the bacterium. It lasts 3 to 6 weeks, and it heals without treatment. However, without treatment, the primary infection progresses to secondary syphilis and eventually to tertiary disease in 30% of cases, after a variable latent phase that usually lasts for years. During pregnancy, syphilis can be transmitted to the fetus and may result in the varied manifestations of congenital syphilis syndrome, which may results in fetal hydrops and intrauterine fetal demise. The diagnosis of syphilis is typically made by examination and serologic testing. Nonspecific nontreponemal tests such as rapid plasma reagin and Venereal Disease Research Laboratories are used for screening, and specific treponemal tests such as fluorescent-labeled treponema antibody absorption and microhemagglutination assay for antibodies to *T. pallidum* are used for confirmation.

CHANCROID

Chancroid is a contagious sexually transmitted ulcerative disease of the vulva caused by *Haemophilus ducreyi*, small gram-negative rods that exhibit parallel alignment on Gram's staining ("school of fish").¹³ After a short incubation period, the patient usually develops multiple painful soft ulcers on the vulva, mainly on the labia majora and, less commonly, on the labia minora or involving the perineal area. The chancroid ulcer has ragged, irregular borders and a base that bleeds easily and is covered with grayish exudates. Approximately half the patients will develop painful inguinal lymphadenitis within 2 weeks of an untreated infection, which may undergo liquefaction and presents as buboes.¹⁴ These may rupture and discharge pus. Diagnosis is made by Gram's stain and, less commonly, by culture.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LVG) is a sexually transmitted infection of lymphatic tissue caused by *Chlamydia trachomatis* serotypes L1, L2, and L3. LVG is rare in the United States.¹⁵ In its primary stage, a genital ulcer develops at the site of inoculation after an incubation period of 3 to 30 days. The primary ulcer heals within a few days without therapy. The secondary phase of LVG develops 2 to 4 weeks later and is precipitated by direct spread to inguinal and perirectal lymph nodes. These painful, enlarged lymph nodes may result in the classic inguinal "groove sign" (double genitocrural fold) and may form buboes and rupture. Without adequate therapy, the patient will progress to the third stage marked by extensive inflammation and scarring. Clinical diagnosis is confirmed by serologic testing and culture. Complications include genital elephantiasis and colorectal fistulae and strictures. Treatment cures the infection and prevents ongoing tissue damage. Buboes occasionally require aspiration or incision and drainage.

GRANULOMA INGUINALE

Granuloma inguinale, donovanosis, is an ulcerative bacterial infection of the vulva and perianal area that is transmitted via sexual contact in the majority of cases. It is caused by the intracellular gram-negative bacterium *Klebsiella granulomatis*. It is endemic in some tropical areas but is rarely seen in the United States. After a variable incubation period, the infection manifests as multiple nodules that ulcerate resulting in "beefy-red" ulcers covered with granulation tissue. These ulcers bleed easily and may coalesce, resulting in destruction of the vulvar architecture. The causative organism is difficult to culture, and diagnosis requires visualization of Donovan bodies on tissue crush preparation or biopsy. Donovan bodies are intracytoplasmic clusters of bacteria found in macrophages.

Molluscum Contagiosum

Molluscum contagiosum is a localized viral infection of the skin that typically spares the palms and soles. It can involve the genital area, and the lesions usually are small shiny papules with central umbilication. The condition is self-limited and resolves spontaneously. Genital lesions can be treated to prevent sexual transmission. Treatment options include curettage, cryotherapy, and laser ablation.

Bartholin's Cysts and Abscesses

Bartholin's glands (great vestibular glands) are located at the vaginal orifice at the 4 and 8 o'clock positions and they are rarely palpable in normal patients. They are lined with cuboidal epithelium and secrete mucoid material to keep the vulva moist. Their ducts are lined with transitional epithelium and their obstruction secondary to inflammation may lead to the development of a Bartholin's cyst or abscess. Bartholin's cysts range in size from 1 to 3 cm, and are detected on examination or recognized by the patient. They occasionally result in discomfort and dyspareunia and require treatment. Cysts and ducts

can become infected and form abscesses. Infections are often polymicrobial; however, sexually transmitted *Neisseria gonorrhea* and *C. trachomatis* are sometimes implicated. Abscesses usually present as acutely inflamed, exquisitely tender masses. Treatment consists of incision and drainage and placement of a Word catheter, a small catheter with a balloon tip, for 2 to 3 weeks to allow for formation and epithelialization of a new duct. Appropriate antibiotic therapy should be instituted and modified based upon culture results. Recurrent cysts or abscesses are usually marsupialized, but on occasion necessitate excision of the whole gland. Marsupialization is done by incising the cyst or abscess wall and securing its lining to the skin edges with interrupted sutures.¹⁶ Cysts or abscesses that fail to resolve after drainage and those occurring in patients >40 years of age should be biopsied to exclude malignancy.

Vulvar Condylomas

Condylomata acuminata (anogenital warts) are viral infections caused by HPV.² Genital infection with HPV is the most common sexually transmitted infection in the United States today. It is estimated that approximately 1% of sexually active adults currently have genital warts. There are more than 100 different types of HPV, and they differ in terms of the type of epithelium they infect. More than 30 types infect the anogenital epithelium, including the cervix, vagina, vulva, urethra, rectum, and anus. These are divided into low- and high-risk types. HPV 6 and 11 are the most common low-risk types and are implicated in 90% of cases of genital warts.¹⁷ High-risk types can be found in association with invasive cancers.

Genital warts are skin colored or pink and range from smooth, flattened papules to verrucous, papilliform lesions. Lesions may be single or multiple and extensive. Diagnosis is made by simple inspection and should be confirmed with biopsy as verrucous and other vulvar cancers can be mistaken for condylomata.¹⁸ Treatment modalities range from patient-applied ointments, physician-applied agents, and office procedures, to outpatient surgery. Patients may be prescribed 5% imiquimod cream to apply once at bedtime and wash off in the morning, three times a week, for up to 16 weeks. Trichloroacetic acid is a commonly used caustic agent for in office application and can be repeated weekly as necessary. Surgical modalities include cryotherapy, laser ablation, cauterization, and surgical excision depending on the severity and extent of the lesions.

Upper Genital Tract Infections

Pelvic inflammatory disease (PID) is an infection of the upper female genital tract involving the uterus, fallopian tubes, and ovaries, resulting in endometritis, salpingitis, and oophoritis. It often involves contiguous pelvic organs resulting in peritonitis, tubo-ovarian abscesses, and occasionally perihepatitis (Fitz-Hugh–Curtis syndrome). Long-term sequelae include infertility, chronic pelvic pain, and increased risk of ectopic pregnancy.^{19,20} PID is mostly a sexually transmitted, ascending infection caused by *N. gonorrhea* and/or *C. trachomatis*, but numerous other organisms have been implicated, including normal vaginal flora. Screening for concomitant HIV infection is strongly recommended. Less commonly, PID may result from extension of other pelvic and abdominal infections such as appendicitis and diverticulitis, or may be precipitated by medical procedure, such as hysterosalpingography, endometrial biopsy, or dilation and curettage.

Risk factors for PID include age <25 years old, young age at first intercourse, nonbarrier contraception, previous episode of PID, other sexually transmitted diseases, and new or multiple sexual partners. Diagnosis can be challenging secondary to a wide range of presentations. Differential diagnosis includes appendicitis, cholecystitis, inflammatory bowel disease, pyelonephritis, nephrolithiasis, ectopic pregnancy, and ovarian torsion.^{19,20} Common symptoms include fever, nausea and vomiting, lower abdominal pain, and purulent vaginal discharge. Clinical diagnosis is made by the triad of lower abdominal tenderness, cervical motion tenderness, and adnexal tenderness and may be confirmed by cervicovaginal cultures, transvaginal ultrasonography (TVUS), computed tomography (CT) scanning, and laparoscopy. Transvaginal ultrasound may

reveal thickened, fluid-filled tubes with or without free pelvic fluid, while findings at the time of laparoscopy include exudates and swollen erythematous tubes. Criteria for hospitalization and IV antibiotic treatment include (Table 41-4)^{7,21,22}:

- Pregnancy
- Febrile illness
- Severe pain
- PO intolerance secondary to nausea and vomiting
- Peritonitis and peritoneal signs
- Medication noncompliance
- Failure to respond to oral medications
- Pelvic or tubo-ovarian abscess

Table 41-4 Centers for Disease Control and Prevention Recommended Treatment of Pelvic Inflammatory Disease (2007)

Oral regimens

Ceftriaxone 250 mg IM in a single dose

plus

Doxycycline 100 mg PO bid × 14 d

with or without

Metronidazole 500 mg PO bid × 14 d

or

Cefoxitin 2 g IM in a single dose and probenecid 1 g PO administered concurrently in a single dose

plus

Doxycycline 100 mg PO bid × 14 d

with or without

Metronidazole 500 mg PO bid × 14 d

or

Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime)

plus

Doxycycline 100 mg PO bid × 14 d

with or without

Metronidazole 500 mg PO bid × 14 d

Parenteral regimens

Recommended regimen A

Cefotetan 2 g IV every 12 h

or

Cefoxitin 2 g IV every 6 h

plus

Doxycycline 100 mg orally or IV every 12 h

Recommended regimen B

Clindamycin 900 mg IV every 8 h

<i>plus</i>
Gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 h. Single daily dosing may be substituted.
Alternative parenteral regimen
Ampicillin/sulbactam 3 g IV every 6 h
<i>plus</i>
Doxycycline 100 mg orally or IV every 12 h

Surgical intervention becomes necessary if medical therapy of a tubo-ovarian abscess fails or if the abscess ruptures. Rupture of a tubo-ovarian abscess is a surgical emergency with a high mortality rate if not recognized and managed promptly. In addition to management of the septic shock state, total abdominal hysterectomy and bilateral salpingo-oophorectomy is the procedure of choice; however, conservative surgery must be considered in young patients desiring of future fertility. The abdomen should be explored for metastatic abscesses, and special attention must be paid to bowel, bladder, and ureteral safety due to the friability of the infected tissue and the adhesions commonly encountered at the time of surgery. Placement of an intraperitoneal drain and mass closure of the peritoneum, muscle, and fascia with delayed-absorbable or permanent sutures is advised. Closure of the skin and subcutaneous layer should be avoided in patients with frank pus and delayed primary closure or closure by secondary intention is recommended because of the high rate of wound infections in these patients. Conservative surgery, when feasible, may be attempted by laparoscopy and may involve unilateral salpingo-oophorectomy or drainage of the abscess and liberal irrigation of the abdomen and pelvis.

SURGICAL CONDITIONS OF THE OBSTETRIC PATIENT

Many women will undergo invasive diagnostic procedures for prenatal diagnosis. Between 0.2 and 2.2% of pregnant women will require surgery in pregnancy for issues both related and unrelated to the pregnancy.^{23–26} Another 25 to 30% will have cesarean deliveries,²⁷ increasing the risks for associated or subsequent emergency hysterectomies with future pregnancies. Although these procedures typically are performed by obstetricians and gynecologists, occasionally a general surgeon will be consulted for assistance with postoperative or intraoperative issues. Physiologic changes due to pregnancy should be kept in mind (Table 41-5).²³

Table 41-5 Physiologic Changes Due to Pregnancy
Cardiovascular changes
Increased cardiac output
Increased blood volume
Decreased systemic vascular resistance
Decreased venous return from lower extremities
Respiratory changes
Increased minute ventilation
Decreased functional residual capacity
GI changes
Decreased gastric motility
Delayed gastric emptying
Coagulation changes

Increased clotting factors (II, V, VII, VIII, IX, X, and XII)
Increased fibrinogen
Increased risk for venous thromboembolism
Renal changes
Increased renal plasma flow and glomerular filtration rate
Ureteral dilation
Initial increased bladder capacity

Trauma in the obstetric patient requires stabilization of the mother, but the fetal compartment needs to be considered. Optimal maternal circulation and oxygenation is important, and when feasible, a left lateral tilt should be instituted to improve venous return because the gravid uterus often impedes blood flow to the right heart through direct pressure on the vena cava. Several coagulation factors are increased in pregnancy, increasing the likelihood for thromboembolic events, but also giving the unsuspecting surgeon false security when low-normal levels are observed during resuscitative efforts.

Procedures Performed before Viability

AMNIOCENTESIS/CHORIONIC VILLUS SAMPLING

Prenatal genetic diagnosis typically requires obtaining fetal tissue or cells. While newer techniques using maternal blood are currently being evaluated, the traditional methods for obtaining fetal genetic material are amniocentesis and chorionic villus sampling. Chorionic villus sampling is typically performed between 10 to 12 weeks gestation by using ultrasound to guide a flexible catheter transcervically into the trophoblastic tissue surrounding the gestational sac. An amniocentesis is performed after about 13 weeks gestation by ultrasound-associated guidance of a 22-gauge spinal needle into the amniotic cavity. Fetal cells can be isolated, while other markers for chromosomal abnormalities and neural tube defects can be obtained from the amniotic fluid. Pregnancy loss attributable to these procedures is around 0.5%.

PREGNANCY TERMINATIONS

Modern methods of contraception are highly effective, but still have a 0.5 to 5% failure rate. In addition, fetal conditions incompatible with life can result in planned termination. While the overall mortality rate related to pregnancy termination in the U.S. is around 1 per 100,000 induced abortions, rising with advanced gestational age, the maternal mortality rate for normal pregnancy and delivery is nine times that high.²⁸ Although legal, nonsurgical options are now available for early pregnancy, the safest and most commonly performed procedure is a cervical dilation and vacuum curettage. After the uterine cervix is grasped with a tenaculum, the cervix is forcibly dilated with tapered rods (occasionally using adjunctive prostaglandins), and an appropriately sized vacuum cannula is inserted into the uterus to remove the products of conception. Additional forceps can be used as necessary. The most common complications are infections, hemorrhage due to uterine atony, cervical lacerations, uterine perforations, and inadvertent bowel injury from the vacuum cannula or forceps.

CERCLAGE

A cervical cerclage may improve pregnancy outcomes in selected patients felt to have cervical incompetence. Shirodkar and McDonald techniques have been described;^{29,30} both involve transvaginally placing a nonabsorbable suture at the uterocervical junction to lengthen and close the cervix. For a patient with a severely shortened or absent cervix, a laparotomy

can access the abdominal portion of the lower uterine segment for an abdominal cerclage.

ECTOPIC PREGNANCIES

Extrauterine pregnancies can be located along the fallopian tubes and on the ovary. Rarely, implantation can occur primarily on other abdominal organs, or secondarily implant after tubal or uterine rupture. Historically, ectopic pregnancies were associated with high mortality rates; early diagnosis is the key to minimizing maternal morbidity and mortality. Sensitive assays for beta-hCG and improvements in ultrasound technology allow potential visualization of early gestations. Early ectopic pregnancies can be managed with methotrexate. Advanced ectopic pregnancy or a patient with unstable vital signs is managed by laparoscopy or laparotomy. Linear salpingostomy along the antimesenteric border and removal of the products of conception is a reasonable option unless the oviduct has already ruptured and a large hemoperitoneum already exists, in which case removal of the tube should be performed.

Procedures Performed after Viability

OBSTETRIC LACERATIONS AND REPAIR

The mean biparietal diameter of a term infant approaches 10 cm. The measured hiatus of the nulliparous vaginal introitus is approximately 2 cm. As a result, at the time of vaginal delivery, perineal lacerations, and with decreasing frequency, episiotomies are quite common. These lacerations involve, in varying degrees, the vaginal mucosa, the muscular elements inserting onto the perineal body, the levator ani, and in 4 to 5% of vaginal deliveries, the anal sphincter or anorectal mucosa. Although these are typically straightforward layered closures, knowledge of the anatomy is important. Incomplete reconstruction can contribute to future pelvic floor disorders as well as the development of fistulae.

CESAREAN DELIVERIES

An increasing proportion of children are born by cesarean delivery. In 2004, 1.2 million or 29% of live births in the United States were cesarean deliveries, and this rate is increasing.²⁷ Current typical indications for cesarean delivery include: nonreassuring fetal status, breech or other malpresentations, triplet and higher order gestations, cephalopelvic disproportion, failure to progress, placenta previa, and active genital herpes. Previous low transverse cesarean delivery is not a contraindication to subsequent vaginal birth after cesarean; however, much of the increase in cesarean delivery in the past decade is attributable to planned repeat cesareans. Because there is decreased blood loss, and the subsequent uterine rupture rate with future pregnancies is about 0.5%, cesarean deliveries typically are performed via a lower anterior (caudal) uterine transverse incision (Fig. 41-11). Abdominal access is obtained by a Pfannenstiel or Maylard incision. Once the abdomen is entered, a vesicouterine reflection is created if a low transverse uterine incision is planned. The uterine incision is then made and extended laterally, avoiding the uterine vessels. After amniotomy, the baby is delivered, and the uterus closed. Approximately 1000 mL of blood typically is lost during a cesarean delivery. Along with rapid closure of the uterine incision, uterotonics such as IV oxytocin are administered. In certain very early viable gestations, or in the case of certain transverse lies, a classical (vertical) uterine incision is made. Following classical cesarean deliveries, future pregnancies have an 8% or greater risk of uterine rupture, and this is an absolute indication for a planned repeat cesarean delivery. Infection, excessive blood loss due to uterine atony, and urinary tract and bowel injuries are potential complications at the time of cesarean delivery, and are increased following labor. Moreover, with each subsequent cesarean delivery, the risk of those injuries, as well as abnormal placentation (placenta accreta, increta, and percreta), rises. Bleeding can only be controlled in some instances by performing a cesarean hysterectomy.

PERIPARTUM HYSTERECTOMY

A cesarean or postpartum (if a cesarean delivery has not previously occurred) hysterectomy involves the same steps as in a nonpregnant patient, but is distinctly different due to the engorged vessels and the pliability of the tissues. If a cesarean section has been performed, occasionally the incision can be used for traction to keep the vessels and tissues attenuated. Vascular pedicles should be secured with clamps, but not ligated until both uterine arteries have been secured to fully control bleeding. Lack of typical anatomic landmarks requires careful identification of the ureters and the dilated cervix visually or by palpation to separate from the bladder and vagina (Fig 41-12). As this procedure is often done for life-threatening hemorrhage, appropriate blood products, including packed red blood cells, fresh-frozen plasma, and fibrinogen, should be on call and usually are required. Because fibrinogen is typically elevated in a pregnant woman, a low-normal fibrinogen level can be cause for alarm and further fibrinogen may be required before any consumptive coagulopathy reverses. A massive transfusion protocol often is helpful.

Gestational Trophoblastic Disease^{31,32}

GTD is an important gynecologic entity to consider when uterine size is significantly greater than expected for date in pregnancy, bleeding occurs in pregnancy, or in abnormal bleeding after pregnancy loss, abortion, or full-term delivery. Diagnosis is by ultrasound and measurement of serum beta-hCG, followed by pathologic examination of curettage specimens. There are two subtypes of GTD: complete, containing no fetal tissue and diploid on karyotype; and partial, containing fetal tissue and triploid. The chromosome pattern suggests paternal origin. These can be associated with theca lutein ovarian cysts often >6 cm in diameter that are fragile and generally should be followed without any surgical intervention as they resolve with removal or treatment of the GTD. Metastatic GTD can present on the cervix, vagina, liver, or lung and should not be managed surgically, as chemotherapy is the primary therapy and the incidence of bleeding complications is significant.

Primary surgery for diagnosis and initial therapy is a suction dilatation and curettage. Oxytocin is started either before anesthesia or immediately as the cervix is being dilated. The largest suction catheter possible (12 mm preferred) is gently inserted through the cervix and suction turned on, to allow the tissue to be removed and the uterus to rapidly decrease, with less blood loss. Following this, a sharp curettage of the uterus is done with a larger curette associated with a higher risk for perforation. Following diagnosis, beta-hCG is followed weekly until normal for 3 weeks, then monthly for at least 6 months. Any increase in beta-hCG may trigger further evaluation and consideration of chemotherapy.

PELVIC FLOOR DYSFUNCTION

Pelvic floor disorders can be categorized, from a urogynecologic perspective, into three main topics: female urinary

incontinence and voiding dysfunction, pelvic organ prolapse, and disorders of defecation.³³ Approximately 11% of women will undergo surgery for incontinence or prolapse.³⁴ The normal functions of support, storage, and evacuation can be altered by derangements in neuromuscular function both centrally and peripherally, and through acquired changes in connective tissue. Reconstructive surgeons aim to repair or compensate for many of these losses.

Evaluation

Diagnostic evaluations, in addition to the history and examinations described above under Gynecologic Examination, can aid in the diagnosis of many pelvic floor disorders. Cystoscopy, multichannel urodynamics, and/or fluoroscopic evaluation of the urinary tract can be obtained for patients with urinary incontinence or voiding dysfunction.³⁵ Defecography, anal manometry, and endorectal ultrasound may be useful for diagnosis of defecatory dysfunction. A standardized examination called the *pelvic organ prolapse quantification*³⁵ helps to clarify which vaginal compartment, and therefore, which specific structure, has lost its anatomic integrity in women with uterovaginal prolapse. Finally, dynamic magnetic resonance imaging (MRI) and pelvic floor electromyography have growing use for all three disorders.

SURGERY FOR PELVIC ORGAN PROLAPSE

Vaginal Procedures³⁶

Many factors are important in determining which reconstructive operation is optimal for a given patient with pelvic organ prolapse. Surgical decisions often are based on case series and expert opinions that may not have universal applicability. However, the few reports with the highest level of evidence suggest that failure rates for prolapse reconstruction may be twice as high using the vaginal approach when compared with the abdominal route.^{36,37}

COLPORRHAPHY

Anterior colporrhaphy begins with incision of the anterior vaginal epithelium in a midline sagittal direction. The epithelium is dissected away from the underlying vaginal muscularis. Although many surgical descriptions refer to plication of the "endopelvic" or "pubocervical" fascia, such structures have not been shown to exist as histologically distinct layers. The vaginal muscularis is plicated with interrupted delayed absorbable stitches, after which the epithelium is trimmed and reapproximated. The vaginal canal is therefore shortened and narrowed proportionately to the amount of removed epithelium. Posterior colporrhaphy is performed in a similar manner, often including the distal pubococcygeus muscles in the plication. In addition to the vaginal shortening and neuropathy that may be induced by these dissections, levator plication is associated with a significant risk of postoperative dyspareunia. These factors influence the selection of appropriate patients for colporrhaphy procedures.

SACROSPINOUS FIXATION

The sacrospinous ligament is used as a unilateral fixation point for the vaginal apex. The procedure begins with entry into the rectovaginal space, usually by incising the posterior vaginal wall at its attachment to the perineal body. The space is developed to the level of the vaginal apex, and the rectal pillar is penetrated to gain access to the pararectal space. The sacrospinous ligament is found embedded in and continuous with the coccygeus muscle, which extends from the ischial spine to the lateral surface of the sacrum. A long-ligature carrier is used to place sutures medial to the ischial spine, through the substance of the ligament-muscle complex. Structures at risk in this procedure include the pudendal neurovascular bundle, the inferior gluteal neurovascular bundle, lumbosacral plexus, and sciatic nerve. After the stitches are placed, the free ends are sewn to the undersurface of the vaginal cuff. The sacrospinous stitches are tied to firmly approximate the vagina to the

ligament without suture bridging. The epithelial incision is closed.

UTEROSACRAL LIGAMENT SUSPENSION

Both sacrospinous fixation and suspension of the vaginal apex to the uterosacral ligaments may be performed immediately following vaginal hysterectomy or applied to posthysterectomy vaginal vault prolapse. The procedure is based on the concept that the natural support structures for the apical vagina and cervix are the uterosacral ligaments. When using the uterosacral ligaments for repair of prolapse, it is important to recall that these structures are not "ligaments" in the true sense of the word, but rather condensations of smooth muscle, collagen, and elastin. The integrity and strength of these structures may vary greatly from patient to patient. The repair uses the middle third of the ligament, which allows firm tissue-to-tissue approximation to the vagina and does not divert the ureter medially. Several support stitches are placed, such that the lateral-most portion of the vaginal cuff is attached to the distal-most part of the ligament and the medial cuff to the proximal ligament. Intraoperative evaluation of the lower urinary tract is important to confirm the absence of ureteral compromise.

COLPOCLEISIS

A colpocleisis removes part or all of the vaginal epithelium. This obliterates the vaginal vault, leaving the external genitalia unchanged. Colpocleisis is reserved for patients who are elderly, who do not wish to retain coital ability, and for whom there is good reason not to perform a more extensive reconstructive operation. The main benefits of colpocleisis operations are their simplicity, speed, and high efficacy. The LeFort colpocleisis technique, done for complete uterovaginal prolapse, involves denudation of a rectangular portion of vaginal epithelium on both the anterior and posterior walls followed by suture reapproximation of the exposed submucosal surfaces. The uterus is left in situ. Lateral drainage canals remain for drainage of uterine secretions. By contrast, total colpocleisis involves hysterectomy, if applicable, followed by excision of the entire anterior and posterior epithelium. Successive purse-string sutures through the vaginal muscularis are used to reduce the prolapsed organs to above the level of the levator plate. The bladder neck is displaced posteriorly by the repair, placing the patient at risk for postoperative stress incontinence; a concomitant procedure to stabilize the urethrovesical junction is recommended. This may involve plication of the anterior vaginal muscularis (Kelly plication), pubourethral ligament plication, or a sling procedure, depending on preoperative urodynamic findings.

Abdominal Procedures

SACROCOLPOPEXY

Pelvic reconstructive surgery by the abdominal approach has, as its main advantage, the use of graft material for support of the vaginal apex. The natural apical support structure, the cardinal–uterosacral ligament complex, is often damaged and attenuated. The use of graft material to compensate for defective vaginal support structures is well described.³⁸ Apical support defects rarely exist in isolation. Therefore, the sacrocolpopexy may be modified to include the anterior and posterior vaginal walls as well as the perineal body in the suspension. Sacrocolpopexies can be performed via laparotomy as well as via laparoscopy. Like rectopexies and low anterior resections, deep pelvic access is needed. Significant suturing at varied angles is required. The advent of the da Vinci robotic laparoscopic system has made visualization and adequate placement of the mesh and sutures easier to perform when using the minimally invasive approach.

A rigid stent is placed into the vagina to facilitate its dissection from the overlying bladder and rectum, and to allow the graft material to be spread evenly over its surface. A strip of synthetic mesh is fixed to the anterior and posterior vaginal wall. The peritoneum overlying the presacral area is opened, extending to the posterior cul-de-sac. The sigmoid colon is retracted

medially and the anterior surface of the sacrum is skeletonized. Two to four permanent sutures are placed through the anterior longitudinal ligament in the midline, starting at the S2 level and proceeding distally. The sutures are passed through the graft at an appropriate location to support the vaginal vault without tension. The peritoneum is then closed with an absorbable running suture. The most dangerous potential complication of sacrocolpopexy is life-threatening sacral hemorrhage.

SURGERY FOR STRESS URINARY INCONTINENCE

There are a multitude of studies addressing the efficacy of different surgical procedures for urinary incontinence. The interpretation of this literature is often difficult because of a lack of standardized definitions or standardized procedures. Stress incontinence is believed to be caused by lack of urethrovaginal support (urethral hypermobility) or intrinsic sphincter deficiency (ISD). *ISD* is a term applied to a subset of stress-incontinent patients who have particularly severe symptoms, including urine leakage with minimal exertion. This condition often is recognized clinically as the low pressure or "drainpipe" urethra. The urethral sphincter mechanism in these patients is severely damaged, limiting coaptation of the urethra. There are no set specific or objective criteria that define ISD, although urodynamic criteria often are used to support it. Standard surgical procedures used to correct stress incontinence share a common feature: partial urethral obstruction that achieves urethral closure under stress. Despite older literature to the contrary, this objective does not require that the bladder neck be "elevated to a high retropubic location."³⁹

Needle Suspension

The transvaginal needle suspension was first described in 1959 by Pereyra.⁴⁰ Variations on this technique include the Stamey, Gittes, and Raz procedures. After an anterior colpotomy is made, the vaginal epithelium is dissected and mobilized to the level of the descending pubic rami. The space of Retzius is entered bilaterally using a blunt clamp or closed heavy Mayo scissors to penetrate the perineal membrane along the inferior aspect of the descending pubic ramus. A long, angled needle is passed through a small transverse suprapubic incision, through the rectus fascia, through the space of Retzius, to bring up the ends of a suture that has been secured to the periurethral vaginal muscularis. Variations exist in the way in which the suture is attached to the periurethral tissue and the method of abdominal wall fixation. Long-term studies of needle procedures have shown evidence of steadily increasing failure rates, likely a result of suture pullout from the periurethral vaginal tissue.

Retropubic Colposuspension

The space of Retzius is approached extraperitoneally, from an abdominal approach, allowing the bladder to be mobilized from the surrounding adipose tissue and lateral pelvis. Overlying fat and blood vessels in the area of the vesical neck are cleared away.

MARSHALL-MARCHETTI-KRANTZ PROCEDURE

In the Marshall-Marchetti-Krantz procedure, a permanent suture is placed lateral to the urethra bilaterally and tied to the periosteum of the pubic ramus or perichondrium of the symphysis pubis. The surgical objective is to appose the urethra to (or within 1 to 2 cm of) the posterior surface of the symphysis pubis. Osteitis pubis is a rare, but serious, potential complication that can result from trauma and devascularization of the symphysis. This and suture pullout from the symphysis has prompted the search for improved techniques.

BURCH PROCEDURE

The most quoted description of the Burch procedure is that of Tanagho in 1976.⁴¹ Two pairs of large-caliber delayed-

absorbable suture are placed through the periurethral vaginal wall, one pair at the midurethra and one at the urethrovesical junction. Each stitch is then anchored to the ipsilateral Cooper's (iliopectineal) ligament. The sutures are tied with the operator's nondominant hand placed vaginally to give preferential support to the urethrovesical junction relative to the anterior vaginal wall without overcorrection. Long-term outcome studies up to 10 years have shown the Burch procedure yields cure rates of 80 to 85%.

Suburethral Sling

A variety of organic and synthetic graft materials have been used to construct suburethral slings. Synthetic materials fell out of favor after a high incidence of postoperative urinary retention and urethral damage were found to be associated with their use. Currently, the most commonly used sling materials include autografts of rectus fascia and processed cadaveric allografts (fascia lata). The procedure is performed by a combined abdominovaginal approach, using a small transverse suprapubic skin incision. The anterior vaginal epithelium is incised in the midline from the midurethra to just proximal to the urethrovesical junction, as identified by the bulb of an indwelling urethral catheter. The epithelium is dissected from the underlying muscularis using sharp dissection bilaterally. The space of Retzius is entered using a blunt clamp or closed heavy Mayo scissors to penetrate the perineal membrane along the inferior aspect of the descending pubic ramus. Maintenance of the proper angle of penetration is important to minimize the risk of injury to the obturator neurovascular bundle or ilioinguinal nerve laterally, and urethra or bladder medially. A Bozeman clamp or long-angled ligature carrier is used to perforate the rectus fascia two fingerbreadths superior to the pubic bone just medial to the pubic tubercle, and the instrument is guided along the back of the pubic bone through the space of Retzius and into the vaginal incision to retrieve one arm of the sling. After bringing up the other side of the sling, and confirming the absence of urinary tract injury, the sling arms are tied. Most often the sling arms are sutured to the rectus fascia or to one another, although procedures using pubic bone anchors also have been described. The base of the sling is positioned at the urethrovesical junction. Cure rates range from 75 to 95% for the many different types of sling procedures. Slings are associated with higher complication rates than most other incontinence procedures, most frequently involving voiding dysfunction, urinary retention, new-onset urge incontinence, and foreign-body erosion.

Tensionless Sling

The tension-free vaginal tape is a modified sling that uses a strip of polypropylene mesh. Unlike traditional sling procedures, the mesh is positioned at the midurethra, not the urethrovesical junction, and is not sutured or otherwise fixed into place. Advantages of tension-free vaginal tape include the ability to perform the procedure under local anesthesia and on an outpatient basis. Small subepithelial tunnels are made bilaterally to the descending pubic rami through an anterior vaginal wall incision. A specialized conical metal needle coupled to a handle is used to drive one end of the sling through the perineal membrane, space of Retzius, and through one of two small suprapubic stab incisions. The tape is set in place without any tension after bringing up the other end of the tape through the other side. Recently, multiple modifications have been made to carry the tape through the bilateral medial portions of the obturator space. Risks of the procedure include visceral injury from blind introduction of the needle, bleeding, and nerve and muscle injury in the obturator space. Additionally, voiding dysfunction and delayed erosion of mesh into the bladder or urethra has been seen.

Collagen

Bulking agent injection is indicated for patients with urodynamically proven stress incontinence that meets criteria for ISD, but is negative for urethral hypermobility. Glutaraldehyde cross-linked bovine dermal collagen has since become the most widely

used injectable agent. Use of other materials, including silicone polymers (Macroplastique) and carbon-coated zirconium beads (Durasphere), also has been described. Anesthesia is easily obtained by using intraurethral 2% lidocaine jelly and/or transvaginal injection of the periurethral tissues with 5 mL of 1% lidocaine. A transurethral or periurethral technique may be used, using a 30° operating female cystourethroscope to directly visualize the injection. The material is injected underneath the urethral mucosa at the bladder neck and proximal urethra, usually at the 4 and 8 o'clock positions, until mucosal apposition is seen. Patients must demonstrate a negative reaction to a collagen skin test before injection. The long-term cure rate is 20 to 30%, with an additional 50 to 60% of patients demonstrating improvement.³¹ Repeat injections frequently are necessary because of migration and dissolution of the collagen material.

PELVIC NEOPLASMS

Vulvagenal Lesions

BENIGN VULVAR LESIONS

Many women suffer with undiagnosed symptoms of vulvar disease. They endure vulvar itching and pain and eventually seek medical help only to be commonly misdiagnosed and treated with repeated courses of antifungals. Vulvar conditions like contact dermatitis, atrophic vulvovaginitis, lichen sclerosis, lichen planus, lichen chronicus simplex, Paget's disease, Bowen's disease, and invasive vulvar cancer are not uncommon. Systemic disease like psoriasis, eczema, Crohn's disease, Behçet's disease, vitiligo, and seborrheic dermatitis may also involve the vulvar skin. Patients presenting with chronic vulvar symptoms should be carefully interviewed, examined, and a vulvar biopsy obtained whenever the diagnosis is in question, the patient is not responding to treatment, or premalignant and malignant disease is suspected.

Atrophic Vulvovaginitis

This is common in postmenopausal patients and causes thinning and atrophy of the vaginal mucosa and vulvar skin secondary to inadequate estrogenation. Patients may be asymptomatic or present with vulvar itching, burning, and/or dyspareunia. This condition is commonly managed with vaginal estrogen preparations used once or twice weekly.

Vulvar Contact Dermatitis

This dermatitis is a common cause of acute or chronic vulvar pruritus and can be irritant or allergic.⁴² Irritant dermatitis usually results from overzealous hygiene habits such as the use of harsh soaps and frequent douching, but is also common in patients with urinary or fecal incontinence, especially the elderly and the disabled. Allergic vulvar dermatitis is caused by a variety of allergens such as fragrances and topical antibiotics. The mainstay of treatment is to identify and discontinue the offending agent or practice, or providing a skin barrier in the case of incontinence.

Leukoplakias

There are three types of leukoplakia, a flat white abnormality. *Lichen sclerosis* is the most common cause of leukoplakia.⁴² It affects women 30 to 40 years of age. Classically, it results in a figure-of-eight pattern of white epithelium around the anus and vulva, resulting in variable scarring and itching, and, less commonly, pain. Diagnosis is confirmed with biopsy and treatment consists of steroids such as clobetasol 0.05% ointment daily for up to 12 weeks. *Lichen planus* is a cause of leukoplakia with an onset in the fifth and sixth decade of life. Lichen planus, in contrast to lichen sclerosis, which is limited to the vulva and perianal skin, can involve the vagina and oral mucosa, and erosions occur in the majority of patients leading to a variable degree of scarring. Patients usually have a history of dysuria and dyspareunia and complain of a burning vulvar

pain. Histology is not specific, and biopsy is recommended. Treatment is with steroid ointments. Systemic steroids are indicated for severe and/or unresponsive cases. *Lichen simplex chronicus* is the third cause of leukoplakia, but is distinguished from the other lichen diseases by epidermal thickening, absence of scarring, and a severe intolerable itch.⁴² Intense scratching is not uncommon and contributes to the severity of the symptoms and predisposes the cracked skin to infections. Treatment consists of cessation of the scratching that sometimes requires sedation, elimination of any allergen or irritant, suppression of inflammation with potent steroid ointments, and treatment of any coexisting infections.

Paget's Disease of the Vulva

Paget's disease of the vulva is an intraepithelial disease of unknown etiology that affects mostly white postmenopausal women in their sixth decade of life. It causes chronic vulvar itching and is sometimes associated with an underlying invasive vulvar adenocarcinoma or invasive cancers of the breast, cervix, or GI tract. Grossly, the lesion is variable but usually confluent, raised, erythematous to violet, and waxy in appearance. Biopsy is required for diagnosis; the disease is intraepithelial and characterized by Paget's cells with large pale cytoplasm. Treatment is assessment for other potential concurrent adenocarcinomas and then surgical removal by wide local resection of the involved area with a 2-cm margin. Free margins are difficult to obtain because the disease usually extends beyond the clinically visible area.^{43,44} Intraoperative frozen section of the margins can be done to ensure complete resection. Unfortunately, Paget's vulvar lesions have a high likelihood of recurrence even after securing negative resection margins.

VULVAR INTRAEPITHELIAL NEOPLASIA

Vulvar intraepithelial neoplasia (VIN) is similar to its cervical intraepithelial neoplasia (CIN) counterpart and is graded on the degree of epithelial involvement as mild (VIN I), moderate (VIN II), severe (VIN III), or vulvar carcinoma in situ (Bowen's disease).⁴⁵ Risk factors include HPV infection, prior VIN, HIV infection, immunosuppression, smoking, vulvar dermatoses such as lichen sclerosis, CIN, and cervical cancer. VIN can be unifocal or multifocal. Unifocal lesions commonly affect postmenopausal women and lack a clear association with HPV, while multifocal disease mostly affects younger reproductive age females and has a strong association with HPV infection. Fifty percent of patients are asymptomatic, with vulvar pruritus being the most common complaint in those with symptoms. Lesions may be vague or raised, and velvety with sharply demarcated borders. Diagnosis is made with a vulvar skin biopsy and multiple biopsies are sometimes necessary. Colposcopy with application of 5% acetic acid and identification of the acetowhite lesions of VIN is a valuable diagnostic tool for subtle lesions and will help guide the biopsy. Evaluation of the perianal and anal area is important as the disease may involve these areas, particularly in immunocompromised and nicotine-addicted women. Once invasive disease is ruled out, treatment usually involves wide surgical excision; however, the initial treatment approach may include 5% imiquimod cream, carbon dioxide laser ablation, or cavitation ultrasonic surgical aspiration and depends on the number of lesions and their severity. When laser ablation is used, a 1-mm depth in hair-free areas is usually sufficient, while hairy lesions require ablation to a 3-mm depth because the hair follicles' roots can reach a depth of 2.5 mm. Unfortunately, VIN tends to recur in up to 30% of cases and high-grade lesions (VIN III, carcinoma in situ) progress to invasive disease in approximately 10% of patients if left untreated.⁴⁶

VULVAR CANCER

Vulvar cancer is the fourth most common gynecologic cancer and is responsible for 4% of the female reproductive cancers and 0.6% of all cancers in women.⁴⁷ It mostly affects postmenopausal women, and the mean age at diagnosis is 65 years old. Risks factors are similar to those for VIN with persistent infection with high-risk HPV types being responsible for the majority

of cases. Patients usually present with a vulvar ulcer or mass. Pruritus is a common complaint, and vulvar bleeding or enlarged inguinal lymph nodes are signs of advanced disease. Careful evaluation of the patient is necessary to rule out concurrent lesions of the vagina and cervix. Biopsy is required and should be sufficient to allow evaluation of the extent of stromal invasion. Vulvar carcinomas are squamous in 90% of cases. Other less common histologies include melanoma (5%), basal cell carcinoma (2%), and soft tissue sarcomas (1 to 2%).

Spread of the vulvar carcinomas is by direct local extension and via lymphatic microembolization. Hematogenous spread is uncommon except for vulvar melanoma. Lymphatic spread seems to follow a stepwise, predictable pattern (Fig. 41-13): (a) the superficial inguinal lymph nodes, which lie in the subcutaneous tissue overlying the inguinal ligament; (b) the deep inguinal lymph nodes, which lie along the course of the round ligament in the inguinal canal; (c) the superficial femoral lymph nodes, grouped around the saphenous vein just superficial to the fossa ovalis; (d) the deep femoral lymph nodes, including the most cephalad node of Cloquet or Rosenmüller; and ultimately, (e) the external iliac lymph nodes.^{48–50} The node of Cloquet is an important sentinel node situated in the route of spread to the pelvic lymph nodes. Vulvar cancer is staged surgically with the inguinofemoral lymph node status being the most important prognostic factor. The International Federation of Gynecology and Obstetrics staging system for vulvar cancer is widely used and provides a schema in which prognosis and therapy are closely linked to stage (Table 41-6).⁵¹ Patients with early-stage disease have a favorable prognosis with approximately 90% 5-year survival rates for stage I disease; stages III and IV disease carry a poor prognosis with 5-year survival rates ranging from 15 to 30%. The exception is melanoma for which the pathologic staging by depth of invasion of the primary tumor and then known metastases is more likely to identify risk for recurrence.

Table 41-6 International Federation of Gynecology and Obstetrics Staging of Vulvar Carcinoma

Stage	

0	Carcinoma in situ, intraepithelial carcinoma
IA	Tumor confined to the vulva or perineum, ≤ 2 cm in greatest dimension, negative nodes, stromal invasion ≤ 1 mm
IB	Tumor confined to the vulva or perineum, ≤ 2 cm in greatest dimension, negative nodes, stromal invasion >1 mm
II	Tumor confined to the vulva and/or perineum, >2 cm in greatest dimension, negative nodes
III	Tumor of any size with adjacent spread to the lower urethra or anus and/or unilateral regional lymph node metastasis
IVA	Tumor invades any of the following: upper urethra, bladder or rectal mucosa, pelvic bone, or bilateral regional node metastasis
IVB	Any distant metastasis including pelvic lymph nodes

Treatment is individualized, especially with early-stage disease. Surgical resection is the mainstay of treatment for early stages. The most conservative procedure should be performed in view of the high morbidity of aggressive surgical management.^{48–50} The historical single-stage en bloc radical vulvectomy championed by Way and Taussig (Fig. 41-14) has been largely abandoned and replaced by the modified radical vulvectomy and bilateral inguinofemoral lymphadenectomy performed through three separate incisions. Stage IA can be adequately treated with an excisional biopsy with a 1-cm disease-free margin. Stages IB and II disease require radical wide excision with a 2-cm margin, but modified radical hemivulvectomy also is used (Fig. 41-15).

Extent of modified radical hemivulvectomy for stages I and II squamous cancer of the vulva.

Treatment options for stage III and IV disease include: (a) chemoradiation followed by limited resection if needed, (b) radical vulvectomy, and (c) radical vulvectomy coupled with pelvic exenteration. Recently, external beam radiotherapy combined with radiosensitizing chemotherapy of cisplatin and 5-fluorouracil is emerging as the preferred initial management of advanced disease followed by limited surgical resection of residual disease.^{52,53} Reconstruction of the vulva and groin, if needed, can be accomplished by using myocutaneous flaps based on the gracilis, sartorius, or tensor fasciae latae muscles.

The need for inguinal lymphadenectomy (Figs. 41-16 and 41-17) is dictated by the extent of the disease and is essential for planning therapy to provide a better opportunity for cure. Nodal involvement is rare in stage IA, and hence, lymphadenectomy is not needed. Inguinal lymphadenectomy is indicated beyond stage IA and unilateral is recommended for lateralized lesions or bilateral for central lesions that cross the midline or those involving the periclitoral area. The extent of dissection varies from superficial in the case of clinically negative nodes, resection of gross-only disease, to full groin dissection. Vulvar sentinel lymph node biopsy is under investigation by the Gynecologic Oncology Group (GOG). This concept is widely used in breast cancer and melanoma and involves peritumor injection of isosulfan blue dye, a radioactive tracer, or a combination of both to facilitate intraoperative identification of involved sentinel nodes in the majority of patients. Preliminary data are encouraging and may allow patients with negative sentinel nodes to avoid complete groin dissection and its attendant morbidity such as lower extremity lymphedema.

Incision recommended for superficial inguinal lymphadenectomy. v. = vein.

Nodal failure in the groin and pelvis is difficult to treat successfully, and attention to primary management of these areas is key. Postoperative adjuvant inguinal and pelvic radiotherapy is indicated when inguinal lymph nodes are positive, and is superior to pelvic lymphadenectomy, which has been largely abandoned. It also is indicated when the vulvectomy margins are positive or close positive for disease and further surgical management is not anatomically feasible.

VAGINAL CANCER

Vaginal carcinoma is a rare gynecologic malignancy and accounts for only about 2 to 3% of cancers affecting the female reproductive system.⁵⁴ Squamous cell carcinomas account for 85 to 90% of cases, while adenocarcinomas, malignant melanomas, and soft tissue sarcomas make up the remaining 10 to 15%. More than two thirds of vaginal cancers are

diagnosed in women 60 years of age or older. Risk factors include vaginal intraepithelial neoplasia (VAIN), persistent HPV infection with high-risk types, VIN, CIN and cervical cancer, diethylstilbestrol (DES) exposure in utero, smoking, HIV infection, and immunosuppression. Patients with vaginal cancer usually present with postmenopausal and/or postcoital bleeding and may also complain of vaginal discharge, vaginal mass, dysuria, hematuria, rectal bleeding, or pelvic pain which may be indicative of advanced disease. Diagnosis is made via biopsy of suspicious lesions, which may require colposcopic guidance.

DES is a drug used in the past in the management of patients with recurrent miscarriages. It was removed from the market in 1971 secondary to reports linking its in utero exposure to the development of clear-cell adenocarcinoma of the cervix and vagina in the exposed daughters, as well as a variety of vaginal, cervical, and uterine anomalies.^{55,56} The risk of clear-cell adenocarcinoma is one in 1000 of those exposed with an average age at diagnosis of 19 years (7 to 33 years). The incidence of vaginal clear-cell adenocarcinoma is in decline as most DES-exposed daughters are now older than 35 years, and beyond the risk range.

Vaginal Intraepithelial Neoplasia

VAIN is similar to VIN and is classified based on the degree of epithelial involvement as mild (I), moderate (II), severe (III), or carcinoma-in-situ.⁴⁵ Upward of 65 to 80% of VAIN or vaginal cancers are associated with HPV infection. The majority of lesions are located in the upper one third of the vagina. Lesions are usually asymptomatic and found incidentally on cytologic screening. Diagnosis is made via guided biopsy of acetowhite lesions at the time of colposcopy. Lesions may appear flat or raised white with sharply demarcated borders and may show vascular changes. The presence of aberrant vessels with marked branching is suggestive of invasive disease. VAIN is treated with laser ablation, surgical excision, or topical 5-fluorouracil therapy.

Vaginal Carcinoma

Vaginal cancer is staged clinically by pelvic exam, chest x-ray, cystoscopy, and proctoscopy (Table 41-7).⁵¹ Studies such as IV pyelogram, barium enema, and CT scans also may be used as needed to define the extent of disease. Vaginal cancer spreads by local extension to adjacent pelvic structures, by lymphatic embolization to regional lymph nodes, and, less commonly, via the hematogenous route to distant organs such as the lungs and liver. Lesions in the upper vagina drain directly into the pelvic lymph nodes and onto the para-aortic nodes, while lesions involving the lower third drain initially to the inguinofemoral lymph nodes from which they then spread to the pelvic nodes.

Table 41-7 International Federation of Gynecology and Obstetrics Staging of Vaginal Carcinoma	
Stage	
0	Carcinoma in situ; intraepithelial neoplasia grade 3
I	Tumor limited to the vaginal wall
II	Tumor has involved the subvaginal tissue but has not extended to the pelvic wall
III	Tumor extends to the pelvic wall
IV	Tumor has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Distant metastasis

Treatment of stage I disease, involving the upper vagina, may be achieved with surgery or via intracavitary radiation therapy.^{48–50} Surgery consists of a radical hysterectomy, upper vaginectomy, and bilateral pelvic lymphadenectomy. Stage I

disease in the mid- to lower vagina usually is treated with radiation and concurrent chemotherapy. External beam pelvic radiation is the mainstay of treatment for stages II–IV and may be followed by intracavitary and/or interstitial brachytherapy. With treatment, prognosis for early-stage disease is excellent with >90% 5-year survival rates. Advanced-stage disease, however, carries a poor prognosis with only 15 to 40% 5-year survival rates for stage III–IV disease.

Lesions of the Cervix

BENIGN CERVICAL LESIONS

Benign lesions of the cervix include endocervical polyps, nabothian cysts (clear, fluid-filled cysts with smooth surfaces), posttrauma (such as delivery-related cervical tear, or prior cervical surgery) malformation of the cervix, and cervical condylomata. If small, office biopsy is appropriate if the diagnosis is not clear. For endocervical polyps, exploration of the base of the polyp with a cotton swab tip to identify that it is cervical and not uterine, and to identify the stalk characteristics, can help identify the appropriate surgical approach. If small, and the base is identified, simply grasping it with ring forceps and slowly rotating it until separated from the base may be adequate. Use of LEEP is appropriate for larger lesions or for specimens of areas identified as abnormal by colposcopy or visual inspection. For condylomata proven by biopsy, LEEP or laser ablation is appropriate.

CERVICAL CANCER

Cervical cancer accounts for about 17,000 cases per year and over 5000 deaths in the United States. It is a major killer worldwide with 250,000 deaths annually. Cervical screening is correlated with early identification and treatment of preinvasive disease.⁵⁷ Cervical cancer is most common in women with long intervals between screening, or with no prior screening. The presence of inherited genetic variations that increase the likelihood of developing cervical cancer when exposed to oncogenic subtypes of HPV is likely and under active investigation.

The oncogenes of high-risk HPV are both initiating and promoting for cervical cancer. Other correlates with disease include concurrent active HIV infection with immunosuppression, smoking, and probably other genetic factors. It is anticipated that early vaccination, before infection, will function as primary prevention for cervical cancer. It is expected to reduce both the risk and frequency of high-grade CIN, but also translate to marked reduction in actual invasive cancer, requiring 20 to 40 years to see full impact. However, not all high-risk HPV subtypes are covered in the two vaccines available in 2009. Thus, vaccination will likely prevent approximately 70% of cancers in the United States, depending on regional area distribution of oncogenic subtypes. Vaccines are approved for girls ages 9 to 26, but are recommended preferentially for the younger girls as there was a stronger immunologic response seen.

Staging and Management

The diagnosis of cervical cancer is made by cervical biopsy, either of a gross lesion or a colposcopically identified lesion. The majority of the histology is squamous, with adenocarcinoma comprising about 20% of cases, and occasional rare and aggressive variants such as neuroendocrine tumors. Staging is clinical, not surgical, and follows the International Federation of Gynecology and Obstetrics guidelines, which mesh with TNM staging. Staging and management options are outlined in Table 41-8.

Table 41-8 International Federation of Gynecology and Obstetrics Cervical Cancer Staging and Management Options		
Stage	Description	Options for Management

0	Carcinoma-in-situ	Adenocarcinoma in situ: hysterectomy, although some may be followed for preservation if all margins negative on cone
		Squamous-in-situ: local excision with loop electrosurgical excision procedure or cone or laser ablation
I	Confined to the cervix	A1 and some A2: fertility preservation through large cone followed by close monitoring, followed by hysterectomy B1 and B2: radical hysterectomy or chemoradiation; radical trachelectomy with uterine preservation for childbearing is under investigation for highly selected patients
	A1: minimal invasion	
	A2: <5 mm from base of epithelium and ≤7 mm lateral spread	
	B1: More than A2 and <4 cm total diameter	
	B2: >4 cm total diameter	
II	Involvement of the upper two thirds of the vagina, without parametrial involvement (A)	For some IIA radical hysterectomy may be considered
	or with parametrial involvement (B)	IIA and B: chemoradiation is preferred
III	A. Involvement of the lower third of the vagina	Chemoradiation
	B. Involvement of a parametria to the sidewall or obstruction of one or both ureters on imaging	
IV	A. Local involvement of the bladder or rectum	A. Chemoradiation
	B. Distant metastases	B. Chemotherapy with palliative radiation as indicated

Surgical Management

Radical Hysterectomy

This procedure generally is performed through an abdominal incision, either vertical or transverse muscle cutting, although laparoscopic and robotic-assisted radical hysterectomy is increasing.⁵⁸ The key elements are dissection of the pelvic and periaortic nodes, and the dissection of the parametrium from the pelvic sidewall to allow en bloc removal with the uterus. Two areas of dissection account for the unique risks of this procedure. The dissection of the ureter out of the tunnel below the uterine arteries, allowing the uterine arteries to be ligated near the internal iliac artery, has a small increase in risk for ureterovaginal fistula equivalent to that of primary radiation. The dissection of the uterosacral ligaments around the rectum and development of the rectal space inferiorly carries an increased likelihood of constipation. These two key elements of the radical hysterectomy are illustrated in Fig. 41-18. Both laparoscopic and open radical hysterectomies allow for the maintenance of the ovaries because the incidence of metastases to this area is very low, providing a clear advantage over radiation therapy.

Radical hysterectomy. **A.** Exposure of the inferior epigastric vessels before transection of the rectus muscles. **B.** Ligation of the inferior epigastric vessels before transection of the rectus muscles. **C.** Ligation and division of the round ligaments opens the pelvic retroperitoneum. **D.** First peritoneal incision lateral to the ovarian vessels and across the vesicouterine fold. **E.** Narrow malleable retractors (Indiana retractors) are placed into the paravesical and pararectal spaces to provide excellent access to the lateral pelvic sidewall and pelvic lymph nodes. **F.** Pelvic lymphadenectomy (external and internal iliac vessels). **G.** Pelvic lymphadenectomy (obturator fossa). **H.** Development of the uterine and superior vesical arteries. **I.** The uterine artery has been clipped and divided near its origin. **J.** The proper ovarian ligament and proximal fallopian tube are clamped and divided if the ovary is to be preserved. **K.** The ureters have been detached from the posterior peritoneum of the broad ligament and are retracted laterally. The rectovaginal space is developed using blunt finger dissection. **L.** Transection of the uterosacral ligaments. **M.** Clamps are placed on the lateral vagina, taking care to remove 3 to 4 cm of the upper vagina.

Initial evaluation of the abdomen and palpation of nodal areas and parametrium should be done to further assess the presence or absence of metastatic disease before proceeding with a radical hysterectomy and node dissection. Access to the retroperitoneum is obtained through opening the round ligaments at their lateral insertion to the pelvic wall (see Fig. 41-18C) and extending the peritoneal incision lateral to the infundibulopelvic ligaments bilaterally and contiguously over the bladder peritoneum. The paravesical space is opened using blunt dissection that follows the contour of the pelvic floor in the shape of

a bowl down and medially around the bladder. A similar dissection, again following the bowl shape of the posterior pelvis, is used to dissect the pararectal space (see Fig. 41-18E), leaving the parametria between these two spaces for palpation for disease and dissection. The infundibulopelvic ligament or utero-ovarian ligament, depending on whether the patient is retaining ovaries, is identified separately from the ureter and separated at this point. The ureter is identified on the medial leaf of the broad ligament, dissected free, and suspended with vessel loops for traction as needed for full dissection through the canal under the uterine artery and into the bladder. The parametria is further dissected by lateral retraction of the superior vesicle artery and identification of the uterine artery and vein coursing in the parametria over the ureter. The ureter is dissected below with a right angle to allow for direct visualization when the artery and vein are clamped lateral to this, and then dissected medially over the ureter. This dissection should continue until the ureter is separated from the parametria down to the level of the ureter's bladder insertion. Posteriorly, the peritoneal incision is continued over the cul-de-sac and the medial peritoneum separated from the ureter. The rectovaginal space is developed bluntly, by opening this cul-de-sac area and then blunt dissection parallel to the vagina (parallel to the floor). The uterosacral ligaments are identified between the pararectal and rectovaginal spaces which can then be ligated with an ENDO GIA or serial clamps. Further dissection anteriorly frees the bladder from the vagina and the vaginal tissue is then clamped and cut. Lymphadenectomy can be performed either before the radical hysterectomy or after and includes the external and internal iliac chains distally to the level of the circumflex vein, the obturator fossa (with direct visualization of the obturator nerve), and para-aortic chains as appropriate.

Radical Trachelectomy with Intact Uterus

Interest in fertility preservation with stage IA1 and 2, and stage IB1 lesions has led to the development of methods of radical trachelectomy with uterine preservation. This procedure depends on an adequate blood supply to the uterus from the ovarian anastomoses, as the cervical portion is removed. The lower uterine segment is closed with a cerclage and attached directly to the vaginal cuff. The rates of recurrence, pregnancy outcomes, and the best surgical candidates for this surgery are still under development.

Radical Trachelectomy after Prior Supracervical Hysterectomy

With the increase in supracervical hysterectomies, the incidence of trachelectomy and radical trachelectomy also is increasing. The procedure follows the same precepts of a radical hysterectomy, but with scarring, and the risk for ureteral, bladder, or bowel injury is higher. Even so, for younger women, this is preferable to primary radiation.

Pelvic Exenteration for Recurrent Disease

Cervical cancer recurrences after primary surgical management are treated with radiation. Surgery may be a consideration in selected patients with recurrent cervical cancer who have received maximal radiation therapy. If the recurrence is locally confined with no evidence of spread or metastatic disease, then pelvic exenteration may be considered. This procedure is becoming less frequent because of the increased local control achieved with chemoradiation, and the frequency of the presence of metastatic disease upon recurrence. Attempted exenteration procedures are aborted intraoperatively if metastatic disease is found. Exenteration is tailored for the disease size and location and may be supralelevator or extend below the levator ani muscle and require vulvar resection as well (Fig. 41-19). Reconstruction of the pelvis may require a continent urinary pouch (if radiation enteritis is limited) or ileal conduit and colostomy, as well as rebuilding the pelvic floor and vagina with gracilis or other grafts.

Fig. 41-19.

Pelvic exenteration may be limited to the supralelevator space (**A**) or can extend below the levator ani muscle (*shaded area*) (**B**).

Uterine Corpus

BENIGN UTERINE DISEASES

The average age of menarche, first menstrual period, in the United States is 12 years and 5 months. Duration of normal menstruation is between 2 to 7 days, with a flow of <80 mL, and cycles of 21 to 35 days. Various female reproductive disorders such as dysfunctional uterine bleeding (DUB), miscarriages, leiomyomas, uterine polyps, adenomyosis, endometrial hyperplasia, and uterine cancer have in common abnormally heavy uterine bleeding as a frequent manifestation.⁵⁹

Nonpregnant patients, who present with heavy bleeding and are 35 years of age and older or have risk factors for endometrial cancer, must be ruled out for malignancy as the first step in their management. Abnormal uterine bleeding is described based on the bleeding pattern:

- Menorrhagia: prolonged (>7 days) or excessive (>80 mL daily) menstrual cycles occurring at regular intervals
- Metrorrhagia: menstrual cycles occurring at irregular intervals and more frequently
- Menometrorrhagia: prolonged or excessive menstrual cycles occurring at irregular and more frequent intervals
- Intermenstrual bleeding (spotting): bleeding of variable amounts occurring between regular menstrual cycles
- Polymenorrhea: menstrual cycles occurring at regular intervals of <21 days
- Oligomenorrhea: menstrual cycles occurring at intervals of >35 days
- Amenorrhea: absence of uterine bleeding for 6 months or a period equivalent to three missed cycles

Dysfunctional Uterine Bleeding

DUB is the most common cause of abnormal uterine bleeding during the reproductive years. DUB is defined as uterine bleeding not explained by an identifiable anatomic or structural cause such as polyps or fibroids. It is common in adolescents and in perimenopausal women and manifests as menorrhagia or menometrorrhagia with intervening periods of oligomenorrhea or complete amenorrhea. Bleeding can at times be severe, and patients may present with anemia and hypovolemia-related symptoms necessitating blood transfusions. The most common cause of DUB is anovulatory cycles that often can be managed by cycling patients on oral contraceptive pills (OCPs) or insertion of a progestin-releasing intrauterine device (Mirena IUD).

Endometrial Polyps

Endometrial polyps are localized hyperplastic growth of endometrial glands and stroma around a vascular core forming sessile or pedunculated projections from the surface of the endometrium.⁶⁰ They may be single or multiple. Many are asymptomatic; however, they are responsible for about 25% of cases of abnormal uterine bleeding, usually metrorrhagia. Polyps are common in patients on tamoxifen therapy (30%) and in perimenopausal and postmenopausal women. Endometrial polyps are rarely neoplastic (<1%). Up to 30% may harbor foci of endometrial hyperplasia. Diagnosis can be made with saline infused hysterosonography, hysterosalpingography, or by direct visualization at the time of hysteroscopy. Treatment, in the absence of malignancy, involves resection with an operative hysteroscope or by sharp curettage.

Adenomyosis

Adenomyosis refers to ectopic endometrial glands and stroma situated within the myometrium. When diffuse, it results in globular uterine enlargement secondary to hyperplasia and hypertrophy of the surrounding myometrium. Adenomyosis is very common, tends to occur in parous women, and is frequently an incidental finding at the time of surgery. Adenomyosis causes heavy painful menses when symptomatic. Diagnosis is suspected in a parous woman with menorrhagia, dysmenorrhea, and diffuse globular uterine enlargement. MRI may reveal islands within the myometrium with increased signal intensity.⁶¹ Definitive diagnosis is made by pathologic examination of the hysterectomy specimen, and hysterectomy is the only definitive treatment for this condition.

Endometriosis

Endometriosis is the finding of ectopic endometrial glands and stroma outside the uterus. It is a common condition affecting 10% of the general population, and it is an incidental finding at the time of laparoscopy in >20% of asymptomatic women. It

is especially prevalent in patients suffering from chronic pelvic pain (80%) and infertility (20 to 50%).⁵⁹ The pathophysiology of endometriosis is poorly understood, and etiologic theories explaining dissemination of endometrial glands include retrograde menstruation, lymphatic and vascular spread of endometrial glands, and coelomic metaplasia. Endometriosis commonly involves the ovaries, pelvic peritoneal surfaces, and uterosacral ligaments. Other possible sites include the rectovaginal septum, sigmoid colon, intraperitoneal organs, retroperitoneal space, ureters, incisional scars, umbilicus, and even the thoracic cavity. Involvement of the fallopian tubes may lead to scarring, blockage, and subsequent infertility. Ovarian involvement varies from superficial implants to large complex ovarian masses called *endometriomas* ("chocolate cysts"). Endometriomas are found in approximately one third of women with endometriosis and often are bilateral.

Endometriosis can be totally asymptomatic, and symptoms, when present, vary from mild dyspareunia and cyclic dysmenorrhea to debilitating chronic pelvic pain with acute exacerbations at the time of menses. Less common manifestations include painful defecation, hematochezia, and hematuria if there is bowel and/or bladder involvement. Pelvic examination in symptomatic patients typically demonstrates generalized pelvic tenderness, nodularity of the uterosacral ligaments, and, at times, a pelvic mass may be appreciated if an endometrioma is present. The severity of symptoms does not correlate with the degree of clinical disease present. Endometriosis also can cause increase in serum CA 125, a biomarker used to monitor response of epithelial ovarian cancer to therapy. CA 125 is neither strongly sensitive nor specific for ovarian cancer and can be elevated with other inflammatory and neoplastic pathologies involving the female reproductive tract and those that irritate the peritoneal and/or serosal surfaces. It can be elevated beyond the normal range (<35 U/mL) in women with ovarian and other sites of endometriosis and does not signify that there is an underlying ovarian cancer. Definite diagnosis of endometriosis usually requires laparoscopy and visualization of the pathognomonic endometriotic implants. These appear as blue, brown, black, white, or yellow lesions that can be raised and, at times, puckered, giving them a "gunpowder" appearance. Biopsy is not routinely done but should be obtained if the diagnosis is in doubt.

Treatment is guided by severity of the symptoms and whether preservation of fertility is desired and varies from expectant, medical, to surgical.^{62,63} Expectant management is appropriate in asymptomatic patients. Those with mild symptoms can be managed successfully with cyclic or continuous OCPs combined with the as-needed use of analgesics such as NSAIDs. Moderate symptoms are treated with medroxyprogesterone acetate 10 to 20 mg orally daily or 150 mg IM injection every 3 months. Its use should be limited to 2 years or less because of its negative effects on bone density. Severe symptoms are treated with either danazol or gonadotropin-releasing hormone (GnRH) agonists to induce medical pseudomenopause. Danazol has been largely abandoned secondary to its marked androgenic side effects, such as acne and hirsutism. GnRH agonists act by suppressing the release of gonadotropins (luteinizing and follicle-stimulating hormones) from the pituitary gland and are available in injections or nasal spray preparations. Common side effects include hot flashes and vaginal dryness secondary to the hypoestrogenic state. They also result in decreased bone density, and their use should not exceed 6 months. Conservative surgical therapy is a popular option because it can be done at the time of the diagnostic laparoscopy and usually involves lysis of adhesions, ablation of endometriotic implants using carbon dioxide laser or electrocautery, and/or resection of deep endometriotic implants.⁶² Patients with moderate to severe symptoms are commonly placed on GnRH agonists for 6 months following the surgery, which usually results in longer remissions. Endometriomas rarely respond to medical therapy, and surgical intervention is indicated and usually involves cystectomy with complete resection of the cyst wall. Medical therapy is no better than expectant management on subsequent pregnancy rates in patients infertile due to endometriosis. Conservative surgical therapy in patients with patent fallopian tubes results in pregnancy in about 50% of cases. Unfortunately, endometriosis is a chronic disease and conservative therapy, medical or surgical, provides only temporary relief, with the majority of patients relapsing within 1 to 2 years. In patients with severe debilitating symptoms who do not

desire future fertility and have not responded to conservative management, extirpative surgery to remove the uterus, ovaries, and fallopian tubes is curative and should be considered.

Uterine Leiomyomas

Leiomyomas, also known colloquially as *fibroids*, are the most common female pelvic tumor and represent growth of the uterine smooth muscle cells (myometrium). They are common in the reproductive years and by age 50 years old, at least 60% of white and up to 80% of black women are or have been affected. Leiomyomas vary in size, location, number, and effect and are described according to their anatomic location (Fig. 41-20) as intramural, subserosal, submucosal, pedunculated, cervical, and can rarely be ectopic.⁵⁹ Most are asymptomatic; however, abnormal uterine bleeding caused by leiomyomas is the most common indication for hysterectomy in the United States. Other manifestations include pain, pregnancy complications, and infertility. Pain generally results from degenerating myomas that outgrew their blood supply or from compression of other pelvic organs such as the bowel, bladder, and ureters. High levels of pregnancy hormones frequently cause significant enlargement of pre-existing myomas, which may lead to significant distortion of the uterine cavity, resulting in recurrent miscarriages, fetal malpresentations, intrauterine growth restriction, obstruction of the birth canal, and the subsequent need for cesarean delivery, abruption, preterm labor, and pain from degeneration.

Fig. 41-20.

Types of uterine myomas.

Bleeding is usually heavy and irregular (menometrorrhagia) and can be severe at times, requiring hospitalization. Examination reveals an enlarged, irregular uterus and, in severe cases, a large, solid pelvic mass extending to the upper abdomen.

Diagnosis is usually made by TVUS, although CT and MRI can be used. Hysterosalpingography or saline-infused hysterosalpingography can be especially useful in the cases of submucosal and intrauterine myomas. Most are benign, and malignant degeneration occurs in <1% of cases and is usually encountered in the menopausal years. A postmenopausal patient presenting with vaginal bleeding and a rapidly enlarging uterine mass must be ruled out for uterine leiomyosarcoma.

Management options of leiomyomas are tailored to the individual patient, depending on her age and desire for fertility and the size, location, and symptoms of the myomas. Conservative management options include OCPs, medroxyprogesterone acetate,

GnRH agonists, uterine artery embolization, and myomectomy. Uterine artery embolization is contraindicated in patients planning future pregnancy and frequently results in acute degeneration of myomas requiring hospitalization for pain control. Myomectomy is indicated in patients with infertility and those who wish to preserve their reproductive capabilities and can be done by laparoscopy, hysteroscopy, or laparotomy.

Unfortunately, medical management provides only temporary relief, and myomas tend to recur after surgery either de novo or from growth and enlargement of smaller myomas that were undetectable at the time of the initial surgery. The only definitive curative therapy is hysterectomy, which can be done vaginally, abdominally, or by laparoscopy. In anemic patients, treatment with GnRH agonists for 3 months before the surgery may allow them time to normalize their hematocrit and avoid transfusions, decreases blood loss at the time of hysterectomy, and shrinks the myomas by an average of 30%, possibly making the preferred vaginal surgical approach more feasible.

Endometrial Hyperplasia and Endometrial Intraepithelial Neoplasia

Endometrial hyperplasia is caused by a chronic unopposed hyperestrogenic state (relative absence of progesterone) and is characterized by proliferation of endometrial glands resulting in increased gland-to-stroma ratio. It can be asymptomatic or, more commonly, results in abnormal vaginal bleeding. It is a histologic diagnosis made upon endometrial biopsy and is classified as simple or complex with and without atypia (World Health Organization classification)⁶⁷:

- Simple hyperplasia: cystically dilated glands
- Complex hyperplasia: crowded, back-to-back, branching glands with minimal intervening stroma
- Atypical hyperplasia: presence of nuclear atypia

Untreated endometrial hyperplasia progresses to malignancy in 1%, 3%, 8%, and 29% of cases of simple hyperplasia, complex hyperplasia, simple hyperplasia with atypia, and complex hyperplasia with atypia, respectively.⁶⁸ Simple and complex hyperplasias can be treated with progestins such as medroxyprogesterone acetate 10 to 20 mg/d for 14 days and followed up with endometrial sampling. Atypical hyperplasia is considered a premalignant condition and is ideally treated with simple hysterectomy. However, if preservation of fertility is desired or surgery contraindicated, treatment with high doses of progestins such as megestrol acetate 40 to 160 mg/d usually reverses these lesions. Close follow-up and repeated sampling are necessary.

Modern molecular precancer diagnostic advances have allowed detection of preclinical disease and have provided a deeper insight into endometrial carcinogenesis. Sporadic, initiating mutations such as the loss of the phosphatase and tensin homologue tumor suppressor function occur frequently and early in the process. Once the mutant clone expands and accumulates additional genetic damage, the lesion can subsequently become recognizable as the earliest morphologic abnormality detectable, endometrial intraepithelial neoplasia (EIN).^{69,70} The diagnostic criteria for EIN are:

- Presence of cytological demarcation
- Glandular crowding (volume percentage of stroma <55%)
- Size of at least 1 mm
- Exclusion of cancer, polyps, mimics, and artifacts

EIN can result from all the hyperplasias, with progression to EIN fueled, in part, by an unopposed estrogenic state.

ENDOMETRIAL CANCER

Endometrial cancer is the most common gynecologic malignancy and fourth most common cancer in women. It is most

common in menopausal women in the fifth decade of life; up to 15 to 25% of cases occur before menopause and 1 to 5% before age 40 years old. Risk factors include unopposed estrogen, obesity, nulliparity, chronic anovulation, late menopause, hypertension, diabetes, hyperplasia with atypia, Lynch II syndrome, and prolonged use of tamoxifen. Protective factors include smoking and use of combination OCPs. Adenocarcinomas are the most prevalent histologic type. Sarcomas are rare; prior pelvic radiation and use of tamoxifen are known risk factors for sarcomas.

Hereditary Nonpolyposis Coli Cancer

Hereditary nonpolyposis coli cancer, a cancer family syndrome, also known as Lynch II syndrome, is an autosomal dominant inherited predisposition to develop colorectal carcinoma and other extracolonic cancers, predominantly including tumors of the uterus and ovaries, with rare but defined inclusion of breast cancer.⁷¹ The risk of colorectal carcinoma is as high as 75% by age 75 years old. Affected female patients have a 40% and 10% lifetime risk of developing uterine and ovarian cancers, respectively. Surveillance has not been proven to identify disease in early stage for these patients but is (informally) recommended and should include annual cervical cytology, mammography, TVUS, CA 125 measurements, and an endometrial biopsy.

Endometrial adenocarcinomas are divided into type I and type II. Type I tumors are estrogen-dependent endometrioid histology and have a relatively favorable prognosis. Women at highest risk are those with morbid obesity (body mass index >30) or abdominal obesity of metabolic syndrome. Type II endometrial cancers are estrogen-independent, aggressive, and characterized by nonendometrioid histology, the most common of which is papillary serous adenocarcinoma. Postmenopausal bleeding is the most common presentation of type I disease and permits diagnosis in early stages of the disease, which explains the relatively favorable prognosis of endometrioid endometrial carcinoma. Abnormal bleeding should prompt endometrial evaluation and sampling, which is usually done with an office endometrial biopsy and at times requires curettage or diagnostic hysteroscopy. TVUS often reveals a thickened endometrial stripe. An endometrial stripe measuring 5 mm or more in a postmenopausal patient raises concern and should be followed by endometrial sampling; patients with stripe of 4 mm or less rarely have occult malignancy, and TVUS may thus be used to triage patients before invasive endometrial sampling. Uterine cancer is surgically staged and is graded based on the degree of histologic differentiation of the glandular components (Table 41-9).⁵¹

Table 41-9 International Federation of Gynecology and Obstetrics Staging of Carcinoma of the Uterine Corpus	
Stages	Characteristics
IA G123	Tumor limited to endometrium
IB G123	Invasion to < ½ myometrium
IC G123	Invasion to > ½ myometrium
IIA G123	Endocervical glandular involvement only
IIB G123	Cervical stromal invasion
IIIA G123	Tumor invades serosa or adnexa or positive peritoneal cytology
IIIB G123	Vaginal metastases
IIIC G123	Metastases to pelvic or para-aortic lymph nodes
IVA G123	Tumor invasion to bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal lymph node
Histopathology—Degree of Differentiation	
Cases should be grouped by the degree of differentiation of the adenocarcinoma:	

G1	5% or less of a nonsquamous or nonmorular solid growth pattern
G2	6–50% of a nonsquamous or nonmorular solid growth pattern
G3	>50% of a nonsquamous or nonmorular solid growth pattern
Notes on Pathologic Grading	
Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade I or grade II tumor by I. In serous adenocarcinomas, clear-cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence. Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.	
Rules Related to Staging	
Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional dilatation and curettage to differentiate between stage I and II. It is appreciated that there may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by the International Federation of Gynecology and Obstetrics in 1971 would still apply, but designation of that staging system would be noted. Ideally, width of the myometrium should be measured along with the width of tumor invasion.	

Treatment is surgical and involves a laparotomy, total abdominal hysterectomy, bilateral salpingo-oophorectomy, peritoneal cytology, pelvic and para-aortic lymph node sampling, and resection of any gross disease.^{48–50} The need for postoperative adjuvant radiation or chemotherapy is individualized based on the histology and stage of the disease. For example, stage IA grade 1 or 2 disease requires no further therapy, patients with stage IB grade 1 or 2 disease often receive intravaginal brachytherapy to decrease the incidence of vaginal cuff recurrence, stage IIC requires pelvic radiation, and for advanced-stage papillary serous histology chemotherapy (carboplatin) often is advocated. Finally, lymph nodal status negatively impacts survival, and patients with positive para-aortic lymph nodes should receive extended-field radiation.

COMMON UTERINE SURGICAL PROCEDURES

Dilatation and Curettage

At one time dilatation of the cervix and curettage of the endometrial cavity was among the most common surgical procedures performed in this country. Simple office biopsy and medical means of dealing with abnormal bleeding have largely replaced the need for diagnostic dilatation and curettage. In some cases curettage is necessary for the relief of profuse uterine hemorrhage. It is indicated for removal of endometrial polyp or therapeutic termination of pregnancy and for retained placental tissue following abortion or obstetric delivery.

The patient is placed on the operating table in a lithotomy position, and the vagina and cervix are prepared as for any vaginal operation. The cervix is grasped on the anterior lip with a tenaculum. Some traction on the cervix is necessary to straighten the cervical canal and the uterine cavity. A uterine sound is inserted into the uterine cavity, and the depth of the uterus is noted. The cervical canal is then systematically dilated beginning with a small cervical dilator. Most operations can be performed after the cervix is dilated to accommodate a number 8 or 9 Hegar dilator or its equivalent. Dilatation is accomplished by firm, constant pressure with a dilator directed in the axis of the uterus (Fig. 41-21).

Fig. 41-21.

After the cervix is dilated to admit the curette, the endocervical canal should be curetted and the sample submitted separate from the endometrial curettings. The endometrial cavity is then systematically scraped with a uterine curette. After the uterus has been thoroughly curetted, a ureteral stone forceps may be used to explore the endometrial cavity, searching for polyps or pedunculated neoplasms. When the procedure is complete, the tenaculum is removed; the tenaculum site is evaluated for bleeding.

The major complication of dilatation and curettage is perforation of the uterus, diagnosed when the operator finds no resistance to a dilator or curette. Laparoscopy to identify any damage to vessels or bowel may be required to assess the perforation. Curettage of the postabortal uterus must be approached carefully because the uterus is extremely soft and perforation can occur with very little warning. Using the largest curette available or suction curettage is a safer choice than a small curette, which tends to cause perforation with less pressure.

Hysteroscopy

Hysteroscopy, like laparoscopy, has gained widespread support as a very useful technique for both diagnosis and treatment of intrauterine pathology and for ablation of the endometrium as an alternative to hysterectomy for the treatment of abnormal uterine bleeding.

GENERAL HYSTEROSCOPIC TECHNIQUES

Type of Instruments

Hysteroscopes can be divided into the categories of diagnostic, operative, and hysteroresectoscope. The lens for all three is identical. This is usually a fiber-optic lens and light source with an outside diameter of 3 mm and an objective lens that is offset up to 30° from the long axis of the instrument. In contrast, the sleeves for the three types of hysteroscopes vary considerably. The diagnostic sleeve usually has an external diameter of 5 mm and a single-direction flow. Because outflow is limited, bleeding may impede a clear intrauterine view. The operative sleeve, with an external diameter usually <10 mm, has a flow-through design with separate channels for input and outflow of distention media. A separate channel is available for placement of operating instruments. The final type of sleeve is the hysteroresectoscope. This is also of a flow-through design and has an integral unipolar resecting loop identical to a urologic resectoscope. The loop can be replaced with a roller ball for endometrial ablation.

Distention Media and Pumps

Several distention media have found widespread use for hysteroscopy. For operative hysteroscopy, one of the first fluid media used was 30% dextran and 70% dextrose. This syrup-like substance usually is introduced by hand with a large syringe. The advantage is simplicity and low cost. The view is excellent in the absence of bleeding. The disadvantage is the difficulty in completely removing the substance from the instruments. More recently, aqueous solutions with pressure-controlled pumps have been used. For operative hysteroscopy, where electrosurgery is not being used, it is safest to use a balanced salt solution. Moderate fluid intravasation will be of no consequence in a healthy individual. However, intravasation of larger volumes can result in fluid overload, especially in a patient with any cardiac compromise. To minimize this risk, the use of a fluid-medium pump is recommended rather than gravity or a pressure cuff to limit pressure to <80 mmHg. When electrosurgery is used for hysteroresectoscope excision of leiomyomas or roller-ball endometrial ablation, a nonconducting solution such as glycine must be used. Significant vascular intravasation can cause hyponatremia, potentially resulting in cerebral edema, coma, or even death. For this reason, protocols must be followed rigorously to detect and treat significant intravasation whenever these solutions are used. Intraoperatively, differences in distention medium input and output should be calculated every 15 minutes. If the difference is >500 mL, a diuretic should be given and the source of the loss identified. If the difference is >1000 mL, the procedure also should be terminated immediately. Whenever significant intravasation is suspected, serum sodium level should be checked immediately postoperatively and a few hours later because later hyponatremia, presumably due to transperitoneal absorption, has been reported.

HYSTEROSCOPIC PROCEDURES

Diagnostic Hysteroscopy

After determining the position of the uterus, the anterior cervix is grasped with a tenaculum and traction placed to straighten the cervical canal. The lens and diagnostic sleeve are placed into the cervix, and distention medium is introduced with a pressure of 80 to 90 mmHg. The hysteroscope is advanced slowly and carefully toward the fundus, using tactile and visual cues to avoid perforation. The entire uterine cavity is inspected, and any abnormal anatomy is documented. As the hysteroscope is withdrawn, the uterocervical junction and the endocervix are examined.

Directed Endometrial Biopsy

If a focal abnormality of the endometrium is observed, directed biopsy may be more accurate than a simple uterine curettage. The cervix is dilated to allow passage of an 8- to 10-mm flow-through operating hysteroscope, and a balanced salt solution is

used for distention. Once the hysteroscope is positioned in the uterine cavity, the area of interest is biopsied under direct visualization.

Polypectomy

If an intrauterine polyp is discovered, the base of the polyp is incised with hysteroscopic scissors, and the polyp is grasped with grasping forceps. The hysteroscope, sleeve, and polyp are removed simultaneously, because most polyps will not fit through the operating channel. Extremely large polyps may have to be removed piecemeal. Any residual base of the polyp may be removed with biopsy forceps.

Uterine Septum Resection

A septum may be resected with scissors, electrosurgery, or laser. Scissors are used most commonly in light of the minimal vascularity of septa and the decreased potential for bowel injury should inadvertent uterine perforation occur. An operating hysteroscope is placed into the uterine cavity, which will appear to be two tubular structures rather than the broad uterine fundus usually encountered. The septum is then evenly divided toward the fundus. If scissors are used, rather than a power cutting instrument, the presence of bleeding indicates that the level of resection is shifting from the avascular septum to the vascular myometrium.

Removal of Intrauterine Synechiae

The removal of synechiae is performed in a manner similar to that described above for a uterine septum in the Uterine Septum Resection section, except that the anatomy, and thus the visual cues for location of normal uterine wall, are completely unpredictable from patient to patient. In difficult cases, simultaneous transabdominal ultrasound is extremely helpful in guiding the direction and limits of resection. Standby laparoscopy should be available in the event of perforation. Following surgery, some type of intrauterine splint, such as an intrauterine device or a balloon catheter, is often placed to avoid synechia reformation. Patients usually are placed on estrogen supplementation for a month and prophylactic antibiotics until the intrauterine splint is removed 1 to 2 weeks later.

Intrauterine Myomectomy

Pedunculated or submucosal leiomyoma can be removed safely hysteroscopically with subsequent improvement in both abnormal uterine bleeding and infertility. Because myoma tissue is relatively dense, a power cutting instrument is required. The choices are either laser or, more commonly, electrosurgery. Both pedunculated and submucosal fibroids are shaved into small pieces with either the laser fiber or the hysteroresectoscope. In the case of a pedunculated fibroid, the urge to simply transect the stalk as a first step should be resisted unless the fibroid is 10 mm or less in size. Fibroids that are larger than this are difficult to remove in one piece without excessive cervical dilatation. Morcellation is much easier when the stalk is still attached for stability.

Endometrial Ablation

A common treatment for abnormal uterine bleeding in the absence of endometrial hyperplasia is ablation of the endometrium. In the recent past, this was performed with an operative hysteroscope using a laser fiber or with a resectoscope using an electrosurgical "roller barrel or ball." As described previously for myoma resection, under Distention Media and Pumps, a balanced salt solution is used for laser resection, and an electrolyte-free solution is used for electrosurgery. For both techniques, the endometrium is destroyed down to the myometrium in a systematic fashion starting at the cornua and ending in the lower uterine segment. More recently, hysteroscopic endometrial ablation has been widely supplanted by variations of

balloon thermal ablation. For this procedure, a probe with attached balloon is blindly placed into the uterus. Heated saline is circulated in the balloon to coagulate the endometrium. Balloon ablation requires less technical skill and appears to have less risk of complication than the hysteroscopic approaches. Both hysteroscopic and balloon ablation techniques result in amenorrhea in approximately half the patients and decreased menstruation in another third of the patients over the first year of therapy.

Myomectomy

Myomectomy can be performed either with open laparotomy or laparoscopic approaches. Hemostasis for the procedure can be aided by direct injection near the base of the fibroid with dilute vasopressin or through the placement of a Penrose drain (Fig. 41-22) around the base of the uterus and pulled through small perforations in the broad ligament lateral to the uterine blood supply on either side and clamped to form a tourniquet for uterine blood flow.

Fig. 41-22.

Myomectomy. **A.** Hemostatic "tourniquet" in place before myomectomy. **B.** Uterine incision for myomectomy. **C.** Removal of myoma. **D.** Several myomas may be removed through a single incision. **E.** The uterine wound is closed with an absorbable suture. **F.** The uterine wound covered with mesh to retard adhesions.

An incision is made through the uterine musculature into the myoma. The pseudocapsule surrounding the tumor is identified and the tumor is bluntly or sharply dissected. After the myoma is freed of its lateral attachments, it can often be twisted to expose a pedicle that frequently contains its major blood supply. On occasion, several myomas may be removed through a single incision. The uterine wounds are closed with absorbable sutures to obliterate the dead space and provide hemostasis. The uterine serosa is closed with a 3-0 absorbable suture placed subserosally if possible. A patch of Interceed to cover the uterine incision may prevent adhesion formation.

Hysterectomy for Benign Disease: Abdominal Hysterectomy

The abdomen is entered through an appropriate incision. The upper abdomen is examined for evidence of extrapelvic disease, and a suitable retractor is placed in the abdominal wound. The uterus is grasped at either cornu with Kocher clamps and pulled up into the wound (Fig. 41-23). The round ligament is identified and divided. If the ovaries are to be removed, the peritoneal incision is extended from the round ligament lateral to the infundibulopelvic ligament for approximately 2.5 cm. The retroperitoneal space is bluntly opened. The ureter is identified on the medial leaf of the broad ligament. The infundibulopelvic ligament is isolated, clamped, and cut, and the suture ligated. A similar procedure is carried out on the opposite side. In the event that the ovaries are not to be removed, the ureter is identified and an opening below the utero-ovarian ligament and fallopian tube created. The fallopian tube and ovarian ligament are divided. The peritoneum is opened over the bladder fold between the divided round ligaments. The bladder is mobilized by sharply dissecting it free of the anterior surface of the uterus and cervix. The peritoneum on the posterior surface of the uterus is dissected free of the uterus and then cut. Clamps are placed on the uterine vessels at the cervicouterine junction, cut, and ligated. The cardinal ligaments are then serially clamped, cut, and ligated. Following division of the remaining cardinal ligaments, the uterus is elevated, and the vagina clamped or opened directly, and then the cervix removed from the vagina with scissors or a knife. Sutures are placed at each lateral angle of the vagina. The remainder of the vagina is closed anterior to posterior with a running absorbable suture. Pelvic reperitonealization is not necessary.

Vaginal Hysterectomy

Vaginal hysterectomy is an acceptable approach in those patients in whom the uterus descends, the bony pelvis allows vaginal operation, the uterine tumors are small enough to permit vaginal removal, and the patient is amenable to vaginal operation. In the presence of large myomas, pretreatment with GnRH analogues may allow vaginal operation that would have been impossible previously. The patient is placed in a lithotomy position. A bladder catheter can be placed before the procedure. A weighted vaginal speculum is placed in the posterior vagina, and the cervix is grasped with a tenaculum and pulled in the axis of the vagina (Figs. 41-24 and 41-25). Injection of the cervix and paracervical tissue with analgesic with epinephrine may be helpful in defining planes and decreasing obscuring bleeding. A circumferential incision may be made with a scalpel or scissors. The posterior cul-de-sac is identified and entered with scissors. The weighted speculum is then placed in this cavity. Mayo scissors are used to dissect down to the pubocervical-vesical fascia. The vaginal mucosa and the bladder are sharply and bluntly dissected free of the cervix and the lower portion of the uterus. When the peritoneum of the anterior cul-de-sac is identified, it is entered with the scissors, and a retractor is placed in the defect. The uterosacral ligaments are identified, doubly clamped, cut, and ligated. Serial clamps are placed on the parametrial structures above the uterosacral ligament; these pedicles are cut, and ligated. At the cornu of the uterus, the tube, round ligament, and suspensory ligament of the ovary are doubly clamped and cut. The procedure is carried out usually concurrently on the opposite side, and the uterus is removed. The pelvis is inspected for hemostasis; all bleeding must be meticulously controlled at this point.

Uterine morcellation through the vagina.

The pelvic peritoneum is closed with a running purse-string suture incorporating those pedicles which were held, the uterosacral and ovarian pedicles. This exteriorizes those areas which might tend to bleed. The sutures attached to the ovarian pedicles are cut. The vagina may be closed with interrupted mattress stitches, incorporating the uterosacral ligaments into the corner of the vagina with each lateral stitch. On occasion, the uterus, which is initially too large to remove vaginally, may be reduced in size by morcellation. After the uterine vessels have been clamped and ligated, serial wedges are taken from the central portion of the uterus to reduce the uterine mass. This procedure will allow the vaginal delivery of even very large uterine leiomyomas.

Endoscopic Surgery

PLACEMENT OF THE VERESS NEEDLE AND PRIMARY TROCAR

The standard method for gynecologic laparoscopy follows the same methodology as all minimally invasive surgery generally with four ports: umbilical, two lateral, and one suprapubic. After transillumination to locate the superficial vessels, an attempt is made to laparoscopically locate the inferior epigastric vessels. Secondary trocars are placed under laparoscopic visualization either 3 to 4 cm above the symphysis pubis in the midline, or 8 cm above the symphysis pubis approximately 8 cm lateral to the midline. This location approximates McBurney's point on the right side of the abdomen. At the end of the procedure, the sleeves are removed and the sites observed for signs of hemorrhage. Any trocar site >5 mm should be closed with a full-thickness suture (to include both the anterior and posterior rectus abdominus fascia) to prevent herniation through the defect.

DIAGNOSTIC LAPAROSCOPY

This common procedure involves the placement of a 5- or 10-mm lens through an intraumbilical port, often with a 5-mm port placed above the symphysis for manipulation with a wand or Babcock graspers. Pelvic organs are closely inspected in a systematic fashion for signs of disease, and if tubal patency is an issue, a dilute dye solution is injected transcervically (chromopertubation).

TUBAL STERILIZATION PROCEDURES

As in diagnostic laparoscopy, a one- or two-port technique can be used. Tubes are occluded in the midisthmic section (approximately 3 cm from the cornua) using clips, elastic bands, or bipolar electrosurgery. With electrosurgery, approximately 2 cm of tube should be desiccated. Pregnancy rates after any of these techniques have been reported in the range of three per 1000 women.

LYSIS OF ADHESIONS

Pelvic adhesions usually are related to previous surgery, endometriosis, or infection, the latter of which can be either genital (i.e., PID) or extragenital (e.g., ruptured appendix) in origin. Adhesions can be lysed mechanically with scissors if not vascular, or harmonic scissors or any of the power techniques discussed in the minimally invasive surgery section. Some degree of adhesion reformation is unavoidable. Adhesion reformation can be minimized by achieving good hemostasis using discrete application of electrosurgery. Postoperatively, barrier methods have been shown to decrease adhesion formation in both animal and human studies but have not been demonstrated to improve outcome in terms of either subsequent pregnancies or pain relief.

OVARIAN CYSTECTOMY

The laparoscopic removal of ovarian cysts <6 cm in diameter in premenopausal women has become common. Using a multiple-port technique, the peritoneal cavity is inspected for signs of malignancy, including ascites, peritoneal or diaphragmatic implants, and liver involvement or unexpected malignant appearance of the ovary. In the absence of signs of malignancy, pelvic washings are obtained, and the ovarian capsule is excised with scissors or a power instrument. The cyst is shelled out carefully and placed in a bag, intact if possible. The bag opening is brought through the lower port incision along with the 10-mm port. The cyst may need to be drained to facilitate removal, but only after the bag edges are firmly out of the abdomen assuring no leakage within the abdomen. Hemostasis of the ovary is achieved with bipolar electrocoagulation, but the ovary usually is not closed, because this may increase postoperative adhesion formation. Except in the obvious cases of simple cysts, endometriomas, or dermoid cysts, the cyst wall should be sent for frozen section to verify the absence of the malignancy. If malignancy is detected, immediate definitive surgery, usually by laparotomy, is recommended. All cyst walls are sent for permanent section and pathologic diagnosis. If a cyst should rupture before removal, the cyst contents are thoroughly aspirated, and the cyst wall is removed and sent for pathologic evaluation. The peritoneal cavity is copiously rinsed with Ringer's lactate solution. This is especially important when a dermoid cyst is ruptured, because the sebaceous material can cause a chemical peritonitis unless all the visible oily substance is carefully removed.

Although malignancies are not commonly encountered using the guidelines outlined in this chapter, there has been concern that rupture may worsen the patient's prognosis and increase risk for port-site metastases. When a malignancy is diagnosed, the timing of definitive surgical treatment is important and would preferably be immediately with the diagnosis at laparoscopy, which lessens the risk for port-site metastases. Ovarian cysts >6 cm and those discovered in postmenopausal women also can be removed laparoscopically. Because of the increased risk of malignancy associated with these situations, laparotomy is more commonly used. Laparoscopy may be a reasonable alternative in select patients if standard methods for staging are used in conjunction with appropriate frozen-section evaluation and expedient definitive therapy when indicated.

REMOVAL OF ADNEXA

Using a multiple-port technique, the vascular supply to the tissue can first be desiccated with bipolar cautery and then divided with harmonic scissors. Special care must be taken to identify and avoid the ureter, which lies retroperitoneally as it

crosses the ovarian vessels and courses along the ovarian fossa (Fig. 41-26). Direct identification of the ureter and visualization before cauterization of the infundibulopelvic ligament is required. The periovarian peritoneum is dissected toward the uterus with power scissors and the connection to the uterus (or in the absence of a uterus, the old round ligament, and cardinal ligament tissue) cauterized and separated as appropriate.

Fig. 41-26.

Changes in the anterior abdominal wall anatomy with weight.

Once the adnexa has been excised and hemostasis is achieved, attention is turned to removing the tissue from the peritoneal cavity. Small specimens can be removed using a retrieval bag via a 12-mm port. The port is removed with the sack, and the fascial incision is enlarged, if required.

For larger specimens, the opening of the sack is exposed outside the abdomen while the specimen remains in the abdomen. A cyst can be aspirated, and the remaining specimen can be removed piecemeal, taking care not to allow intraperitoneal spillage. In difficult cases, the specimen can be removed via a vaginal colpotomy incision. For this procedure, a 12-mm port is placed through the posterior cul-de-sac under direct visualization. A retrieval sack is placed through the port, and the port and specimen in the sack are removed together. The distensible peritoneum and vaginal wall will allow the removal of a large specimen through a relatively small defect, which can then be closed with a running suture vaginally. Prophylactic antibiotics may decrease the risk of infection.

MYOMECTOMY

Uterine leiomyomas often are approachable via the laparoscope. Hemostasis is assisted by intrauterine injection of dilute

vasopressin (10 U in 50 mL) at the site of incision. Pedunculated leiomyomas can be excised at the base using scissors or a power instrument. Intramural leiomyomas require deep dissection into the uterine tissue, which must be closed subsequently with laparoscopic suturing techniques. Because myomectomies are associated with considerable postoperative adhesion formation, barrier techniques are used to decrease adhesion formation. Removing the specimen often requires morcellation and power morcellators have been developed that significantly expedite this technique.

HYSTERECTOMY

Laparoscopy has been used to augment vaginal hysterectomy to avoid laparotomy in patients with known pelvic adhesions, endometriosis, or in whom the uterus is enlarged by leiomyoma. Although multiple variations in technique exist, there are three basic laparoscopic approaches for hysterectomy: laparoscopic-assisted vaginal hysterectomy, laparoscopic hysterectomy (LH), and laparoscopic supracervical hysterectomy (LSH). The technically simplest, and probably the most widely applied, is the laparoscopic-assisted vaginal hysterectomy. For this procedure, a multiple-port approach is used to survey the peritoneal cavity, and any pelvic adhesions are lysed. The round ligaments are then occluded and divided, and the uterovesical peritoneum and peritoneum lateral to the ovarian ligament are incised. The course of the ureter and any adhesions or implants such as endometriosis that might place the ureter in the way of the surgical dissection are carefully dissected. Next, the proximal uterine blood supply is dissected for identification and then occluded and divided often with cauterization and then power scissors to complete the separation. When the ovaries are removed, the infundibulopelvic ligaments (containing the ovarian vessels) are divided. If the ovaries are conserved, the utero-ovarian ligament and blood vessels are divided and occluded. In many cases, the posterior cul-de-sac also is incised laparoscopically and the uterosacral ligaments separated with coagulation and power scissors. The amount of dissection that is done before the vaginal portion depends on the individual patient characteristics, and may include as little as the ovarian and adhesion management to full dissection including the bladder dissection with only the last vaginal incision done by the vaginal approach, which would be a LH. This procedure is used for the indications listed above and also when lack of uterine descent makes the vaginal approach impossible.

The third common laparoscopic approach is the LSH. This procedure has been advocated for all benign indications for hysterectomy. Technically, it is begun in a manner identical to the first two approaches. However, after the proximal vessels are divided and the bladder is dissected from the anterior uterus, the ascending branches of the uterine arteries are occluded and the entire uterine fundus is removed from the cervix. The endocervix is either cauterized or cored out. The fundus is then morcellated and removed through a 12-mm abdominal port or through a special transcervical morcellator. The end result is an intact cervix and cuff, with no surgical dissection performed near the uterine artery and adjacent ureter. This approach avoids both a large abdominal incision and a vaginal incision. According to its advocates, this approach minimizes operating time, recovery time, and risk of both infection and ureteral injury. LSH has yet to be widely applied, in part out of concern for the subsequent risk of developing cancer in the residual cervical stump. In addition, women may develop bleeding from the remaining lower uterine segment that can be bothersome, even if preventive measures have been taken.

INJURY TO ABDOMINAL WALL VESSELS

Abdominal wall vessel injuries have become more common with the development of more complicated operative laparoscopic procedures that use lateral trocar placement and larger trocars. These vessels include the inferior ("deep") epigastric vessels, the superficial epigastric vessels, and the superficial circumflex iliac vessels (Fig. 41-27). Injury to the inferior epigastric artery can result in life-threatening hemorrhage. Injury to these or other vessels can result in significant hematoma or postoperative blood loss if unrecognized.

Fig. 41-27.

The primary methods to avoid vessel injury are knowledge of the vessels at risk and visualization of them before trocar placement when possible. The superficial vessels often can be seen and avoided by transillumination of the abdominal wall with the laparoscope. In contrast, the larger inferior epigastric vessels cannot be seen by transillumination because of their deeper location. But these vessels often can be seen laparoscopically and avoided as they course along the peritoneum between the lateral umbilical fold of the bladder and the insertion of the round ligament into the inguinal canal.

Because the vessels may not be visible in some patients either by transillumination or laparoscopically, it is important to know their most likely location and place lateral trocars accordingly. Although the traditional location used for lateral trocar placement was approximately 5 cm from the midline, a safer location may be 8 cm or more above the symphysis pubis and 8 cm from the midline, because both the superficial and inferior epigastric arteries are located approximately 5.5 cm from the midline (see Fig. 41-27).

Anatomic variation and anastomoses between vessels make it impossible to know the exact location of all the abdominal wall vessels. For this reason, other strategies also should be used to avoid vessel injury, including the use of trocars with conical tips rather than pyramid tips, and the use of the smallest trocars possible lateral to the midline.

INTESTINAL INJURY

Another potentially serious complication of laparoscopic surgery is injury to either small or large intestines. An unrecognized bowel injury may occur at the time of trocar insertion, especially if the patient has had previous abdominal procedures that often result in bowel adhesions to the anterior abdominal wall peritoneum. To minimize the risk of bowel injury in patients who have undergone previous laparotomy, an open technique for placement of the first port is advocated.

Because of the limited field of view, some bowel injuries may not be seen during surgery. These injuries usually manifest 1 to

3 days after surgery, well after the patient has been released following these primarily outpatient procedures and any patient concerns in this time period should be addressed seriously and rapidly.

UROLOGIC INJURIES

Bladder injury is an uncommon laparoscopic injury, most commonly occurring as a result of retroperitoneal perforation during lower trocar placement or during sharp dissection of the bladder from the lower uterine segment during hysterectomy. The latter of these two situations is usually recognized intraoperatively; the first sign of the former may be postoperative hematuria or lower-port incisional drainage. Once diagnosed, large defects require layered closure, whereas smaller defects usually close spontaneously within days or weeks with the aid of transurethral catheter drainage.

Ureteral injury may occur as a result of any procedure that requires dissection or ligation of sidewall vessels, such as removal of an adnexa, because the ureter is adjacent to the pelvic peritoneum in the area of the ovarian fossa (see Fig. 41-5). This complication also has been reported after fulguration of endometriosis on the pelvic sidewall.

Another common cause of ureteral injury is hysterectomy, because the ureter often is located <2 cm from the cervix. This type of injury appears to be increased during LH when compared to abdominal or vaginal hysterectomy, apparently because of the modification of the standard techniques required for the laparoscopic approach.

Ureteral injuries, including complete ligation, partial resection, or thermal injuries, usually will manifest within hours to days of surgery. Complete obstruction most often manifests as flank pain, whereas the first sign of partial or complete transection may be symptoms of intra-abdominal irritation caused by urine leakage. Transperitoneal thermal injuries resulting from fulguration of endometriosis may be similar to those after transection, but the appearance of symptoms may be delayed several days until tissue necrosis occurs.

EPITHELIAL FALLOPIAN TUBE AND OVARIAN MALIGNANCY

Presentation and Screening of Tubal and Epithelial Ovarian Neoplasms

There were an estimated 22,400 new cases and 15,280 deaths due to ovarian cancers in 2007, yielding a fractional death rate of 68% and making this the most deadly of gynecologic cancers.^{72,73} Developing a method for early and accurate diagnosis can and will save lives. Gynecologic neoplasms can present with symptoms, although these symptoms are neither sensitive nor specific to the pathologic process. Common symptoms for either benign or malignant ovarian tumors include pelvic discomfort, cramping, pain, fullness, headache, backache, and others. These are all symptoms that can be attributed to a variety of pathology from infection to pregnancy to irritable bowel syndrome to cancer. Recent work has identified an ovarian cancer symptom index (Table 41-10), now adopted/supported by the Ovarian Cancer National Alliance, the Gynecologic Cancer Foundation, the Society of Gynecologic Oncologists, and the American Cancer Society. It is based on a 2007 publication by Goff and colleagues, and describes symptoms of bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms of urgency or frequency.⁷⁴ These are symptoms that women with ovarian cancer report as newly developed and persistent, or representing a distinct change from their personal norm. The consensus statement says that if the symptom(s) persist for more than a few weeks, the woman should seek medical care. This medical attention should include an evaluation specifically targeted for identification of gynecologic malignancy.

Table 41-10 Ovarian Cancer Symptom Index (2007) and ACOG Guidelines for Patient Referral to Gynecologic Oncology		
Ovarian Cancer	ACOG Guidelines for Referral of	ACOG Guidelines for Referral of

Symptom Index	Premenopausal Women with Mass Suspicious for Ovarian Cancer	Postmenopausal Women with Mass Suspicious for Ovarian Cancer
Development of, change in, and/or persistence in:	One or more of:	One or more of:
Bloating	CA 125 > 200 U/mL	Elevated CA 125
Pelvic or abdominal pain	Ascites	Ascites
Difficulty eating or feeling full quickly	Evidence of abdominal or distant metastasis	Nodular or fixed pelvic mass
Urinary symptoms of urgency or frequency	Family history of one or more first-degree relatives with ovarian or breast cancer	Evidence of abdominal or distant metastasis
		Family history of one or more first-degree relatives with ovarian or breast cancer

ACOG = American College of Obstetricians and Gynecologists.

A reliable, highly specific and highly sensitive format for early diagnosis of ovarian and tubal cancers does not exist. CA 125 is used commonly but has only been approved by the U.S. Food and Drug Administration for use as a biomarker to follow response to therapy for ovarian and tubal cancer patients.⁷⁵ Longitudinal studies are ongoing looking at changes in CA 125 over time as a trigger to advance to transvaginal ultrasound and subsequent diagnostics.⁷⁶ CA 125, for endometriosis, cannot reliably differentiate benign and malignant disease, nor can it reliably identify early-stage disease where patients with ovarian cancer may realize potential for cure of their disease. The ability to identify those women with a high likelihood of malignant ovarian disease, and especially early-stage malignant disease, is needed.

Triage to the proper professional for intervention of women with masses related to the ovary and fallopian tube is a point of concern. Current American College of Obstetrics and Gynecology recommendations do not support direct referral of a patient with undiagnosed pelvic/ovarian mass to a gynecologic oncologist (see Table 41-10). A recent study indicates that the American College of Obstetrics and Gynecology referral guidelines were 93% sensitive and 60% specific with a positive predictive value of 64% for postmenopausal women, but only 80% sensitive and 70% specific with a positive predictive value of 40% in premenopausal women. This suggests that there are a number of women, especially premenopausal women, who may have benefited from early referral to a gynecologic oncologist.⁷⁷ Multiple studies have shown that only 25 to 33% of women with ovarian/tubal cancers have their diagnostic and debulking surgical procedure done by gynecologic oncologists; the remainder are seen by general surgeons and general gynecologists. These studies show inferior patient outcome for women who have had primary surgical attention by nongynecologic oncologists. Development of reliable tools to guide triage of patients to gynecologic oncologists remains important; the utility of the ovarian cancer symptom index needs to be validated prospectively. Criteria strictly based upon lesion size are neither logical nor optimal for ovarian/tubal cancer diagnosis.

Risk Factors

No common risk factors have been identified for most benign ovarian and tubal masses or neoplasms of low malignant potential (LMP or borderline). Ovarian endometriosis can mimic ovarian/tubal cancer symptoms and also can be associated with an increase in CA 125. It has been associated with an increased risk of malignant ovarian disease of endometrioid and clear-cell histology with reported relative risks in the range of 1.4. The cause of endometriosis and how it is a risk for ovarian malignancy remains a point of study. Risk factors for malignancy are presented in Table 41-11. No risk factors have been

found that are applicable to LMP disease.

Table 41-11 Risk and Protective Factors for Epithelial Ovarian and Fallopian Tube Cancers	
Protective Factors	Risks
Oral contraceptive use, especially >5 y	Primary and secondary infertility
Tubal ligation	Nulliparity
Lactation	<i>BRCA1/2</i> mutation and HNPCC syndrome
Pregnancy	Family history without genetic risk
Oophorectomy, salpingectomy	Endometriosis
	Personal history of breast cancer or first-degree relative with breast cancer
	? Hormone replacement therapy

HNPCC = hereditary nonpolyposis colorectal cancer.

Family history of breast and/or epithelial ovarian cancer is one of the strongest factors for lifetime risk of having breast or epithelial ovarian cancer. Approximately 90% of ovarian cancer is sporadic; of the remaining 10% of cases, 75% of hereditary ovarian cancers has been attributed to mutations in the *BRCA1* and *BRCA2* genes, 7% to hereditary nonpolyposis colorectal cancer syndrome, and the remainder to familial cancer of undefined genetic origin.⁷⁸ The lifetime risk of ovarian cancer in *BRCA1* mutation carriers range has been estimated at 40 to 60%, and it is 15 to 45% in *BRCA2* carriers. Controversy exists as to the protective effect of oral contraception pills. The only confirmed prevention is risk-reducing salpingo-oophorectomy (RRSO).^{79,80} The risk of ovarian or tubal malignancy is reduced to approximately 5% with RRSO, the resultant cancer presenting as a primary peritoneal cancer. A RRSO procedure must include, at a minimum, the complete resection of the ovaries and extrauterine fallopian tubes bilaterally. In the absence of hysterectomy, an intrauterine remnant of tube is left behind, raising concerns regarding the risk of cancer development in this portion of the tube. This procedure can be done readily by laparoscopy with the smallest morbidity to the patient barring other surgical risks for the laparoscopic approach. Current evolving data suggest that the risk of tumor arises predominantly from the fimbria, suggesting that this less aggressive surgery may be adequate for most patients. Some patients still undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy as a definitive procedure. Postoperative estrogen replacement therapy is controversial. Retrospective data suggest that it may remove some of the breast-cancer protective effect of the surgery but is unlikely to affect ovarian/tubal cancer risk.

Types of Epithelial Tubal and Ovarian Neoplasms

BENIGN NEOPLASMS

Benign tubal and ovarian neoplasms have been described. However, the progression of benign tumors to invasive malignant disease remains unclear. Cystic masses are the most common benign findings and include follicular cysts, endometriomas, and cystadenomas or cystadenofibromas. These appear to arise from the surface epithelium, inclusion cyst epithelium, and or epithelium of endometriosis; their advancement to frank malignancy is a point of contention. These lesions present most commonly as incidental findings of hyperechogenic simple cystic masses, predominantly in younger women.

TUBAL INTRAEPITHELIAL NEOPLASIA

Data to support progressive development of tubal and epithelial ovarian malignancies, similar to what is now recognized in

colorectal and lung carcinomas, are limited. No clear consensus defining a precursor lesion has emerged. The ovary contains limited epithelium, the single-cell thick-surface epithelial layer and the epithelium lining inclusion cysts. Transition zones within the surface epithelium have been identified in early-stage disease and LMP tumors suggesting the surface epithelium may be a cell source. The fallopian tube contains the largest surface area of epithelium in the gynecologic organs. This epithelium is organized in a serous papillary pattern, one that is seen in well-differentiated ovarian and tubal neoplasms and is aggravated with worsening differentiation.

Recent studies suggest that the fallopian tube may be the source of the serous cancers of women with *BRCA1/2* mutations, and by extension, perhaps all serous cancers.⁸¹ Convention in pathology is to call a serous cancer of the adnexa ovarian in origin if a clear separation of tubal and ovarian origin cannot be made. This commonly occurs with advanced disease where the integrity of the local adnexa is disrupted. Careful pathologic review of the RRSO specimens has revealed transition zones and shown carcinoma-in-situ and progression to invasion in microscopic lesions. Molecular analysis has identified a p53 signature that can be seen in purportedly benign cells maintained through progression to tubal intraepithelial neoplasia, consisting of p53 mutation, evidence of DNA damage by expression of gamma-H2AX, increasing MiB1 index, changes in epithelial polarity, and development of pseudostratification leading to intraepithelial neoplasm. Studies suggest that tubal intraepithelial neoplasia may be a precursor to aggressive and highly disseminated disease.

LOW MALIGNANT POTENTIAL TUMOR

LMP tumor, also known as *borderline tumor*, is histologically different from true malignancy. It is seen in the ovary with case reports of occurrences in fallopian tubes and accounts for approximately 15% of ovarian neoplasms. The World Health Organization defines LMP tumors as characterized by epithelial proliferation greater than seen in benign tumors and lack of destructive (ovarian) stromal invasion. This entity has an earlier median age of onset, up to two decades earlier than epithelial malignant tumors. Presentation is predominantly stage I and II, and histology includes all subtypes identified for frank malignancy: papillary serous, mucinous, clear-cell, endometrioid, and transitional or Brenner tumor.^{82,83} Surgical intervention is the recommendation of choice. Stages I and II LMP tumors have a 10-year survival of nearly 100%.

A subset of LMP papillary tumor, micropapillary, has been identified.^{84,85} Micropapillary tumors have a profusion of micropapillary tufts, sometimes with destruction of architecture. A controversy exists as to whether or not this is further down the progression toward malignancy or just another presentation of a serous neoplasm. In 2004, a consensus review occurred from which criteria for diagnosis were developed and from which the position was taken that this histology does not portend a worse prognosis, and therefore, should not be subject to postsurgical treatment. There are series published indicating a potentially worse outcome; the controversy is whether or not these academic center series are a biased presentation of the subset of LMP disease.

LMP and micropapillary LMP may have sites of dissemination, consistent with the observation of stage II and III disease. Ovarian and tubal neoplasms spread to the peritoneal cavity, and an early site of deposit is on serosal surfaces. Sites of LMP dissemination do not have single-cell or clustered cell invasion nor do they induce a desmoplastic response in the secondary site. They are thus called implants rather than actual invasive metastases. There is a subset of LMP that has true microinvasion and controversy exists as to postsurgical intervention. Microinvasive LMP involves invasion into the ovarian stroma, through either the capsule for surface LMP disease, or through the epithelial basement membrane from inclusion cyst sources. There is greater consensus that microinvasion is a risk factor for a worse prognosis. Other potential poor prognostic factors include nodal involvement, aneuploidy, and residual disease after debulking surgery. Chemotherapy is not routinely advocated and is addressed on a case-by-case basis.

INVASIVE TUBAL AND EPITHELIAL OVARIAN CANCERS

Malignancy of the fallopian tube is predominantly papillary serous in histology. Epithelial ovarian cancer includes (papillary) serous, endometrioid, clear-cell, transitional, and mucinous histotypes. There are differences in gene expression patterns of the different histotypes, but not driving identification of different initial cells of origin. Surgery is used in epithelial ovarian and fallopian tube cancers in five settings:

- Initial staging and cytoreduction (Tables 41-12 and 41-13)
- Interval debulking
- Second look procedures
- Secondary cytoreduction
- Palliation of disease complications

Table 41-12 International Federation of Gynecology and Obstetrics Staging of Epithelial Ovarian Cancer	
Stage	Characteristic
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites; no tumor on the external surfaces, capsule intact
IB	Growth limited to both ovaries; no ascites; no tumor on the external surfaces, capsule intact
IC	Tumor either stage IA or stage IB but with tumor on the surface of one or both ovaries, or with capsule ruptured, or with ascites containing malignant cells or with positive peritoneal washings
II	Growth involving one or both ovaries on pelvic extension
IIA	Extension or metastases to the uterus or tubes
IIB	Extension to other pelvic tissues
IIC	Tumor either stage IIA or IIB with tumor on the surface of one or both ovaries, or with capsule(s) ruptured, or with ascites containing malignant cells or with positive peritoneal washings
III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal nodes; superficial liver metastases equals stage III; tumor is limited to the true pelvis but with histologically verified malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
IIIB	Tumor of one or both ovaries; histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter; nodes negative
IIIC	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes
IV	Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV; parenchymal liver metastases equals stage IV

Table 41-13 Components of Comprehensive Surgical Staging and Debulking of Epithelial Ovarian Cancer
Vertical abdominal incision adequate to visualize the diaphragms
Evacuation of ascites
Peritoneal washings of each pelvic gutter and diaphragm
En bloc hysterectomy and bilateral salpingo-oophorectomy
Supracolic omentectomy

Retroperitoneal and pelvic lymph node dissection
Examination of the entire bowel
Random biopsies of apparently uninvolved areas of peritoneum, pericolic gutters, diaphragm

Interval debulking is surgical intervention done after several cycles of chemotherapy; this chemotherapy may have been neoadjuvant or after initial diagnostic and staging laparotomy. It is usually done in situations where the gynecologic oncologist cannot safely cytoreduce the patient. The Gynecologic Oncology Group (GOG)-152 study did not show a survival benefit for interval debulking in patients undergoing maximal initial cytoreduction followed by platinum/taxane therapy.⁸⁶ There are situations where the management of the individual leads to use of this route. Second-look surgery, which is done after the completion of adjuvant chemotherapy to assess residual disease or benefit of therapy, is now less commonly done. The amount of residual disease after completion of chemotherapy has long been known to have prognostic importance. The advent of more sensitive noninvasive imaging has further reduced the frequency of second-look operations. Secondary cytoreduction is debulking surgery done upon recurrence of disease after an initial postchemotherapy remission. Patients who have had a disease-free period of at least 12 months following initial therapy, who, on examination and imaging, have no evidence of carcinomatosis or miliary spread, and have localized disease, are considered optimal candidates. Retrospective studies have suggested a possible survival advantage of secondary debulking under these circumstances. A prospective randomized trial is ongoing to confirm this hypothesis. Debulking done after subsequent relapses has not been shown to result in an outcome benefit. Finally, surgery is used to palliate disease complications. The most common cause of palliative surgery is bypass of bowel obstruction.

Ovarian cancer does not progress logically following the same format as other gynecologic cancers. Local dissemination to pelvic organs and side walls are seen and define stage II disease; this disease presents in stage III or IV in >75% of cases, intraperitoneal dissemination or beyond. Common sites of dissemination include along the pericolic gutters, on the peritoneal surface of the diaphragms, on serosal surfaces, and in periaortic and pelvic lymph nodes. Negative pelvic lymph nodes do not rule out periaortic disease, and evidence of nodal disease immediately upstages a patient to stage III disease and is important in subsequent treatment planning.

Primary Debulking Surgery

The primary goal of the initial surgical intervention for a suspected ovarian malignancy is complete dissection and removal of the primary and metastatic implants of ovarian carcinoma. When epithelial ovarian cancer is identified on frozen section, node dissection is also indicated (see Table 41-13). Decisions about the benefits and risks of radical debulking for individual presentations and diverse pathology depend on the age and medical stability of the patient as well as the pathologic type of the cancer. Conservative, fertility-sparing surgery can be considered only for likely stage I grade 1 or 2 epithelial ovarian cancer or for germ cell malignancies with no obvious metastases. It is the decision making related to the underlying pathology and understanding of the disease process that determines the extent and type of procedure more so than the surgical techniques themselves.

Standard primary debulking of epithelial ovarian cancer includes removal of the uterus, tubes, ovaries, and omentum. Dissection of pelvic and periaortic lymph nodes is required if no gross intraperitoneal disease (>2 cm in longest diameter) is seen, if the patient is eligible for and interested in a cooperative group trial where surgical practice is normalized across the group, or if there are enlarged nodes that require removal to complete debulking in a situation where clinical trial does not so dictate. Hysterectomy and bilateral salpingo-oophorectomy are usually completed with standard techniques, although

extensive dissection of the peritoneum to remove disease over the bladder peritoneum or cul-de-sac or radical parametrial dissection to achieve debulking may be required. The retroperitoneum usually is spared, allowing dissection from the underside of the peritoneum throughout the cul-de-sac, gutters, and the pelvic peritoneum for debulking. Omentectomy is usually supracolic, performed after separation of the avascular posterior leaf of the omentum over the transverse colon and then dissection of the lesser sac separating the mesentery from the anterior portion of the omentum. This is particularly important when bulky disease is present, to assure that dissection of the omentum is separated from any mesenteric or bowel adhesions or disease process that would be addressed separately if feasible. This is then serially dissected with ligation of the right and left gastroepiploic vessels and the short gastrics as they course through the omentum. Radical resection of disease may require splenectomy, bowel, liver, and/or diaphragm resection, which is appropriate based on likelihood of complete debulking at the end of the surgery and the overall health status of the patient, as it is directly related to significant morbidity and mortality.

PLACEMENT OF INTRAPERITONEAL PORT FOR INTRAPERITONEAL CHEMOTHERAPY

If surgical resection has resulted in complete debulking and no significant residual adhesions preventing complete intra-abdominal spread of fluid are present, and the patient has been counseled and agrees to intraperitoneal therapy, then placement of an intraperitoneal port is appropriate. This is usually a 9.6F venous port, with the port placed over the right or left lower abdominal wall and tunneled to an insertion through the fascia in the lower abdomen. The tip should be placed in the right or left pelvis. If done secondarily, this will require two incisions, one for the port pocket and one for the direct visualization of the placement through the fascia and peritoneum to assure a tight but not constricting seal with sutures in this lower incision.

Postsurgical Adjuvant Therapy and Therapy of Recurrent Disease

POSTSURGICAL TREATMENT OF EARLY-STAGE DISEASE

Early-stage tubal and epithelial ovarian cancers, stage I disease specifically, have an excellent outcome. Stages IA and B, restricted to one or both ovaries or one or both of the fallopian tubes (see Table 41-12), and of low grade can be cured in up to 90 to 95% of cases by a complete surgical staging procedure. The prevailing position in the United States is that women with stage IA or IB, grade 1 or 2 disease do not benefit from chemotherapy. This stems in part from the GOG-7601 study, showing no benefit of melphalan adjuvant therapy compared with observation.⁸⁷ The standard of care for women with stages IC and II and all women with grade 3 or clear-cell histology is adjuvant chemotherapy. The current treatment recommendations are found in Table 41-14, three to six cycles of carboplatin in combination with paclitaxel or docetaxel (stages IC and II for the latter). The GOG-157 study was a randomization of three vs. six cycles of carboplatin and paclitaxel and yielded no significant difference in progression-free or overall survival.⁸⁸ The subsequent study, GOG-175, a randomization between three cycles of carboplatin and paclitaxel with or without 6 months of weekly paclitaxel at 40 mg/m² is maturing and has not yet been reported. Natural history and delayed intervention studies from Europe suggest that withholding therapy until recurrence in stage I patients can have a good outcome.^{89,90} Treatment with a platinum agent upon recurrence is associated with potential for cure but not to the level seen with adjuvant treatment. The GOG has now recommended that stage II patients be considered for advanced-stage clinical trials.

Table 41-14 Standards of Care for Adjuvant Therapy of Epithelial Ovarian or Tubal Carcinoma			
	Platinum	Taxane	No. of

			Cycles
Early stage	Carboplatin AUC 5–7.5 IV	Paclitaxel 175 mg/m ² over 3 h IV	3–6
Optimally debulked <1 cm residual	Carboplatin AUC 5–7.5 IV	Paclitaxel 175 mg/m ² over 3 h IV	6
	<i>or</i>	<i>or</i>	
	See Table 41-15 for intraperitoneal therapy	Docetaxel 75 mg/m ² over 1 h	
Suboptimally debulked	Carboplatin AUC 5–7.5 IV	Paclitaxel 175 mg/m ² over 3 h IV	6
		<i>or</i>	
		Docetaxel 75 mg/m ² over 1 h	

AUC = area under curve using the Calvert formula.

ADJUVANT THERAPY OF ADVANCED-STAGE TUBAL AND OVARIAN CANCERS

Defining Optimal and Suboptimal Disease

Completeness of initial staging and debulking surgery is important as a prognostic indicator in addition to defining stage of disease. Data since the mid-1970s have consistently confirmed that the more completely resected a patient, the better her outcome. This led to segregating patients into subsets of optimally and suboptimally debulked disease for treatment purposes. The initial definition of optimal debulking was residual disease where no lesion had a diameter >2 cm; note the summation of disease or estimate of total bulk residual has not been used in ovarian cancer. Since GOG-111,⁹¹ the study that introduced paclitaxel into epithelial ovarian cancer treatment, the definition of optimal disease has been no residual lesion >1 cm in diameter. Recent GOG studies have segregated patient entry by optimal and suboptimal disease residual using this definition.

Intraperitoneal Therapy for Optimally Cytoreduced Stage III Patients

In 2006, the National Cancer Institute issued a Clinical Alert indicating that intraperitoneal administration of adjuvant chemotherapy should be considered first line for all women with optimally cytoreduced epithelial ovarian cancer. This Clinical Alert occurred in response to the completion and analysis of three independent randomized clinical trials, all of which showed a significant survival advantage for intraperitoneal therapy. It recommended all optimally cytoreduced patients be treated with intraperitoneal cisplatin 100 mg/m² with a taxane, following the GOG-172 study (Table 41-15).^{92,93} Patients who are not good candidates for intraperitoneal therapy should receive the IV standard of care applied to all other advanced-stage ovarian cancer patients. Intraperitoneal therapy can be administered through a variety of means. These include Tenckhoff catheter and intraperitoneal Port-A-Cath type catheters. However, the use of vascular ports is preferred due to decreased incidence of bowel and adhesive complications compared to intraperitoneal catheters with multiple holes on the end, such as a Tenckhoff. It is further recommended that the intraperitoneal access device be consented for and placed at initial surgery when the diagnosis of ovarian cancer is made pre- or intraoperatively and there is high likelihood of complete debulking. These devices can be removed with minimal trauma at the bedside or with outpatient surgery should an alternative therapy be selected.

Table 41-15 Seminal Clinical Trials of Intraperitoneal Therapy in Optimally Cytoreduced Ovarian Cancer Patients

Trial	No. of Patients	Disease-Free Survival	Overall Survival
SWOG-8501/GOG-104 ^a	654		41 vs. 49 mo
C 100 mg/m ² IV + CTX 600 mg/m ² IV vs. C 100 mg/m ² IP + CTX 600 mg/m ² IV			<i>P</i> = .02, HR 0.76
GOG-114	462	22 vs. 28 mo <i>P</i> = .02,	52 vs. 63 mo
P 135 mg/m ² IV over 24 h, C 75 mg/m ² IV d2 vs. Carb AUC 9 IV x two cycles followed by C 100 mg/m ² IP + P 135 mg/m ² IV over 24 h		RR 0.78	<i>P</i> = .05, RR 0.81
GOG-172	415	18.2 vs. 23.8 mo	49.7 vs. 65.6 mo
P 135 mg/m ² IV over 24 h, C 75mg/m ² IV d2 vs. P 135 mg/m ² IV over 24 h, C 100 mg/m ² IP d2 and P 60 mg/m ² IP d8		RR 0.8, <i>P</i> = .05	RR 0.75, <i>P</i> = .03

^aAllowed optimal patients defined as <2 cm residual disease.

AUC = area under curve using the Calvert formula; C = cisplatin; Carb = carboplatin; CTX = cyclophosphamide; GOG = Gynecologic Oncology Group; HR = hazard ratio; IP = intraperitoneal; P = paclitaxel; RR = relative risks; SWOG = Southwest Oncology Group.

Chemotherapy for Advanced-Stage Disease

Patients who have suboptimally debulked disease and/or who are not candidates for intraperitoneal therapy should receive IV adjuvant chemotherapy. Randomized clinical trials of the past decade support use of a platinum compound and a taxane as the standard of care (see Table 41-14). Although eight cycles of therapy were administered in the international intergroup study, GOG-182, a five-arm trial with carboplatin/paclitaxel as the control arm, the recommended standard is six cycles. The arms incorporating a third agent as a triplet, alternating doublet/triplet, or sequential doublets showed no improvement over the control arm, and at present, no additional agents are standard for initial therapy. In addition, there are no randomized data to validate the use of drug sensitivity testing to select adjuvant therapy. Data suggest that the normalization of CA 125 by the third treatment cycle may be prognostic for later recurrence. The role of targeted therapies in the treatment of newly diagnosed ovarian and tubal cancer patients is under investigation. The GOG-218 study includes arms in which bevacizumab is included in adjuvant therapy and/or in a postadjuvant maintenance phase, given at a dose of 15 mg/kg; a similar cooperative group study is ongoing in Europe using bevacizumab at 7.5 mg/kg.

Intervention in Recurrent Disease

Chemotherapy is the mainstay of therapy for recurrent tubal and epithelial ovarian cancers. Treatment approaches are based upon platinum sensitivity⁹⁴ (Table 41-16). Exceptions include recurrence after a >12-month disease-free interval with isolated resectable disease, late recurrence with sites of disease causing organ risk, and palliation for disease-related complications. Radiation therapy, while very effective against tubal and ovarian cancer, is not commonly used in the United States except for isolated sites of recurrence and in situations where surgical palliation may not be feasible. Referral to an oncologist with specific expertise in chemotherapeutic treatment of ovarian cancer and access to clinical trials is important. In determining

secondary and subsequent therapy, consideration of prior therapies, sites of disease, organs at risk from cancer, organs sustaining injury from prior therapy, and quality of life desires of the patient should be taken into consideration.

Table 41-16 Definitions of Platinum Resistance and Guidelines for Treatment of Recurrent Disease		
Platinum Sensitivity	Definition	Intervention
Refractory	Progression while receiving a platinum	Nonplatinum-based chemotherapy
		Platinum with gemcitabine
Resistant	Progression within 6 mo of completing treatment	Nonplatinum-based chemotherapy
		Platinum with gemcitabine
Sensitive	Progression beyond 6 mo of completing treatment	Consider secondary debulking if >12 mo since treatment
		Consider platinum ± taxane
		Nonplatinum-based chemotherapy

NONEPITHELIAL CANCERS OF THE OVARY AND FALLOPIAN TUBE

Germ Cell Tumors

Germ cell tumors occur most commonly in women under age 30 years old, grow and disseminate rapidly, and are symptomatic. The rapid growth may be accompanied by torsion producing an acute abdomen and need for emergent intervention. Most common are the benign forms of teratomas; within the malignant category, the most common malignant form is dysgerminoma, which is made up of pure undifferentiated germ cells. Bilaterality occurs in up to 15% of patients and elevated beta-hCG may occur. Staging, including removal of the involved ovary, biopsy of any suspicious areas, node dissection, and omentectomy, should be done initially but does not require hysterectomy or removal of the second ovary if fertility preservation is of concern and no extension of disease is observed. Evidence of extraovarian spread, such as nodal metastases, requires adjuvant therapy. Chemotherapy is the most common adjuvant intervention, although radiation therapy, the previous standard, may be considered. The cure rate remains high, near 90% with metastatic disease; recurrent disease is more difficult to eradicate.

Less common are immature teratomas, endodermal sinus or yolk sac tumors, mixed tumors, malignant teratomas (embryonal carcinomas), and choriocarcinomas. Endodermal sinus tumors may have elevated alpha-fetoprotein levels in the blood and, in the case of mixed germ cell tumors, beta-hCG may also be elevated. Both markers are useful to follow during definitive therapy. Early spread of these tumors occurs and other than completely resected stage I, grade 1 immature teratoma, all others require adjuvant therapy with a platinum-containing regimen. In addition, women of older age than the usual germ cell malignancy (>30 years old) can have midline (mediastinal) germ cell tumors. These are treated with chemotherapy after careful assessment for a pelvic primary. The success of therapy for this germ cell presentation does not carry the positive prognosis that the pelvic germ cell cancer does.

Sex Cord-Stromal Cell Tumors

Although rare, stromal cell tumors can present with symptoms referable to endocrine activity of the tumor. These include combinations of the mesenchymal (fibromas, sarcomas) and sex cord cell components (granulosa, theca, Sertoli, Leydig). Granulosa cell tumors are the most common in this group and are a low-grade malignancy treated with conservative surgery

similar to germ cell in young women as <3% are bilateral. Debulking surgery is the primary means of management if more extensive. These tumors and the thecomas in the same class often stimulate estrogen production and can be found in association with endometrial hyperplasia and cancer (5%) as well. Granulosa cell tumors can recur over a prolonged period given their low rate of proliferation and tendency for local or intraperitoneal recurrence. Inhibin has been shown to be elaborated by these tumors and often is followed to identify recurrence of the disease. The Sertoli/Leydig cell tumors can present with virilization as a primary symptom. Evaluation of the ovary when this symptom is found is always of value. For the most part, these are benign and unilateral tumors and removal alone is adequate.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 42. Neurosurgery >

KEY POINTS

1. Neurologic surgery specializes in primarily surgical management of central, peripheral, and autonomic nervous system disorders.
2. Although clinical examination is paramount, neurosurgical diagnosis and treatment are aided largely by a variety of modalities, such as magnetic resonance imaging and intracranial pressure monitoring.
3. The common treatment goals for traumatic brain and spinal injury are aimed at preventing secondary insults of hypoxia and hypotension.
4. Aneurysmal subarachnoid hemorrhage remains one of the most morbid and intensive neurosurgical diseases. Endovascular therapy is a growing technology that allows for safer securing of ruptured aneurysms.
5. Brain tumors can arise from primary or metastatic tissues. Treatment typically involves resection, followed by radiation and/or chemotherapy, depending on the type and grade of tumor.
6. Degenerative spine disease affects mainly the cervical and lumbar regions. Narrowing of the canal in the cervical spine may cause myelopathy or radiculopathy, while narrowing in the lumbar spine results in radiculopathy, neurogenic claudication, or cauda equina syndrome.
7. Spinal instrumentation is used for surgical stabilization of many types of spinal instability, including traumatic, infectious, oncologic, and degenerative.
8. Infection of the nervous system is a serious and prevalent medical problem. Operative management is indicated for most conditions in which there is symptomatic compression of neural structures.
9. Functional neurosurgery via device implantation is a rapidly evolving discipline that has already become the standard of care in treating medically refractory Parkinson's disease and essential tremor. A wider variety of deep brain stimulation targets will treat additional neuropsychiatric diseases.
10. Stereotactic radiosurgery is a powerful treatment option for intracranial disease, whether it is primary or adjunct. Gamma knife surgery can be used to treat tumors, vascular malformations, and cranial neuralgias.

OVERVIEW

Neurologic surgery is a discipline of medicine and the specialty of surgery that provides the operative and nonoperative management (i.e., prevention, diagnosis, evaluation, treatment, critical care, and rehabilitation) of disorders of the central, peripheral, and autonomic nervous systems (ANSs). This includes their supporting structures and vascular supply; the evaluation and treatment of pathologic processes that modify the function or activity of the nervous system, including the hypophysis; and the operative and nonoperative management of pain. Such disorders include those of the brain, meninges, skull and skull base, and their blood supply, including surgical and endovascular treatment of disorders of the intracranial and extracranial vasculature supplying the brain and spinal cord; disorders of the pituitary gland; disorders of the spinal cord, meninges, and vertebral column, including those that may require treatment by fusion, instrumentation, or endovascular techniques; and disorders of the cranial and spinal nerves throughout their distribution.

An accurate history is the first step toward neurologic diagnosis. A history of trauma or of neurologic symptoms is of obvious interest, but general constitutional symptoms are also important. Neurologic disease may have systemic effects, while diseases of other systems may affect neurologic function. The patient's general medical ability to withstand the physiologic stress of anesthesia and surgery should be understood. A detailed history from the patient and/or family, along with a reliable physical examination, will clarify these issues.

NEUROANATOMY

An understanding of neuroanatomy is the foundation of comprehensive neurologic examination and diagnosis. Salient features will be considered, from cephalad to caudad. The cerebral hemispheres (or telencephalon) consist of the cerebral cortex, underlying white matter, the basal ganglia, hippocampus, and amygdala. The cerebral cortex is the most recently evolved part of the nervous system. Its functions are mapped to discrete anatomic areas. The frontal areas are involved in executive function, decision making, and restraint of emotions. The motor strip, or precentral gyrus, is the most posterior component of the frontal lobes, and is arranged along a homunculus with the head inferior and lateral to the lower extremities superiorly and medially. The motor speech area (Broca's area) lies in the left posterior inferior frontal lobe in almost all right-handed people and in up to 90% of left-handed people. The parietal lobe lies between the central sulcus anteriorly and the occipital lobe posteriorly. The postcentral gyrus is the sensory strip, also arranged along a homunculus. The rest of the parietal lobe is involved with awareness of one's body in space and relative to the immediate environment, body orientation, and spatial relationships. The occipital lobes are most posterior. The visual cortex is arrayed along the apposing medial surfaces of the occipital lobes. The left occipital lobe receives and integrates data from the left half of each retina. A left occipital lesion would therefore result in inability to see objects right of center. The temporal lobes lie below the sylvian fissures. The hippocampus, amygdala, and lower optic radiations (Meyer's loops) are important components of the temporal lobe and are involved in memory, emotion, and visual pathways, respectively. The receptive speech area (Wernicke's area) lies in the area of the posterior superior temporal lobe and the inferior parietal lobe, usually on the left. The basal ganglia include the caudate, putamen, and the globus pallidus. Basal ganglia structures are involved with modulation of movement via inhibition of motor pathways.

Lying deep to the cerebral hemispheres is the diencephalon, which includes the thalamus and hypothalamus. The thalamus is a key processor and relay circuit for most motor and sensory information going to or coming from the cortex. The hypothalamus, at the base of the brain, is a key regulator of homeostasis, via the autonomic and neuroendocrine systems.

The brain stem consists of the midbrain (mesencephalon), pons (metencephalon), and medulla (myelencephalon). Longitudinal fibers run through the brain stem, carrying motor and sensory information between the cerebral hemispheres and the spinal cord. The corticospinal tract is the major motor tract, while the medial lemniscus and the spinothalamic tracts are the major sensory tracts. The nuclei of cranial nerves III through XII are also located within the brain stem. These nerves relay the motor, sensory, and special sense functions of the eye, face, mouth, and throat. The cerebellum arises from the dorsal aspect of the brain stem. It integrates somatosensory, vestibular, and motor information for coordination and timing of movement. Midline, or vermian, lesions lead to truncal ataxia. Lateral, or hemispheric, lesions lead to tremor and dyscoordination in the extremities.

The ventricular system is a cerebrospinal fluid (CSF)-containing contiguous space inside the brain, continuous with the subarachnoid space outside the brain. The paired lateral ventricles consist of temporal, occipital, and frontal horns, as well as the main body. CSF travels from each lateral ventricle through the foramina of Monroe to the third ventricle, located between the left and right thalami. CSF then drains through the cerebral aqueduct to the fourth ventricle in the brain stem. The foramen of Magendie (midline) and paired foramina of Luschka (lateral) drain to the subarachnoid space. Choroid plexus creates the CSF, mostly in the lateral ventricles. The average adult has an approximate CSF volume of 150 mL and creates approximately 500 mL per day.

The spinal cord starts at the bottom of the medulla and extends through the spinal canal down to approximately the first lumbar vertebra. Motor tracts (efferent pathways) continue from the brain stem down via the lateral and anterior corticospinal tracts to anterior horn cells, and then exit via ventral nerve roots. Sensory information (afferent pathways) enters via dorsal nerve roots, travels up the dorsal columns (proprioception and fine touch) or the spinothalamic tract (pain and temperature), and into the brain stem. Paired nerves exit the spinal cord at each level. There are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal.

The dorsal and ventral nerve roots at each level fuse to form mixed motor-sensory spinal nerves and spread through the body to provide innervation to muscles and sensory organs. The C5–T1 spinal nerves intersect in the brachial plexus and divide to form the main nerve branches to the arm, including the median, ulnar, and radial nerves. The L2–S4 spinal nerves intersect in the lumbosacral plexus and divide to form the main nerve branches to the leg, including the common peroneal, tibial, and femoral nerves.

The principal motor tract is the corticospinal tract. It is a two-neuron path, with an upper motor neuron and a lower motor neuron. The upper motor neuron cell body is located within the motor strip of the cerebral cortex. The axon travels through the internal capsule to the brain stem, decussates at the brain stem–spinal cord junction, and travels down the contralateral corticospinal tract to the lower motor neuron in the anterior horn at the appropriate level. The lower motor neuron axon then travels via peripheral nerves to its target muscle. Damage to upper motor neurons results in hyperreflexia and mild atrophy. Damage to lower motor neurons results in flaccidity and significant atrophy.

The two major sensory tracts are three-neuron pathways. Fine touch and proprioceptive signals enter the spinal cord via the dorsal root ganglia and then ascend ipsilaterally via the dorsal columns. They then synapse and decussate in the lower medulla, travel up the contralateral medial lemniscus to make a second synapse in the thalamus, and then finally ascend to the sensory cortex. Pain and temperature fibers first synapse in the dorsal horn of the spinal cord at their entry level, decussate, and then travel up the contralateral spinothalamic tracts to the thalamus. The second synapse occurs in the thalamus, and the output axons ascend to the sensory cortex.

The aforementioned motor and sensory tracts together constitute the somatic nervous system. In addition to this system, the ANS is the other constituent of the nervous system. The ANS carries messages for homeostasis and visceral regulation from the central nervous system (CNS) to target structures such as arteries, veins, the heart, sweat glands, and the digestive tract.¹ CNS control of the ANS arises particularly from the hypothalamus and the nucleus of the tractus solitarius. The ANS is divided into the sympathetic, parasympathetic, and enteric systems. The sympathetic system drives the "fight or flight" response, using epinephrine to increase heart rate, blood pressure, blood glucose, and temperature, as well as to dilate the pupils. It arises from the thoracolumbar spinal segments. The parasympathetic system promotes the "rest and digest" state, and uses acetylcholine to maintain basal metabolic function under nonstressful circumstances. It arises from cranial nerves III, VII, IX, and X, and from the second to fourth sacral segments. The enteric nervous system controls the complex synchronization of the digestive tract, especially the pancreas, gallbladder, and small and large bowels. It can run autonomously but is regulated by the sympathetic and parasympathetic systems.

NEUROLOGIC EXAMINATION

The neurologic examination is divided into several components and generally is done from head to toe. First assess mental status. A patient may be awake, lethargic (will follow commands and answer questions, but then returns to sleep), stuporous (difficult to arouse at all), or comatose (no purposeful response to voice or pain). Cranial nerves may be thoroughly tested in the awake patient, but pupil reactivity, eye movement, facial symmetry, and gag are the most relevant when mental status is impaired. Motor testing is based on maximal effort of major muscle groups in those able to follow commands, while assessing for amplitude and symmetry of movement to deep central pain may be all that is possible for stuporous patients. Table 42-1 details scoring for motor assessment tests. Characteristic motor reactions to pain in patients with depressed mental status include withdrawal from stimulus, localization to stimulus, flexor (decorticate) posturing, extensor (decerebrate) posturing, or no reaction (in order of worsening pathology). Figure 42-1 diagrams the clinical patterns of posturing. This forms the basis of determining the Glasgow Coma Scale (GCS) motor score, as detailed in Table 42-2. Light touch, proprioception, temperature, and pain testing may be useful in awake patients but is often impossible without good cooperation. It is critical to document sensory patterns in spinal cord injury (SCI) patients. Muscle stretch reflexes should be checked. Often comparing left to right or upper extremity to lower extremity reflexes for symmetry is the most useful for localizing a lesion. Check for ankle-jerk clonus or up-going toes (Babinski's test). Presence of either is pathologic and signifies upper motor neuron disease.

Table 42-1 Motor Scoring System	
Grade	Description
0	No muscle contraction
1	Visible muscle contraction without movement across the joint
2	Movement in the horizontal plane, unable to overcome gravity
3	Movement against gravity
4	Movement against some resistance
5	Normal strength

Fig. 42-1.

Patterns of motor responses associated with various lesions. **A.** Left hemispheric lesion with right hemiplegia and left localization. **B.** Deep cerebral/thalamic lesion with bilateral flexor posturing. **C.** Midbrain or pontine lesion with bilateral extensor posturing. **D.** Medullary lesion with general flaccidity.

[Adapted with permission from Rengachary SS: Impaired consciousness, in Rengachary SS, Ellenbogen RG (eds): *Principles of Neurosurgery*, 2nd ed. Edinburgh: New York, Elsevier Mosby, 2005, p 87. Copyright Elsevier.]

Table 42-2 The Glasgow Coma Scale Score ^a				
Motor Response		Verbal Response	Eye-Opening Response	
Obeys commands	6	Oriented	5 Opens spontaneously	4
Localizes to pain	5	Confused	4 Opens to speech	3
Withdraws from pain	4	Inappropriate words	3 Opens to pain	2
Flexor posturing	3	Unintelligible sounds	2 No eye opening	1
Extensor posturing	2	No sounds	1	
No movement	1			

^a Add the three scores to obtain the Glasgow Coma Scale (GCS) score, which can range from 3 to 15. Add "T" after the GCS if intubated and no verbal score is possible. For these patients, the GCS can range from 3T to 10T.

Diagnostic Studies

PLAIN FILMS

Plain x-rays of the skull may demonstrate fractures, osteolytic or osteoblastic lesions, or pneumocephaly (air in the head). The use of skull plain films has decreased given the rapid availability and significantly increased detail of head computed tomography (CT) scans. Plain films of the cervical, thoracic, and lumbar spine are used to assess for evidence of bony trauma or soft tissue swelling suggesting fracture. Spinal deformities and osteolytic or osteoblastic pathologic processes also will be apparent. The shoulder girdle usually poses problems in visualizing the cervicothoracic junction clearly.

COMPUTED TOMOGRAPHY

The noncontrast CT scan of the head is an extremely useful diagnostic tool in the setting of new focal neurologic deficit, decreased mental status, or trauma. It is rapid and almost universally available in hospitals in the United States. Its sensitivity allows for the detection of acute hemorrhage. A contrast-enhanced CT scan will help show neoplastic or infectious processes. In the current era, contrast CT generally is used for those patients who cannot undergo magnetic resonance imaging (MRI) scanning due to pacemakers or metal in the orbits. Fine-slice CT scanning of the spine is helpful for defining bony anatomy and pathology, and is usually done after an abnormality is seen on plain films, or because plain films are inadequate (especially to visualize C7 and T1 vertebrae). Finally, high-speed multislice scanners, combined with timed-bolus contrast injections, allow CT angiography. A thin-slice axial scan is obtained during the passage of contrast through the cerebral arteries and reconstructed in three dimensions to assess for vascular lesions. CT angiography does not reliably detect lesions, such as cerebral aneurysms <3 mm across, but can provide detailed morphologic data of larger lesions. Newer, multislice scanner technology is approaching the resolution of conventional angiography.

MAGNETIC RESONANCE IMAGING

MRI provides excellent imaging of soft tissue structures in the head and spine. It is a complex and evolving science. Several of the most clinically useful MRI sequences are worth describing. T1 sequences made before and after gadolinium administration are useful for detecting neoplastic and infectious processes. T2 sequences facilitate assessment of neural compression in the spine by the presence or absence of bright T2 CSF signals around the cord or nerve roots. Diffusion-weighted images can detect ischemic stroke earlier than CT. Fine-slice time-of-flight axial images can be reformatted in three dimensions to build MRI angiograms and MRI venograms. MRI angiograms can detect stenosis of the cervical carotid arteries or intracranial aneurysms >3 mm in diameter. MRI venograms can assess the dural venous sinuses for patency or thrombosis.

ANGIOGRAPHY

Transarterial catheter-based angiography remains the gold standard for evaluation of vascular pathology of the brain and spine. The current state of the art is biplanar imaging to reduce dye load and facilitate interventional procedures. Digital subtraction technologies minimize bony interference in the resultant images. Bilateral carotid arteries and bilateral vertebral arteries may be injected and followed through arterial, capillary, and venous phases for a complete cerebral angiogram.

ELECTROMYOGRAPHY AND NERVE CONDUCTION STUDIES

Electromyography and nerve conduction studies (EMG/NCS) are useful for assessing the function of peripheral nerves. EMG records muscle activity in response to a proximal stimulation of the motor nerve. NCS record the velocity and amplitude of the nerve action potential. EMG/NCS typically is performed approximately 3 to 4 weeks after an acute injury, as nerves distal to the injury continue to transmit electrical impulses normally until degeneration of the distal nerve progresses.

INVASIVE MONITORING

There are several methods of monitoring intracranial physiology. The three described here are bedside intensive care unit (ICU) procedures and allow continuous monitoring. All three involve making a small hole in the skull with a hand-held drill. They generally are placed in the right frontal region to minimize the neurologic impact of possible complications such as hemorrhage. The most reliable monitor, *always*, is an alert patient with a reliable neurologic examination. If a reliable neurologic examination is not possible due to the presence of brain injury, sedatives, or paralytics, and if there is active and unstable intracranial pathology, then invasive monitoring is required.

EXTERNAL VENTRICULAR DRAIN

An external ventricular drain is also known as a *ventriculostomy*. A perforated plastic catheter is inserted into the frontal horn of the lateral ventricle. An uninterrupted fluid column through a rigid tube allows transduction of intracranial pressure (ICP). CSF also can be drained to reduce ICP or sampled for laboratory studies.

INTRAPARENCHYMAL FIBER-OPTIC PRESSURE TRANSDUCER

An intraparenchymal fiber-optic pressure transducer is commonly referred to as a *bolt*. Again, a small hole is drilled in the skull. A threaded post locks securely into the skull and holds the fiber-optic catheter in place. A bolt allows ICP monitoring only, but it is smaller and less invasive than a ventriculostomy, and may be associated with fewer complications, although the data do not clearly support this.

BRAIN TISSUE OXYGEN SENSORS

The brain tissue oxygen sensor is a recent development that has already demonstrated a mortality benefit in traumatic brain injury patients.² The device is screwed into the skull in the same manner as the bolt; however, the sensor catheter is an electrochemical oxygen–tension sensitive membrane. A single bolt can be designed to accept a pressure sensor, oxygen sensor, and brain temperature sensor. Patients with severe brain injury due to trauma or aneurysmal hemorrhage may benefit from placement of these three sensors and a ventriculostomy to drain CSF for control of ICP. This treatment requires two twist-drill holes, which may be placed on adjacent or opposite sides of the head.

NEUROLOGIC AND NEUROSURGICAL EMERGENCIES

Raised Intracranial Pressure

ICP normally varies between 4 and 14 mmHg. Sustained ICP levels above 20 mmHg can injure the brain. The Monro-Kellie doctrine states that the cranial vault is a rigid structure, and therefore, the total volume of the contents determines ICP. The three normal contents of the cranial vault are brain tissue, blood, and CSF. The brain's contents can expand due to swelling from traumatic brain injury (TBI), stroke, or reactive edema. Blood volume can increase by extravasation to form a hematoma, or by reactive vasodilation in a hypoventilating, hypercarbic patient. CSF volume increases in the setting of hydrocephalus. Figure 42-2 demonstrates classic CT findings of hydrocephalus. Addition of a fourth element, such as a tumor or abscess, also will increase ICP. The pressure-volume curve depicted in Fig. 42-3 demonstrates a compensated region with a small $\Delta P/\Delta V$, and an uncompensated region with large $\Delta P/\Delta V$. In the compensated region, increased volume is offset by decreased volume of CSF and blood.

Fig. 42-2.

Increased ICP can injure the brain in several ways. Focal mass lesions cause shift and herniation. Temporal lesions push the uncus medially and compress the midbrain. This phenomenon is known as *uncal herniation*. The posterior cerebral artery (PCA) passes between the uncus and midbrain and may be occluded, leading to occipital infarct. Masses higher up in the hemisphere can push the cingulate gyrus under the falx cerebri. This process is known as *subfalcine herniation*. The anterior cerebral artery (ACA) branches run along the medial surface of the cingulate gyrus and may be occluded, leading to medial frontal and parietal infarcts. Diffuse increases in pressure in the cerebral hemispheres can lead to central, or transtentorial, herniation. Increased pressure in the posterior fossa can lead to upward central herniation or downward tonsillar herniation through the foramen magnum. Uncal, transtentorial, and tonsillar herniation can cause direct damage to the very delicate brain stem. Figure 42-4 diagrams patterns of herniation.

Fig. 42-4.

Schematic drawing of brain herniation patterns. 1. Subfalcine herniation. The cingulate gyrus shifts across midline under the falx cerebri. 2. Uncal herniation. The uncus (medial temporal lobe gyrus) shifts medially and compresses the midbrain and cerebral peduncle. 3. Central transtentorial herniation. The diencephalon and midbrain shift caudally through the tentorial incisura. 4. Tonsillar herniation. The cerebellar tonsil shifts caudally through the foramen magnum.

Patients with increased ICP, also called intracranial hypertension (ICH), often will present with headache, nausea, vomiting, and progressive mental status decline. Cushing's triad is the classic presentation of ICH: hypertension, bradycardia, and irregular respirations. This triad is usually a late manifestation. Focal neurologic deficits such as hemiparesis may be present if there is a focal mass lesion causing the problem. Patients with these symptoms should undergo head CT as soon as possible.

Initial management of ICH includes airway protection and adequate ventilation. A bolus of mannitol up to 1 g/kg causes free water diuresis, increased serum osmolality, and extraction of water from the brain. The effect is delayed by about 20 minutes and has a transient benefit. Driving serum osmolality above 300 mOsm/L is of indeterminate benefit and can have deleterious cardiovascular side effects, such as hypovolemia that leads to hypotension and decreased brain perfusion. Cases of ICH typically require rapid neurosurgical evaluation. Ventriculostomy, craniotomy, or craniectomy may be needed for definitive decompression.

It is critical to note that lethargic or obtunded patients often have decreased respiratory drive. This causes the partial pressure of arterial carbon dioxide (PaCO_2) to increase, resulting in cerebral vasodilation and worsening of ICH. This cycle causes a characteristic "crashing patient," who rapidly loses airway protection, becomes apneic, and herniates. Emergent intubation and ventilation to reduce PaCO_2 to roughly 35 mmHg can reverse the process and save the patient's life.

Brain Stem Compression

Disease in the posterior fossa (brain stem and cerebellum) requires special consideration. The volume of the posterior fossa is small. Hemorrhage or stroke in the posterior fossa that causes mass effect can rapidly kill the patient in two ways. Occlusion of the fourth ventricle causes acute obstructive hydrocephalus, leading to raised ICP, herniation, and then death. The mass effect can also lead directly to brain stem compression (Fig. 42-5). Symptoms of brain stem compression include agitation, progressive obtundation, and hypertension, followed rapidly by brain death. A patient exhibiting any of these symptoms needs an emergent neurosurgical evaluation for possible ventriculostomy or suboccipital craniectomy (removal of the bone covering the cerebellum). This situation is especially critical, as expeditious decompression can lead to

significant functional recovery of patients who present near brain death.

Fig. 42-5.

Maturing cerebellar stroke seen as a hypodense area in the right cerebellar hemisphere (*arrowhead*) on head computed tomography in a patient with rapidly progressing obtundation 2 days after the initial onset of symptoms. Swelling of the infarcted tissue causes posterior fossa mass effect. The fourth ventricle is obliterated and not visible, and the brain stem is being compressed.

Stroke

Patients presenting with acute focal neurologic deficits at a clearly defined time of onset (i.e., when the patient was last seen in a normal state of health) must be evaluated as rapidly as possible. An emergent head CT scan should be done. The study is often normal, because CT changes from ischemic stroke may take up to 24 hours to appear (Fig. 42-6). A patient with a clinical diagnosis of acute stroke <3 hours old, without hemorrhage on CT, may be a candidate for thrombolytic therapy with tissue plasminogen activator (tPA). Emergent MRI is helpful but not diagnostically necessary.

A. Head computed tomography scan of a patient with a 4-day-old stroke that occluded the right middle cerebral and posterior cerebral arteries. The infarcted tissue is the hypodense (*dark*) area indicated by the *arrowheads*. The patient presented with left-sided weakness and left visual field loss, but then became less responsive, prompting this head computed tomography. Note the right-to-left midline shift. **B.** Same patient status post decompressive right hemicraniectomy. Note the free expansion of swollen brain outside the normal confines of the skull. **C.** Patient with a right middle cerebral artery ischemic stroke with areas of hemorrhagic conversion, seen as hyperdense (*bright*) areas within the infarcted tissue. This patient also required hemicraniectomy for severe mass effect. Note the lack of midline shift postoperatively.

Seizure

A seizure is defined as an uncontrolled synchronous organization of neuronal electrical activity. A new-onset seizure often signifies an irritative mass lesion in the brain, particularly in adults, in whom tumors commonly present with seizure. Patients with traumatic intracranial hemorrhage are at risk for seizure. In addition to airway and ventilatory problems, a seizing patient is also at risk for neural excitotoxicity if the activity is prolonged, such as in *status epilepticus*. Any patient with a new-onset seizure should have imaging of the brain, such as a head CT scan, after the seizure is controlled and the patient is resuscitated.

TRAUMA

Trauma is the leading cause of death in children and young adults; however, the incidence of death and disability from trauma has been slowly decreasing. This decline is partly attributable to increased awareness of safety devices such as seat belts and motorist helmets. Nonetheless, trauma remains a major cause of morbidity and mortality, and it can affect every major organ system in the body. The three main areas of neurosurgical focus are: TBI, spine and SCI, and peripheral nerve injury.

Head Trauma

GLASGOW COMA SCALE SCORE

The initial assessment of the trauma patient includes the primary survey, resuscitation, secondary survey, and definitive care. Neurosurgical evaluation begins during the primary survey with the determination of the GCS score (usually referred to simply as the GCS) for the patient. The GCS is determined by adding the scores of the best responses of the patient in each of three categories. The motor score ranges from 1 to 6, verbal from 1 to 5, and eyes from 1 to 4. The GCS therefore ranges from 3 to 15, as detailed in Table 42-2.

SCALP INJURY

Blunt or penetrating trauma to the head can cause injury to the densely vascularized scalp, and significant blood loss can occur. Direct pressure initially controls the bleeding, allowing close inspection of the injury. If a simple laceration is found, it should be copiously irrigated and closed

primarily. If the laceration is short, a single-layer percutaneous suture closure will suffice. If the laceration is long or has multiple arms, the patient may need débridement and closure in the operating room (OR), with its superior lighting and wider selection of instruments and suture materials. Careful reapproximation of the galea will provide a more secure closure and better hemostasis. Blunt trauma also can cause crush injury with subsequent tissue necrosis. These wounds require débridement and consideration of advancement flaps to cover the defect.

SKULL FRACTURES

The usual classification system for bone fractures may be applied to the skull. The fracture may be characterized by skull x-rays or head CT.³ A closed fracture is covered by intact skin. An open, or compound, fracture is associated with disrupted overlying skin. The fracture lines may be single (linear); multiple and radiating from a point (stellate); or multiple, creating fragments of bone (comminuted). Closed skull fractures do not normally require specific treatment. Open fractures require repair of the scalp and operative débridement. Indications for craniotomy include depression greater than the cranial thickness, intracranial hematoma, and frontal sinus involvement.⁴ Skull fractures generally indicate that a significant amount of force was transmitted to the head and should increase the suspicion for intracranial injury. Fractures that cross meningeal arteries can cause rupture of the artery and subsequent epidural hematoma (EDH) formation.

Depressed skull fractures may result from a focal injury of significant force. The inner and outer cortices of the skull are disrupted, and a fragment of bone is pressed in toward the brain in relation to adjacent intact skull. The fragment may overlap the edge of intact bone, or may plunge completely below the level of adjacent normal skull. The inner cortex of the bone fragments often has multiple sharp edges that can lacerate dura, brain, and vessels. Craniotomy is required to elevate the fracture, repair dural disruption, and obtain hemostasis in these cases (Fig. 42-7). However, fractures overlying dural venous sinuses require restraint. Surgical exploration can lead to life-threatening hemorrhage from the lacerated sinus.

Fig. 42-7.

A. Bone-window axial head computed tomography (CT) of a patient who presented aphasic after being struck with the bottom of a beer bottle. CT demonstrates a depressed skull fracture in the left posterior temporoparietal area. **B.** Brain-window axial head CT demonstrating intraparenchymal hematoma caused by laceration of cortical vessels by the edge of the fractured bone. *Arrowhead* indicates traumatic subarachnoid hemorrhage in the sylvian fissure.

Fractures of the skull base are common in head-injured patients, and they indicate significant impact. They are generally apparent on routine head CT, but should be evaluated with dedicated fine-slice coronal-section CT scan to document and delineate the extent of the fracture and involved structures. If asymptomatic, they require no treatment. Symptoms from skull base fractures include cranial nerve deficits and CSF leaks. A fracture of the temporal bone, for instance, can damage the facial or vestibulocochlear nerve, resulting in vertigo, ipsilateral deafness, or facial paralysis. A communication may be formed between the subarachnoid space and the middle ear, allowing CSF drainage into the pharynx via the eustachian tube or from the ear (otorrhea). Extravasation of blood results in ecchymosis behind the ear, known as *Battle's sign*. A fracture of the anterior skull base can result in anosmia (loss of smell from damage to the olfactory nerve), CSF drainage from the nose (rhinorrhea), or periorbital ecchymoses, known as *raccoon eyes*.

Copious clear drainage from the nose or ear makes the diagnosis of CSF leakage obvious. Often, however, the drainage may be discolored with blood or small in volume if some drains into the throat. The halo test can help differentiate. Allow a drop of the fluid to fall on an absorbent surface such as a facial tissue. If blood is mixed with CSF, the drop will form a double ring, with a darker center spot containing blood components surrounded by a light halo of CSF. If this test is indeterminate, the fluid can be sent for beta-transferrin testing, which will only be positive if CSF is present.

Many CSF leaks will heal with elevation of the head of the bed for several days. A lumbar drain can augment this method. A lumbar drain is a catheter placed in the lumbar CSF cistern to decompress the cranial vault and allow the defect to heal by eliminating normal hydrostatic pressure. There is no proven efficacy of antibiotic coverage for preventing meningitis in patients with CSF leaks.

Traumatic cranial neuropathies generally are managed conservatively, with documentation of the extent of impairment and signs of recovery. Patients with traumatic facial nerve palsies may benefit from a course of steroids, although their benefit is unproven. Patients with facial nerve palsy of abrupt onset, who do not respond to steroids within 48 to 72 hours, may be considered for surgical decompression of the petrous portion of the facial nerve. Patients also may present with delayed-onset facial nerve palsy. Again, steroids are used and surgery is considered, with mixed results.

CLOSED HEAD INJURY

Closed head injury (CHI) is the most common type of TBI and a significant cause of morbidity and mortality in the United States. There are two important factors that affect the outcome in CHI and TBI in general. The initial impact causes the *primary injury*, defined as the immediate injury to neurons from transmission of the force of impact. The long, delicate axons of the neurons can shear as they undergo differential acceleration or deceleration along their projecting pathways. Prevention strategies, such as wearing helmets, remain the best means to decrease disability from primary injury. Subsequent neuronal damage due to the sequelae of trauma is referred to as *secondary injury*. Hypoxia, hypotension, hydrocephalus, intracranial hypertension, and intracranial hematoma are all mechanisms of secondary injury. The focus of basic research in brain trauma, critical care medicine, and neurosurgical intervention is to decrease the effects of secondary injury.

The Brain Trauma Foundation's most recent summary of management recommendations for brain-injured patients was published in 2007 and is endorsed by the American Association of Neurological Surgeons, Congress of Neurological Surgeons, and the World Health Organization. The guidelines standardize the care of these patients with the hope of improving outcomes. Some of the common patterns of CHI, including concussion, contusion, and diffuse axonal injury, are discussed below in Types of Closed Head Injury.⁵

Initial Assessment

The initial evaluation of a trauma patient remains the same whether or not the primary surveyor suspects head injury. The first three elements of the ABCDs of resuscitation—*airway*, *breathing*, and *circulation*—must be assessed and stabilized. Hypoxia and hypotension worsen outcome in TBI (due to secondary injury), making cardiopulmonary stabilization critical. Patients who cannot follow commands require intubation for airway protection and ventilatory control. The fourth element, assessment of "D," for *disability*, is undertaken next. Motor activity, speech, and eye opening can be assessed in a few seconds and a GCS score assigned.

The following is an example of how a primary surveyor may efficiently assess disability and GCS: Approach the patient and enter his or her field of view. Observe whether the patient is visually attentive. Clearly command: "Tell me your name." Then ask the patient to lift up two fingers on each side sequentially, and wiggle the toes. A visually or verbally unresponsive patient should be assessed for response to peripheral stimuli such as nail-bed pressure, or deep central painful stimulation, such as a firm, twisting pinch of the sensitive supraclavicular skin. Watch for eye opening and movement of the extremities, whether purposeful or reflexive. Assess the verbal response. The motor, verbal, and eye-opening scores may be correctly assigned using this rapid examination. An initial assessment of the probability of significant head injury can be made, assuming that pharmacologic and toxic elements have not obscured the examination. The surveyor must also take note of any external signs of head injury, including bleeding from the scalp, nose, or ear, or deformation of the skull or face.

Medical Management

Several medical steps may be taken to minimize secondary neuronal injury and the systemic consequences of head injury. Patients with a documented CHI and evidence of intracranial hemorrhage or depressed skull fracture should receive a 17-mg/kg phenytoin loading dose, followed by 1 week of therapeutic maintenance phenytoin, typically 300 to 400 mg/d. Phenytoin prophylaxis has been shown to decrease the incidence of early posttraumatic seizures.⁶ There is no evidence to support longer-term use of prophylactic antiepileptic agents. Blood glucose levels should be closely monitored by free blood sugar checks and controlled with sliding scale insulin. Fevers also should be evaluated and controlled with antipyretics, as well as source-directed therapy when possible. Hyperglycemia and hyperthermia are toxic to injured neurons and contribute to secondary injury. Head-injured patients have an increased prevalence of peptic ulceration and GI bleeding. Peptic ulcers occurring in patients with head injury or high ICP are referred to as Cushing's ulcers, and may be related to hypergastrinemia. Ulcer prophylaxis should be used. Compression stockings or athrombic pumps should be used when the patient cannot be mobilized rapidly.

Classification

Head injury can be classified as mild, moderate, or severe. For patients with a history of head trauma, classification is as follows: severe head injury if the GCS score is 3 to 8, moderate head injury if the GCS score is 9 to 12, and mild head injury if the GCS score is 13 to 15. Many patients present to emergency rooms and trauma bays with a history of head trauma. A triage system must be used to maximize resource utilization while minimizing the chance of missing occult or progressing injuries.

Head trauma patients who are asymptomatic, who have only headache, dizziness, or scalp lacerations, and who did not lose consciousness have

a low risk for intracranial injury and may be discharged home without a head CT scan. Head-injured patients who are discharged should be sent home with reliable family or friends who can observe the patient for the first postinjury day. Printed discharge instructions, which describe monitoring for confusion, persistent nausea, weakness, or speech difficulty, should be given to the caretaker. The patient should return to the emergency department for evaluation of such symptoms.

Patients with a history of altered consciousness, amnesia, progressive headache, skull or facial fracture, vomiting, or seizure have a moderate risk for intracranial injury and should undergo prompt head CT. If the CT is normal, and the neurologic examination has returned to baseline (excluding amnesia of the event), then the patient can be discharged to the care of a responsible adult, again with printed criteria for returning to the emergency room. Otherwise the patient must be admitted for a 24-hour observation period.

Patients with depressed consciousness, focal neurologic deficits, penetrating injury, depressed skull fracture, or changing neurologic examination have a high risk for intracranial injury. These patients should undergo immediate head CT and admission for observation or intervention as needed.

TYPES OF CLOSED HEAD INJURY

Concussion

A concussion is defined as temporary neuronal dysfunction following nonpenetrating head trauma. The head CT is normal, and deficits resolve over minutes to hours. Definitions vary; some require transient loss of consciousness, while others include patients with any alteration of mental status. Memory difficulties, especially amnesia of the event, are very common. Concussions may be graded. One method is the Colorado grading system.⁹ Head trauma patients with confusion only are grade 1, patients with amnesia are grade 2, and patients who lose consciousness are grade 3. Studies have shown that the brain remains in a hypermetabolic state for up to a week after injury. The brain is also much more susceptible to injury from even minor head trauma in the first 1 to 2 weeks after concussion. This is known as second-impact syndrome, and patients should be informed that, even after mild head injury, they might experience memory difficulties or persistent headaches.

Contusion

A *contusion* is a bruise of the brain, and occurs when the force from trauma is sufficient to cause breakdown of small vessels and extravasation of blood into the brain. The contused areas appear bright on CT scan, as seen in Fig. 42-8. The frontal, occipital, and temporal poles are most often involved. The brain sustains injury as it collides with rough, bony surfaces. Contusions themselves rarely cause significant mass effect as they represent small amounts of blood in injured parenchyma rather than coherent blood clots. Edema may develop around a contusion, causing mass effect. Contusions may enlarge or progress to frank hematoma, particularly during the first 24 hours. Contusions also may occur in brain tissue opposite the site of impact. This is known as a *contre-coup injury*. These contusions result from deceleration of the brain against the skull.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Severe bilateral contusions in the basal aspect of the frontal lobes, caused by the brain moving over the rough, irregular skull base during sudden cranial acceleration.

Diffuse Axonal Injury

Diffuse axonal injury is caused by damage to axons throughout the brain, due to rotational acceleration and then deceleration. Axons may be completely disrupted and then retract, forming axon balls. Small hemorrhages can be seen in more severe cases, especially on MRI. Hemorrhage is classically seen in the corpus callosum and the dorsolateral midbrain.

Penetrating Injury

These injuries are complex and must be evaluated individually. The two main subtypes are missile (e.g., due to bullets or fragmentation devices) and nonmissile (e.g., due to knives or ice picks). Some general principles apply. If available, skull x-rays and CT scans are useful in assessing the nature of the injury. Cerebral angiography must be considered if the object passes near a major artery or dural venous sinus. Operative exploration is necessary to remove any object extending out of the cranium, as well as for débridement, irrigation, hemostasis, and definitive closure. Small objects contained within brain parenchyma are often left in place to avoid iatrogenic secondary brain injury. Antibiotics are given to decrease the chances of meningitis or abscess formation. High-velocity missile injuries (from high-powered hunting rifles or military weapons) are especially deadly, because the associated shock wave causes cavitory tissue destruction of an area that is much larger than the projectile itself. Projectiles that penetrate both hemispheres or traverse the ventricles are almost universally fatal.

TRAUMATIC INTRACRANIAL HEMATOMAS

The various traumatic intracranial hematomas contribute to death and disability secondary to head injury. Hematomas can expand rapidly and cause brain shifting and subsequent herniation. Emergent neurosurgical evaluation and intervention often are necessary.

Epidural Hematoma

EDH is the accumulation of blood between the skull and the dura. EDH usually results from arterial disruption, especially of the middle meningeal artery. The dura is adherent to bone, and some pressure is required to dissect between the two. EDH has a classic three-stage clinical presentation that is probably seen in only 20% of cases. The patient is initially unconscious from the concussive aspect of the head trauma. The

patient then awakens and has a lucid interval while the hematoma subclinically expands. As the volume of the hematoma grows, the decompensated region of the pressure-volume curve is reached, ICP increases, and the patient becomes lethargic and herniates. Uncal herniation from an EDH classically causes ipsilateral third nerve palsy and contralateral hemiparesis.

On head CT the clot is bright, biconvex (lentiform), and has a well-defined border that usually respects cranial suture lines. The clot generally forms over the convexities but may rarely occur in the posterior fossa as well.

Open craniotomy for evacuation of the congealed clot and hemostasis generally is indicated for EDH. Patients who meet all of the following criteria may be managed conservatively: clot volume $<30\text{ cm}^3$, maximum thickness $<1.5\text{ cm}$, and GCS score >8 .¹⁰ Prognosis after successful evacuation is better for EDH than subdural hematoma (SDH). EDHs are associated with lower-energy trauma with less resultant primary brain injury. Good outcomes may be seen in 85 to 90% of patients, with rapid CT scan and intervention.¹¹

Acute Subdural Hematoma

An acute SDH is the result of an accumulation of blood between the arachnoid membrane and the dura. Acute SDH usually results from venous bleeding, typically from tearing of a bridging vein running from the cerebral cortex to the dural sinuses. The bridging veins are subject to stretching and tearing during acceleration/deceleration of the head, because the brain shifts in relation to the dura, which firmly adheres to the skull. Elderly and alcoholic patients are at higher risk for acute SDH formation after head trauma due to the greater mobility of their atrophied brains within the cranial vault.

On head CT scan, the clot is bright or mixed-density, crescent-shaped (lunate), may have a less distinct border, and does not cross the midline due to the presence of the falx. Most SDHs occur over the cerebral hemispheres, but they may also occur between the hemispheres or layer over the tentorium.

Open craniotomy for evacuation of acute SDH is indicated for any of the following: thickness $>1\text{ cm}$, midline shift $>5\text{ mm}$, or GCS drop by two or more points from the time of injury to hospitalization. Nonoperatively managed hematomas may stabilize and eventually reabsorb, or evolve into chronic SDHs.¹² This management requires frequent neurologic examinations until stabilization of the clot as proven by serial head CT scans.

The prognosis for functional recovery is significantly worse for acute SDH than EDH because it is associated with greater primary injury to brain parenchyma from high-energy impacts. Prompt recognition and intervention minimizes secondary injury. The elderly, patients with low admission GCS, or high postoperative ICP do poorly, with as few as 5% attaining functional recovery.¹³

Chronic Subdural Hematoma

Chronic SDH is a collection of blood breakdown products that is at least 2 to 3 weeks old. Acute hematomas are bright white (hyperdense) on CT scan for approximately 3 days, after which they fade to isodensity with brain, and then to hypodensity after 2 to 3 weeks. A true chronic SDH will be as dark as CSF on CT. Traces of white are often seen due to small hemorrhages into the collection. These small bleeds may expand the collection enough to make it symptomatic. This phenomenon is referred to as an *acute-on-chronic SDH*. Figure 42-9 demonstrates the CT appearance of an acute-on-chronic SDH. Vascularized membranes form within the hematoma as it matures. These membranes may be the source of acute hemorrhage.

Head computed tomography scan of an elderly patient with progressing left hemiplegia and lethargy, demonstrating an acute-on-chronic subdural hematoma. History revealed that the patient sustained a fall 4 weeks before presentation. *Arrowheads* outline the hematoma. The acute component is slightly denser and is seen as the hyperdense area in the dependent portion.

Chronic SDHs often occur in patients without a clear history of head trauma, as they may arise from minor trauma. Alcoholics, the elderly, and patients on anticoagulation are at higher risk for developing chronic SDH. Patients may present with headache, seizure, confusion, contralateral hemiparesis, or coma.

A chronic SDH >1 cm or any symptomatic SDH should be surgically drained. Unlike acute SDH, which consists of a thick, congealed clot, chronic SDH typically consists of a viscous fluid, with a texture and the dark brown color reminiscent of motor oil. A simple burr hole can effectively drain most chronic SDHs. However, the optimal treatment of chronic SDH remains controversial.¹⁴ Most authorities agree that burr hole drainage should be attempted first to obviate the risks of formal craniotomy. A single burr hole placed over the dependent edge of the collection can be made, and the space copiously irrigated until the fluid is clear. A second, more anterior burr hole can then be placed if the collection does not drain satisfactorily due to containment by membranes. The procedure is converted to open craniotomy if the SDH is too congealed for irrigation drainage, the complex of membranes prevents effective drainage, or persistent hemorrhage occurs that cannot be reached with bipolar cautery through the burr hole. The required surgical prepping and draping are always performed to allow simple conversion to craniotomy, and the incisions and burr holes are placed to allow easy incorporation into question mark-shaped craniotomy flaps.

There are various strategies to prevent reaccumulation of blood. Subdural or subgaleal drains may be left in place for 1 to 2 days. Mild hydration and bedrest with the head of the bed flat may encourage brain expansion. High levels of inspired oxygen may help draw nitrogen out of the cavity. Regardless of the strategy used, follow-up head CT scans are required postoperatively and approximately 1 month later to document resolution.

Intraparenchymal Hemorrhage

Isolated hematomas within the brain parenchyma are more often associated with hypertensive hemorrhage or arteriovenous malformations (AVMs). Bleeding may occur in a contused area of brain. Mass effect from developing hematomas may present as a delayed neurologic deficit. Delayed traumatic intracerebral hemorrhage is most likely to occur within the first 24 hours. Patients with contusion on the initial head CT scan should be reimaged 24 hours after the trauma to document stable pathology. Indications for craniotomy include: any clot volume >50 cm³ or a

clot volume $>20\text{ cm}^3$ with referable neurologic deterioration (GCS 6–8) and associated midline shift $>5\text{ mm}$ or basal cistern compression.¹⁵

VASCULAR INJURY

Trauma to the head or neck may cause damage to the carotid or vertebrobasilar systems. Generally, *dissection* refers to violation of the vessel wall intima. Blood at arterial pressure can then open a plane between the intima and media, within the media, or between the media and adventitia. The newly created space within the vessel wall is referred to as the *false lumen*. Tissue or organs supplied by dissected vessels may subsequently be injured in several ways. Expansion of the hematoma within the vessel wall can lead to narrowing of the true vessel lumen and reduction or cessation of distal blood flow. Slow-flowing or stagnant blood within the false lumen exposed to thrombogenic vessel wall elements may thrombose. Pieces of thrombus may then detach and cause distal embolic arterial occlusion. Also, the remaining partial-thickness vessel wall may rupture, damaging adjacent structures.

Traumatic dissection may occur in the carotid artery (anterior circulation) or the vertebral or basilar arteries (posterior circulation). Dissections may be extradural or intradural. Intradural dissection can present with subarachnoid hemorrhage (SAH), whereas extradural dissection cannot.

Traditional angiography remains the basis of diagnosis and characterization of arterial dissection. Angiographic abnormalities include stenosis of the true lumen, or "string-sign," visible intimal flaps, and the appearance of contrast in the false lumen. Four-vessel cerebral angiography should be performed when suspicion of dissection exists.

Historically, patients with documented arterial dissection have been anticoagulated with heparin and then warfarin to prevent thromboembolic stroke. Trauma patients often have concomitant absolute or relative contraindications to anticoagulation, complicating management. Antiplatelet therapy is often implemented in lieu of full anticoagulation, however, there is no randomized clinical trial comparing the two therapies.¹⁶ Consider surgical intervention for persisting embolic disease and for vertebral dissections presenting with SAH. Surgical options include vessel ligation and bypass grafting. Interventional radiology techniques include stenting and vessel occlusion. Occlusion techniques depend on sufficient collateral circulation to perfuse the vascular territory previously supplied by the occluded vessel.

Carotid Dissection

Carotid dissection may result from neck extension combined with lateral bending to the opposite side, or trauma from an incorrectly placed shoulder belt tightening across the neck in a motor vehicle accident. Extension or bending stretches the carotid over the bony transverse processes of the cervical vertebrae, while seat belt injuries cause direct trauma. Symptoms of cervical carotid dissection include contralateral neurologic deficit from brain ischemia, headache, and ipsilateral Horner's syndrome from disruption of the sympathetic tracts ascending from the stellate ganglion on the surface of the carotid artery. The patient may complain of hearing or feeling a bruit.

Traumatic vessel wall injury to the portion of the carotid artery running through the cavernous sinus may result in a carotid-cavernous fistula (CCF). This creates a high-pressure, high-flow pathophysiologic blood flow pattern. CCFs classically present with pulsatile proptosis (the globe pulses outward with arterial pulsation), retro-orbital pain, and decreased visual acuity or loss of normal eye movement (due to damage to cranial nerves III, IV, and VI as they pass through the cavernous sinus). Symptomatic CCFs should be treated to preserve eye function. Fistulae may be closed by balloon occlusion using interventional neuroradiology techniques. Fistulae with wide necks are difficult to treat and may require total occlusion of the parent carotid artery.

Vertebrobasilar Dissection

Vertebrobasilar dissection may result from sudden rotation or flexion/extension of the neck, chiropractic manipulation, or a direct blow to the neck. Common symptoms are neck pain, headache, and brain stem stroke or SAH. The risks and benefits of aspirin therapy are unclear when a vertebral dissection extends intracranially. The theoretically increased friability of the vessel wall may increase the risk of SAH when coupled with an antiplatelet agent. Consultation of a stroke neurologist is recommended in this situation.

BRAIN DEATH

Brain death occurs when there is an absence of signs of brain stem function or motor response to deep central pain in the absence of pharmacologic or systemic medical conditions that could impair brain function.

Clinical Examination

A neurologist, neurosurgeon, or intensivist generally performs the clinical brain death examination. Two examinations consistent with brain death 12 hours apart, or one examination consistent with brain death followed by a consistent confirmatory study generally is sufficient to declare brain death (see below). Hospital regulations and local laws regarding documentation should be followed closely.

Establish the absence of complicating conditions before beginning the examination. The patient must be normotensive, eutermic, and oxygenating well. The patient may not be under the effects of any sedating or paralytic drugs.

Documentation of no brain stem function requires the following: nonreactive pupils; lack of corneal blink, oculocephalic (doll's eyes), oculovestibular (cold calorics) reflexes; and loss of drive to breathe (apnea test). The apnea test demonstrates no spontaneous breathing even when Paco_2 is allowed to rise above 60 mmHg.

Deep central painful stimuli are provided by bilateral forceful twisting pinch of the supraclavicular skin and pressure to the medial canthal notch. Pathologic responses such as flexor or extensor posturing are *not* compatible with brain death. Spinal reflexes to peripheral pain, such as triple flexion of the lower extremities, are compatible with brain death.

Confirmatory Studies

Confirmatory studies are performed after a documented clinical examination consistent with brain death. A study consistent with brain death may obviate the need to wait 12 hours for a second examination. This is especially important when the patient is a potential organ donor, as brain-dead patients often have progressive hemodynamic instability. Lack of cerebral blood flow consistent with brain death may be documented by cerebral angiography or technetium radionuclide study. A "to-and-fro" pattern on transcranial Doppler ultrasonography indicates no net forward flow through the cerebral vasculature, consistent with brain death. An electroencephalogram (EEG) documenting electrical silence has been used, but it generally is not favored because there is often artifact or noise on the recording. EEG may confuse the situation and is especially difficult for families to understand.

Spine Trauma

The spine is a complex biomechanical and neural structure. The spine provides structural support for the body as the principal component of the axial skeleton, while protecting the spinal cord and nerve roots. Trauma may fracture bones or cause ligamentous disruption. Often, bone and ligament damage occur together. Damage to these elements reduces the strength of the spine and may cause instability, which compromises both supportive and protective functions. Spine trauma may occur with or without neurologic injury. Neurologic injury from spine trauma is classified as either incomplete or complete. If there is some residual motor or sensory neurologic function below the level of the lesion, as assessed by clinical examination, the injury is incomplete.¹⁷ A patient with complete neurologic dysfunction persisting 24 hours after injury has a very low probability of return of function in the involved area.

Neurologic injury from spine trauma may occur immediately or in delayed fashion. Immediate neurologic injury may be due to direct damage to the spinal cord or nerve roots from penetrating injuries, especially from stab wounds or gunshots. Blunt trauma may transfer sufficient force to the spine to cause acute disruption of bone and ligament, leading to subluxation, which is a shift of one vertebral element in relation to the adjacent level. Subluxation decreases the size of the spinal canal and neural foramina and causes compression of the cord or roots. Such neural impingement can also result from retropulsion of bone fragments into the canal during a fracture. Transection, crush injury, and cord compression impairing perfusion are mechanisms leading to SCI. Delayed neurologic injury may occur during transportation, examination of an improperly immobilized patient, or during a hypotensive episode.

THE MECHANICS OF SPINE TRAUMA

Trauma causes a wide variety of injury patterns in the spine due to its biomechanical complexity. A mechanistic approach facilitates an understanding of the patterns of injury, as there are only a few types of forces that can be applied to the spine. Although these forces are discussed individually, they often occur in combination. Several of the most common injury patterns are then presented to illustrate the clinical results of these forces applied at pathologically high levels.

Flexion/Extension

Bending the head and body forward into a fetal position flexes the spine. Flexion loads the spine anteriorly (the vertebral bodies) and distracts the spine posteriorly (the spinous process and interspinous ligaments). High flexion forces occur during front-end motor vehicle collisions, and

backward falls when the head strikes first. Arching the neck and back extends the spine. Extension loads the spine posteriorly and distracts the spine anteriorly. High extension forces occur during rear-end motor vehicle collisions (especially if there is no headrest), frontward falls when the head strikes first, or diving into shallow water.

Compression/Distraction

Force applied along the spinal axis (axial loading) compresses the spine. Compression loads the spine anteriorly and posteriorly. High compression forces occur when a falling object strikes the head or shoulders, or when landing on the feet, buttocks, or head after a fall from height. A pulling force in line with the spinal axis distracts the spine. Distraction unloads the spine anteriorly and posteriorly. Distraction forces occur during a hanging, when the chin or occiput strikes an object first during a fall, or when a passenger submarines under a loose seat belt during a front-end motor vehicle collision.

Rotation

Force applied tangential to the spinal axis rotates the spine. Rotation depends on the range of motion of intervertebral facet joints. High rotational forces occur during off-center impacts to the body or head or during glancing automobile accidents.

PATTERNS OF INJURY

Certain patterns of injury resulting from combinations of the above mentioned forces occur commonly and should be recognized during plain film imaging of the spine. Always completely evaluate the spine. A patient with a spine injury at one level has a significant risk for additional injuries at other levels.

Cervical

The cervical spine is more mobile than the thoracolumbar spine. Stability comes primarily from the multiple ligamentous connections of adjacent vertebral levels. Disruption of the cervical ligaments can lead to instability in the absence of fracture. The mass of the head transmits significant forces to the cervical spine during abrupt acceleration or deceleration, increasing risk for injury.

Jefferson Fracture

Jefferson fracture is a bursting fracture of the ring of C1 (the atlas) due to compression forces. There are usually two or more fractures through the ring of C1. The open-mouth odontoid view may show lateral dislocation of the lateral masses of C1. The rule of Spence states that 7 mm or greater combined dislocation indicates disruption of the transverse ligament. The transverse ligament stabilizes C1 with respect to C2. Jefferson fractures dislocated <7 mm usually are treated with a rigid collar, while those dislocated 7 mm or greater usually are treated with a halo vest. Surgical intervention is not indicated.

Odontoid Fractures

The odontoid process, or dens, is the large ellipse of bone arising anteriorly from C2 (the axis) and projecting up through the ring of C1 (the atlas). Several strong ligaments connect the dens to C1 and to the base of the skull. Odontoid fractures usually result from flexion forces. Odontoid fractures are classified as type I, II, or III. A type I fracture involves the tip only. A type II fracture passes through the base of the odontoid process. A type III fracture passes through the body of C2. Types II and III are considered unstable and should be externally immobilized by a halo vest or fused surgically. Surgery often is undertaken for widely displaced fractures (poor chance of fusing) and for those that fail external immobilization. Type I fractures usually fuse with external immobilization only.

Hangman's Fracture

Traditionally considered a hyperextension/distract injury from placement of the noose under the angle of the jaw, hangman's fractures also may occur with hyperextension/compression, as with diving accidents, or hyperflexion. The injury is defined by bilateral C2 pars interarticularis fractures. The pars interarticularis is the bone between superior and inferior facet joints. Thus, the posterior bony connection between C1 and C3 is lost. Hangman's fractures heal well with external immobilization. Surgery is indicated if there is spinal cord compression or after failure of external immobilization.

Jumped Facets—Hyperflexion Injury

The facet joints of the cervical spine slope forward. In a hyperflexion injury, the superior facet can "jump" pathologically up and forward over the inferior facet if the joint capsule is torn. Hyperflexion/rotation can cause a unilateral jumped facet, whereas hyperflexion/distraction leads to bilateral jumped facets. Patients with a unilateral injury usually are neurologically intact, while those with bilateral injury usually have spinal cord damage. The anteroposterior diameter of the spinal canal decreases more with bilateral injury, leading to spinal cord compression (Fig. 42-10).

A. Lateral cervical spine x-ray of an elderly woman who struck her head during a backward fall. *Arrowhead* points to jumped facets at C5–C6. Note the anterior displacement of the C5 body with respect to the C6 body. **B.** Sagittal T2-weighted magnetic resonance imaging of the same patient, revealing compromise of the spinal canal and compression of the cord. Note the bright signal within the cord at the level of compression, indicating spinal cord injury. **C.** Lateral cervical spine x-ray of same patient after application of cervical traction and manual reduction. Note restoration of normal alignment. **D.** Lateral cervical spine x-ray after posterior cervical fusion to restabilize the C5–C6 segment of the spine.

Thoracolumbar

The thoracic spine is stabilized significantly by the rib cage. The lumbar spine has comparatively large vertebrae. Thus, the thoracolumbar spine has a higher threshold for injury than the cervical spine. A three-column model is useful for categorizing thoracolumbar injuries.¹⁸ The anterior longitudinal ligament and the anterior half of the vertebral body constitute the anterior column. The posterior half of the vertebral body and the posterior longitudinal ligament constitute the middle column. The pedicles, facet joints, laminae, spinous processes, and interspinous ligaments

constitute the posterior column.

Compression Fracture

Compression fracture is a compression/flexion injury causing failure of the anterior column only. It is stable and not associated with neurologic deficit, although the patient may still have significant pain (Fig. 42-11).

Fig. 42-11.

A. Lateral lumbar spine x-ray showing a compression fracture of L2. *Arrowhead* points to anterior wedge deformity. Note the posterior wall of the vertebral body has retained normal height and alignment. **B.** Axial computed tomography scan through the same fracture. *Arrowhead* demonstrates a transverse discontinuity in the superior endplate of the L2 body.

Burst Fracture

Burst fracture is a pure axial compression injury causing failure of the anterior and middle columns. It is unstable, and perhaps half of patients have neurologic deficit due to compression of the cord or cauda equina from bone fragments retropulsed into the spinal canal.

Chance Fracture

Chance fracture is a flexion-distraction injury causing failure of the middle and posterior columns, sometimes with anterior wedging. Typical injury is from a lap seat-belt hyperflexion with associated abdominal injury. It often is unstable and associated with neurologic deficit.

Fracture-Dislocation

Fracture-dislocation is failure of the anterior, middle, and posterior columns caused by flexion/distraction, shear, or compression forces. Neurologic deficit can result from retropulsion of middle column bone fragments into the spinal canal, or from subluxation causing decreased canal diameter (Fig. 42-12).

INITIAL ASSESSMENT AND MANAGEMENT

The possibility of a spine injury must be considered in all trauma patients. A patient with no symptoms referable to neurologic injury, a normal neurologic examination, no neck or back pain, and a known mechanism of injury unlikely to cause spine injury is at minimal risk for significant injury to the spine. Victims of moderate or severe trauma, especially those with injuries to other organ systems, usually fail to meet these criteria or cannot be assessed adequately. The latter often is due to impaired sensorium or significant pain. Because of the potentially catastrophic consequences of missing occult spine instability in a neurologically intact patient, a high level of clinical suspicion should govern patient care until completion of clinical and radiographic evaluation.

The trauma patient should be kept on a hard flat board with straps and pads used for immobilization. A hard cervical collar is kept in place. These steps minimize forces transferred through the spine, and therefore decrease the chance of causing dislocation, subluxation, or neural compression during transport to the trauma bay. The patient is then moved from the board to a flat stretcher. The primary survey and resuscitation are completed. Physical examination and initial x-rays follow.

For the examination, approach the patient as described in the section on Neurologic Examination earlier in this chapter. Evaluation for spine or SCI is easier and more informative in awake patients. If the patient is awake, ask if he or she recalls details of the nature of the trauma, and if there was loss of consciousness, numbness, or inability to move any or all limbs. Assess motor function by response to commands or pain, as appropriate. Assess pinprick, light touch, and joint position, if possible. Determining the anatomically lowest level of intact sensation can pinpoint the level of the lesion along the spine. Testing sensation in an ascending fashion will allow the patient to better discern the true stimulus as opposed to determine when it is extinguished. Document muscle stretch reflexes, lower sacral reflexes (i.e., anal wink and bulbocavernosus), and rectal tone.

American Spinal Injury Association Classification

The American Spinal Injury Association provides a method of classifying patients with spine injuries. The classification indicates completeness and level of the injury and the associated deficit. A form similar to that shown in Fig. 42-13 should be available in the trauma bay and

Fig. 42-13.

ASIA IMPAIRMENT SCALE

☐ **A = Complete:** No motor or sensory function is preserved in the sacral segments S4-S5.

☐ **B = Incomplete:** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5.

☐ **C = Incomplete:** Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.

☐ **D = Incomplete:** Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 or more.

☐ **E = Normal:** motor and sensory function are normal

☐ Cauda Equina

The American Spinal Injury Association system for categorizing spinal cord injury patients according to level and degree of neurologic deficit.

Penetrating, compressive, or ischemic cord injury can lead to several characteristic presentations based on the anatomy of injury. The neurologic deficits may be deduced from the anatomy of the long sensory and motor tracts and understanding of their decussations (Fig. 42-14). Four patterns are discussed. First, injury to the entire cord at a given level results in anatomic or functional cord transection with total loss of motor and sensory function below the level of the lesion. The typical mechanism is severe traumatic vertebral subluxation reducing spinal canal diameter and crushing the cord. Second, injury to half the cord at a given level results in Brown-Séquard syndrome, with loss of motor control and proprioception ipsilaterally and loss of nociception and thermoception contralaterally. The typical mechanism is a stab or gunshot wound. Third, injury to the interior gray matter of the cord in the cervical spine results in a central cord syndrome, with upper extremity worse than lower extremity weakness and varying degrees of numbness. The typical mechanism is transient compression of the cervical cord by the ligamentum flavum buckling during traumatic neck hyperextension. This syndrome occurs in patients with pre-existing cervical stenosis. Fourth, injury to the ventral half of the cord results in the anterior cord syndrome, with paralysis and loss of nociception and thermoception bilaterally. The typical mechanism is an acute disc herniation or ischemia from anterior spinal artery occlusion.

STUDIES

Anteroposterior and lateral plain films provide a rapid survey of the bony spine. Plain films detect fractures and dislocations well. Adequate visualization of the lower cervical and upper thoracic spine often is impossible because of the shoulder girdle. Complete plain film imaging of the cervical spine includes an open-mouth view to assess the odontoid process and the lateral masses of C1. Fine-slice CT scan with sagittal and coronal reconstructions provides good detail of bony anatomy and is good for characterizing fractures seen on plain films, as well as visualizing C7–T1 when not well seen on plain films. MRI provides the best soft tissue imaging. Canal compromise from subluxation, acute disc herniations, or ligamentous disruption is clearly seen. MRI also may detect EDHs or damage to the spinal cord itself, including contusions or areas of ischemia.

DEFINITIVE MANAGEMENT

Spinal-Dose Steroids

The National Acute Spinal Cord Injury studies (NASCIS I and II) provide the basis for the common practice of administering high-dose steroids to patients with acute SCI. A 30-mg/kg IV bolus of methylprednisolone is given over 15 minutes, followed by a 5.4-mg/kg per hour infusion begun 45 minutes later. The infusion is continued for 23 hours if the bolus is given within 3 hours of injury, or for 47 hours if the bolus is given within 8 hours of injury. The papers indicate greater motor and sensory recovery at 6 weeks, 6 months, and 1 year after acute SCI in patients who received methylprednisolone.^{19,20} However, the NASCIS trial data have been extensively criticized, as many argue that the selection criteria and study design were flawed, making the results ambiguous. Patients who receive such a large corticosteroid dose have increased rates of medical and ICU complications, such as pneumonias, which have a deleterious effect on outcome. A clear consensus on the use of spinal-dose steroids does not exist.²¹ A decision to use or not use spinal-dose steroids may be dictated by local or regional practice patterns, especially given the legal liability issues surrounding SCI. Patients with gunshot or nerve root (cauda equina) injuries, or those who are pregnant, <14 years old, or on chronic steroids were excluded from the NASCIS studies and should not receive spinal-dose steroids. In addition to steroids, hypothermia for SCI has also received attention. There is even less evidence supporting the use of this treatment, and thus, it is not recommended.²²

Orthotic Devices

Rigid external orthotic devices can stabilize the spine by decreasing range of motion and minimizing stress transmitted through the spine. Commonly used rigid cervical orthoses include Philadelphia and Miami-J collars. Cervical collars are inadequate for C1, C2, or cervicothoracic instability. Cervicothoracic orthoses brace the upper thorax and the neck, improving stabilization over the cervicothoracic region. Minerva braces

improve high cervical stabilization by bracing from the upper thorax to the chin and occiput. Halo-vest assemblies provide the most external cervical stabilization. Four pins are driven into the skull to lock the halo ring in position. Four posts arising from a tight-fitting rigid plastic vest immobilize the halo ring. Lumbar stabilization may be provided by thoracolumbosacral orthoses. A variety of companies manufacture lines of spinal orthotics. A physician familiar with the technique should fit a halo-vest. Assistance from a trained orthotics technician improves fitting and adjustment of the other devices.

Surgery

Neurosurgical intervention has two goals. First is the decompression of the spinal cord or nerve roots in patients with incomplete neurologic deficits. These patients should be decompressed expeditiously, especially if there is evidence of neurologic deterioration over time. Second is the stabilization of injuries judged too unstable to heal with external immobilization only. Spine trauma patients with complete neurologic deficit, without any signs of recovery, or those without any neurologic deficits who have bony or ligamentous injury requiring open fixation, may be medically stabilized before undergoing surgery. Surgical stabilization may be indicated for some injuries that would eventually heal with conservative treatment. Surgical stabilization can allow early mobilization, aggressive nursing care, and physical therapy. Solid surgical stabilization may also allow a patient to be managed with a rigid cervical collar who would otherwise require halo-vest immobilization.

CONTINUED CARE

Regional SCI centers with nurses, respiratory therapists, pulmonologists, physical therapists, physiatrists, and neurosurgeons specifically trained in caring for these patients may improve outcomes. Frequently encountered ICU issues include hypotension and aspiration pneumonia. Chronically, prevention and treatment of deep venous thrombosis, autonomic hyperreflexia, and decubitus ulcer formation are important. Many patients with cervical or high thoracic cord injuries require prolonged ventilatory support until the chest wall becomes stiff enough to provide resistance for diaphragmatic breathing. Patients with high cervical cord injuries (C4 or above) will often require permanent ventilatory support. Patients should be transferred to SCI rehabilitation centers after stabilization of medical and surgical issues.

Peripheral Nerve Trauma

The peripheral nervous system extends throughout the body and is subject to injury from a wide variety of trauma. Peripheral nerves transmit motor and sensory information between the CNS and the body. An individual nerve may have pure motor, pure sensory, or mixed motor and sensory functions. The key information-carrying structure of the nerve is the axon. The axon transmits information from the neuronal cell body and may measure from <1 mm to >1 m in length. Axons that travel a significant distance are often covered with myelin, which is a lipid-rich, electrically insulating sheath formed by Schwann cells. Myelinated axons transmit signals much more rapidly than unmyelinated axons because the voltage shifts and currents that define action potentials effectively jump from gap to gap over the insulated lengths of the axon.

Axons, whether myelinated or unmyelinated, travel through a collagenous connective tissue known as *endoneurium*. Groups of axons and their endoneurium form bundles known as *fascicles*. Fascicles run through a tubular collagenous tissue known as *perineurium*. Groups of fascicles are suspended in mesoneurium. Fascicles and their mesoneurium run through another tubular collagenous tissue known as *epineurium*. The epineurium and its contents form the nerve.

There are four major mechanisms of injury to peripheral nerves. Nerves may be lacerated, stretched, compressed, or contused. Knives, passing bullets, or jagged bone fractures may lacerate nerves. Adjacent expanding hematomas or dislocated fractures may stretch nerves. Expanding hematomas, external orthoses such as casts or braces, or blunt trauma over a superficial nerve may compress or crush nerves. Shock waves from high-velocity bullets may contuse nerves. These mechanisms of injury cause damage to the various anatomic components of the nerve. The patterns of damage are categorized below.

Certain nerve segments are particularly vulnerable to injury. The following four characteristics make a nerve segment more vulnerable: proximity to a joint, superficial course, passage through a confined space, and being fixed in position.

TYPES OF INJURY

The traditional classification system for peripheral nerve injury is the Seddon classification. Seddon described three injury patterns as defined below in the Neurapraxia, Axonotmesis, and Neurotmesis sections. The Seddon classification provides a simple, anatomically based approach to peripheral nerve injury.²³

Neurapraxia

Neurapraxia is defined as the temporary failure of nerve function without physical axonal disruption. Axon degeneration does not occur. Return of normal axonal function occurs over hours to months, often in the 2- to 4-week range.

Axonotmesis

Axonotmesis is the disruption of axons and myelin. The surrounding connective tissues, including endoneurium, are intact. The axons degenerate proximally and distally from the area of injury. Distal degeneration is known as *Wallerian degeneration*. Axon regeneration within the connective tissue pathways can occur, leading to restoration of function. Axons regenerate at a rate of 1 mm per day. Significant functional recovery may occur for up to 18 months. Scarring at the site of injury from connective tissue reaction can form a neuroma and interfere with regeneration.

Neurotmesis

Neurotmesis is the disruption of axons and endoneurial tubes. Peripheral collagenous components, such as the epineurium, may or may not be intact. Proximal and distal axonal degeneration occurs. The likelihood of effective axonal regeneration across the site of injury depends on the extent of neuroma formation and on the degree of persisting anatomic alignment of the connective tissue structures. For instance, an injury may damage axons, myelin, and endoneurium, but leave perineurium intact. In this case, the fascicle sheath is intact, and appropriate axonal regeneration is more likely to occur than if the sheath is interrupted.

MANAGEMENT OF PERIPHERAL NERVE INJURY

The sensory and motor deficits should be accurately documented. Deficits are usually immediate. Progressive deficit suggests a process such as an expanding hematoma and may warrant early surgical exploration. Clean, sharp injuries may also benefit from early exploration and reanastomosis. Most other peripheral nerve injuries should be observed. EMG/NCS studies should be done 3- to 4 weeks postinjury if deficits persist. Axon segments distal to the site of injury will conduct action potentials normally until Wallerian degeneration occurs, rendering EMG/NCS before 3 weeks uninformative. Continued observation is indicated if function improves. Surgical exploration of the nerve may be undertaken if no functional improvement occurs over 3 months. If intraoperative electrical testing reveals conduction across the injury, continue observation. In the absence of conduction, the injured segment should be resected and end-to-end primary anastomosis attempted. However, anastomoses under tension will not heal. A nerve graft may be needed to bridge the gap between the proximal and distal nerve ends. The sural nerve often is harvested, as it carries only sensory fibers and leaves a minor deficit when resected. The connective tissue structures of the nerve graft may provide a pathway for effective axonal regrowth across the injury.

PATTERNS OF INJURY

Brachial Plexus

The brachial plexus may be injured in a variety of ways. Parturition or a motorcycle accident can lead to plexus injury due to dislocation of the glenohumeral joint. Attempting to arrest a fall with one's hands can lead to a stretch injury of the plexus due to abrupt movement of the shoulder girdle. An apical lung (Pancoast) tumor can cause compression injury to the plexus. There are many patterns of neurologic deficits possible with injury to the various components of the brachial plexus, and understanding them all would require extensive neuroanatomic discussion. Two well-known eponymous syndromes are Erb's palsy and Klumpke's palsy. Injury high in the plexus to the C5 and C6 roots resulting from glenohumeral dislocation causes Erb's palsy with the characteristic "bellhop's tip" position. The arm hangs at the side, internally rotated. Hand movements are not affected. Injury low in the plexus, to the C8 and T1 roots, resulting from stretch or compression injury, causes Klumpke's palsy with the characteristic "claw hand" deformity. There is weakness of the intrinsic hand muscles, similar to that seen with ulnar nerve injury.

Radial Nerve

The radial nerve courses through the axilla, then laterally and posteriorly in the spiral groove of the humerus. Improper crutch use can cause damage to the axillary portion. The section of the nerve traversing the spiral groove can be damaged by humerus fractures or pressure from improper positioning during sleep. This classically occurs when the patient is intoxicated and is called "Saturday night palsy." The key finding is wrist drop (i.e., weakness of hand and finger extensors). Axillary (proximal) injury causes triceps weakness in addition to wrist drop.

Common Peroneal Neuropathy

The common peroneal nerve forms the lateral half of the sciatic nerve (the medial half being the tibial nerve). It receives contributions from L4, L5, S1, and S2. It emerges as a separate nerve in the popliteal fossa and laterally wraps around the fibular neck, after which it splits to form the deep and superficial peroneal nerves. The superficial, fixed location at the fibular neck makes the common peroneal nerve susceptible to compression. The classic cause of traumatic peroneal neuropathy is crush injury from a car bumper striking the lateral aspect of the leg at the knee. Symptoms of common peroneal neuropathy include foot drop (weakness of the tibialis anterior), eversion weakness, and numbness over the anterolateral surface of the lower leg and dorsum of the foot. In contrast, a foot drop due to L5 radiculopathy spares eversion because the S1 fibers are intact. Surgical exploration of a common peroneal crush lesion is typically a low yield endeavor. Rare cases may be due to compressive fibers or adhesions that may be lysed, with the possibility of return of function.

CEREBROVASCULAR DISEASE

Cerebrovascular disease is the most frequent cause of new, rapid-onset, nontraumatic neurologic deficit. It is far more common than seizures or tumors. Vascular structures are subject to a variety of chronic pathologic processes that compromise vessel wall integrity. Diabetes, high cholesterol, high blood pressure, and smoking are risk factors for vascular disease. These conditions can lead to vascular damage by such mechanisms as atheroma deposition causing luminal stenosis, endothelial damage promoting thrombogenesis, and weakening of the vessel wall resulting in aneurysm formation or dissection. These processes may coexist. For instance, a vessel containing an atheromatous plaque will have a decreased luminal diameter. The plaque also may have compromised endothelium, providing the opportunity for thrombus formation, which can lead to acute total occlusion of the remaining lumen. Aneurysms and dissection often occur in atheromatous vessels. Specific patterns of disease relevant to the cerebrovascular system include atheromatous and thrombotic carotid occlusion, brain ischemia from proximal embolic disease, vessel wall rupture leading to hemorrhage, and rupture of abnormal, thin-walled structures, specifically aneurysms and AVMs.

Ischemic Diseases

Ischemic stroke accounts for approximately 85% of acute cerebrovascular events. Symptoms of acute ischemic stroke vary based on the functions of the neural tissues supplied by the occluded vessel, and the presence or absence of collateral circulation. The circle of Willis provides extensive collateral circulation, as it connects the right and left carotid arteries to each other and each to the vertebrobasilar system. Patients with complete occlusion of the carotid artery proximal to the circle of Willis may be asymptomatic if the blood flow patterns can shift and provide sufficient circulation to the ipsilateral cerebral hemisphere from the contralateral carotid and the basilar artery. However, the anatomy of the circle of Willis is highly variable. Patients may have a hypoplastic or missing communicating artery with resultant bilateral ACA supply by one carotid; or the PCA may be supplied by the carotid artery rather than the basilar. Similarly, one vertebral artery is often dominant and the other is hypoplastic. These variations may make disease in a particular vessel more neurologically devastating than in a patient with full collateral circulation. Occlusion distal to the circle of Willis generally results in a stroke in the territory supplied by that particular artery.

Neurologic deficit from occlusive disease may be temporary or permanent. A patient with sudden-onset focal neurologic deficit that resolves within 24 hours has had a transient ischemic attack. A patient with permanent deficit has had a completed stroke.

Thrombotic Disease

The most common area of neurologically significant vessel thrombosis is the carotid artery in the neck. Disease occurs at the carotid bifurcation. Thrombosis of a carotid artery chronically narrowed by atheroma can lead to acute carotid occlusion. As discussed above, this can be asymptomatic. The more common concern is thromboembolus. Intracranial arterial occlusion by local thrombus formation may occur, but it is rare compared to embolic occlusion.

MANAGEMENT

Complete occlusion of the carotid artery without referable neurologic deficit requires no treatment. A patient with new neurologic deficit and an angiographically confirmed complete carotid occlusion contralateral to the symptoms should be considered for emergent carotid endarterectomy.²⁴ Surgery should be performed within 2 hours of symptom onset. This time restriction significantly reduces the number of candidates. Surgery should not be performed on obtunded or comatose patients. This time restriction significantly reduces the number of candidates.

Embollic Disease

Emboli causing strokes may originate from a number of sources, including: the left atrium, during atrial fibrillation, a hypokinetic left ventricular wall segment, valvular vegetations, an atheromatous aortic arch, stenotic/atheromatous carotid bifurcations, or from the systemic venous system in the presence of a right-to-left shunt, such as a patent foramen ovale. The majority of emboli enter the anterior (carotid) circulation rather than the posterior (vertebrobasilar) circulation. Characteristic clinical syndromes result from embolic occlusion of the various vessels.

COMMON TYPES OF STROKES

Anterior Cerebral Artery Stroke

The ACA supplies the medial frontal and parietal lobes, including the motor strip, as it courses into the interhemispheric fissure. ACA stroke results in contralateral leg weakness.

Middle Cerebral Artery Stroke

The MCA supplies the lateral frontal and parietal lobes and the temporal lobe. MCA stroke results in contralateral face and arm weakness. Dominant-hemisphere MCA stroke causes language deficits. Proximal MCA occlusion with ischemia and swelling in the entire MCA territory can lead to significant intracranial mass effect and midline shift (see Fig. 42-6).

Posterior Cerebral Artery Stroke

The PCA supplies the occipital lobe. PCA stroke results in a contralateral homonymous hemianopsia (see Fig. 42-6).

Posterior Inferior Cerebellar Artery Stroke

The PICA supplies the lateral medulla and the inferior half of the cerebellar hemispheres. PICA stroke results in nausea, vomiting, nystagmus, dysphagia, ipsilateral Horner's syndrome, and ipsilateral limb ataxia. The constellation of symptoms resulting from PICA occlusion is referred to as the *lateral medullary* or *Wallenberg's syndrome*.

MANAGEMENT

Ischemic stroke management has two goals: reopen the occluded vessel and maintain blood flow to ischemic "penumbra" tissues bordering the vascular territory. Reopening the vessel may be attempted with recombinant tPA.²⁵ tPA administration within 3 hours of the onset of neurologic deficit improves outcome at 3 months. In the setting of suspected ischemic stroke, a head CT must be performed immediately to differentiate ischemic from hemorrhagic stroke. Intracranial hemorrhage, major surgery within the previous 2 weeks, GI or genitourinary hemorrhage in the previous 3 weeks, platelet count less than 100,000/ μ L, and systolic blood pressure >185 mmHg are among the contraindications to tPA therapy.

Patients not eligible for tPA require hemodynamic optimization and neurologic monitoring. Admit such patients to the ICU stroke service for blood pressure management and frequent neurologic checks. Permissive hypertension allows for maximal cerebral perfusion. Systolic blood pressure >180 mmHg may require treatment, but the optimal mean arterial pressure goal is between 100 to 140 mmHg. Give normal saline solution without glucose (which could injure neurons in the penumbra), and aim for normovolemia. A stroke patient who worsens clinically should undergo repeat head CT to evaluate for hemorrhage or increasing mass effect from swelling, which typically peaks 3 to 5 days after the stroke. Significant swelling from an MCA or cerebellar strokes may cause herniation and brain stem injury. A decompressive hemicraniectomy or suboccipital craniectomy can be a life-saving intervention for these select stroke patients.

Hemorrhagic Diseases

Intracranial hemorrhage from abnormal or diseased vascular structures accounts for approximately 15% of acute cerebrovascular events. Hypertension and amyloid angiopathy account for most intraparenchymal hemorrhages, although AVMs, aneurysms, venous thrombosis, tumors, hemorrhagic conversion of ischemic infarct, and fungal infections also may be the cause. The term *intracranial hemorrhage* frequently is used to mean intraparenchymal hemorrhage and will be used here. Intracranial hemorrhage causes local neuronal injury and dysfunction and also may cause global dysfunction due to mass effect if sufficiently large. AVM or aneurysm rupture results in SAH because the major cerebral and cortical blood vessels travel in the subarachnoid space, between the pia and the arachnoid membrane. SAH can cause immediate concussive-like neuronal dysfunction by exposure of the brain to intra-arterial pressure pulsations during the hemorrhage; it can cause delayed ischemia from

cerebral arterial vasospasm. Patients presenting with intracranial hemorrhages that do not follow typical patterns should undergo angiography or MRI to evaluate for possible underlying lesions, such as AVM or tumor.

Hemorrhagic stroke typically occurs within the basal ganglia or cerebellum. The patient is usually hypertensive on admission and has a history of poorly controlled hypertension. Such patients are more likely to present with lethargy or obtundation, compared to those who suffer an ischemic stroke. Depressed mental status results from brain shift and herniation secondary to mass effect from the hematoma in deep structures. Ischemic stroke does not cause mass effect acutely; and therefore, patients are more likely to present with normal consciousness and a focal neurologic deficit. Hemorrhagic strokes tend to present with a relatively gradual decline in neurologic function as the hematoma expands, rather than the immediately maximal symptoms caused by ischemic stroke. Table 42-3 provides a listing of relative incidences of intracranial hemorrhage by anatomic distribution.

Table 42-3 Anatomic Distribution of Intracranial Hemorrhages and Correlated Symptoms		
% of Intracranial Hemorrhages	Location	Classic Symptoms
50	Basal ganglia (putamen, globus pallidus), internal capsule	Contralateral hemiparesis
15	Thalamus	Contralateral hemisensory loss
10–20	Cerebral white matter (lobar)	Depends on location (weakness, numbness, partial loss of visual field)
10–15	Pons	Hemiparesis; may be devastating
10	Cerebellum	Lethargy or coma due to brain stem compression and/or hydrocephalus
1–6	Brain stem (excluding pons)	Often devastating

HYPERTENSION

Hypertension increases the relative risk of intracranial hemorrhage by approximately fourfold, likely due to chronic degenerative vasculopathy. Hypertensive hemorrhages often present in the basal ganglia, thalamus, or pons, and result from breakage of small perforating arteries that branch off of much larger parent vessels (Fig. 42-15).

A. Head computed tomography scan of a patient with left-sided weakness and progressive lethargy reveals a right basal ganglia hemorrhage (*arrowhead*). The blood clot is bright white. Hypodensity around the clot represents cerebral edema. There is blood within the ventricular system. **B.** Another patient with intraventricular extension of a basal ganglia hemorrhage. The patient developed right-sided weakness and then lethargy. Head computed tomography indicated hydrocephalus. A ventriculostomy was placed for cerebrospinal fluid drainage (*arrowhead* indicates cross-sectional view of the catheter entering the anterior horn of the right lateral ventricle).

Most hypertensive hemorrhages should be medically managed. The hematoma often contains intact, salvageable axons because the blood dissects through and along neural tracts, and surgical clot evacuation destroys these axons. Factors potentially favoring surgery include: superficial clot location, young age, nondominant hemisphere, rapid deterioration, and significant mass effect. However, the most comprehensive randomized clinical trials to date did not show an overall improved outcome in surgically evacuated intracranial hemorrhage, except for the subgroup of patients with clot <1 cm from the cortical surface.²⁶ Medical management includes moderate blood pressure control, normalizing platelet and clotting function, phenytoin, and electrolyte management. Intubate patients who cannot clearly follow commands to prevent aspiration and hypercarbia. Follow and document the neurologic examination and communicate with the family regarding appropriateness for rehabilitation vs. withdrawal of care.

AMYLOID ANGIOPATHY

The presence of pathologic amyloid deposition in the media of small cortical vessels compromises vessel integrity and tends to cause more superficial (lobar) hemorrhages than hypertensive intracranial hemorrhage. Amyloid laden vessels may hemorrhage multiple times. The superficial location of amyloid hemorrhages may make surgical evacuation less morbid compared to typical deep hypertensive hemorrhages. Nonetheless, medical management and family counseling should be approached similarly to patients with hypertensive hemorrhages.

CEREBRAL ANEURYSM

An aneurysm is a focal dilatation of the vessel wall and is most often a balloon-like outpouching, but may also be fusiform. Aneurysms usually occur at branch points of major vessels (e.g., internal carotid artery bifurcation), or at the origin of smaller vessels (e.g., posterior communicating artery or ophthalmic artery). Approximately 85% of aneurysms arise from the anterior circulation (carotid) and 15% from the posterior circulation (vertebrobasilar). Table 42-4 shows the percentage distribution of cerebral aneurysms by location. Aneurysms are thin

walled and at risk for rupture. The major cerebral vessels, and therefore aneurysms, lie in the subarachnoid space. Rupture results in SAH. The aneurysmal tear may be small and seal quickly, or it may not. SAH may consist of a thin layer of blood in the CSF spaces, or thick layers of blood around the brain and extending into brain parenchyma, resulting in a clot with mass effect. Because the meningeal linings of the brain are sensitive, SAH usually results in a sudden, severe "thunderclap" headache. A patient will classically describe "the worst headache of my life." Presenting neurologic symptoms may range from mild headache to coma to sudden death. The Hunt-Hess grading system categorizes patients clinically (Table 42-5).

Table 42-4 Prevalence of Cerebral Aneurysm by Location	
Prevalence	Aneurysm Location (Vernacular Name)
Anterior circulation 85%	30% Anterior communicating artery (A-Comm)
	25% Posterior communicating artery (P-Comm)
	20% Middle cerebral artery bifurcation
	10% Other
Posterior circulation 15%	10% Basilar artery, most frequently at the basilar tip
	5% Vertebral artery, usually at the posterior inferior cerebellar artery

Table 42-5 The Hunt-Hess Clinical Grading System for Subarachnoid Hemorrhage	
Hunt-Hess Grade	Clinical Presentation
0	Asymptomatic; unruptured aneurysm
1	Awake; asymptomatic or mild headache; mild nuchal rigidity
2	Awake; moderate to severe headache, cranial nerve palsy (e.g., cranial nerve III or IV), nuchal rigidity
3	Lethargic; mild focal neurologic deficit (e.g., pronator drift)
4	Stuporous; significant neurologic deficit (e.g., hemiplegia)
5	Comatose; posturing

Patients with symptoms suspicious for SAH should have a head CT immediately. Acute SAH appears as a bright signal in the fissures and CSF cisterns around the base of the brain, as shown in Fig. 42-16. CT is rapid, noninvasive, and approximately 95% sensitive. In patients with suspicious symptoms but negative head CT, a lumbar puncture (LP) should be performed. An LP with xanthochromia and high red blood cell counts (usually 100,000/mL), which do not decrease between tubes 1 and 4, is consistent with SAH. Negative CT and LP essentially rules out SAH. Patients diagnosed with SAH require four-vessel cerebral angiography within 24 hours to assess for aneurysm or other vascular malformation. Catheter angiography remains the gold standard for assessing the patient's cerebral vasculature, relevant anomalies, and presence, location, and morphology of the cerebral aneurysms. Figure 42-17A and 42-17B demonstrate the typical digital subtraction angiographic view of a cerebral aneurysm. Figure 42-17C shows the anatomy of the circle of Willis in a simplified graphic representation to assist in visualizing the locations of various cerebral aneurysms.

Head computed tomography scan of a patient who experienced a sudden, severe headache. Subarachnoid hemorrhage is visible as hyperdense signal in the interhemispheric fissure (1), bilateral sylvian fissures (2 shows the left fissure), and in the ambient cisterns around the midbrain (3). This gives the classic five-pointed-star appearance of a subarachnoid hemorrhage. Visible temporal tips of the lateral ventricles indicate hydrocephalus.

SAH patients should be admitted to the neurologic ICU. Hunt-Hess grade 4 and 5 patients require intubation and hemodynamic monitoring and stabilization. The current standard of care for ruptured aneurysms requires early aneurysmal occlusion. There are two options for occlusion. The patient may undergo craniotomy with microsurgical dissection and placement of a titanium clip across the aneurysm neck to exclude the aneurysm from the circulation and reconstitute the lumen of the parent vessel. The second option is to "coil" the aneurysm via an endovascular approach. The patient is taken to the interventional neuroradiology suite for placement of looped titanium coils inside the aneurysm dome. The coils support thrombosis and prevent blood flow into the aneurysm. Factors favoring craniotomy and clipping include young age, good medical condition, and broad aneurysm necks. Factors favoring coiling include age, medical comorbidities, and narrow aneurysm necks. Due to coil migration or compaction over time, surgical clipping is believed to result in a more definitive cure. The decision to clip or coil is complex and should be fully explored. The International Subarachnoid Aneurysm Trial researchers suggested that endovascular occlusion resulted in better outcomes for certain types of cerebral aneurysms, although this trial was marred by poor selection and randomization techniques, and the validity of its conclusions have been questioned.²⁷ Long-term outcomes may be better in younger patients with clipped aneurysms.²⁸ Debate also continues regarding optimal care for unruptured intracranial aneurysms.²⁹

SAH patients often require 1 to 3 weeks of ICU care after aneurysm occlusion for medical complications that accompany neurologic injury. In addition to routine ICU concerns, SAH patients are also at risk for cerebral vasospasm. In vasospasm, cerebral arteries constrict pathologically and can cause ischemia or stroke from 4 to 21 days after SAH. Current vasospasm prophylaxis includes maintenance of optimal perfusion with

hypertension and mild hypervolemia, as well as administration of nimodipine, a calcium channel blocker that may decrease the incidence and degree of spasm. Neurointerventional options for treating symptomatic vasospasm include intra-arterial papaverine or nicardipine, and balloon angioplasty for larger caliber vessels.

Aneurysmal SAH has an approximate mortality rate of 50% in the first month. Approximately one third of survivors return to pre-SAH function, and the remaining two thirds have mild to severe disability. Most require rehabilitation after hospitalization.

ARTERIOVENOUS MALFORMATIONS

AVMs are abnormal, dilated arteries and veins without an intervening capillary bed. The nidus of the AVM contains a tangled mass of vessels but no neural tissue. AVMs may be asymptomatic or present with SAH or seizures. Small AVMs present with hemorrhage more often than large AVMs, which tend to present with seizures. Headache, bruit, or focal neurologic deficits are less common symptoms. AVMs hemorrhage at an average rate of 2 to 4% a year. Figure 42-18 demonstrates the angiographic appearance of an AVM in arterial and venous phases.

Fig. 42-18.

A. Lateral view after injection of contrast dye in the left internal carotid artery demonstrates a 3 x 4 cm left frontal arteriovenous malformation indicated by *arrowheads*. This image was taken 1.06 seconds after dye injection, and is referred to as an *arterial phase image*. **B.** Same view taken 4.10 seconds after dye injection, providing a *venous phase image*. The *arrow* points to the arteriovenous malformation nidus. The *arrowheads* indicate two pathologically enlarged draining veins. ACA = anterior cerebral artery; ICA = internal carotid artery; MCA = middle cerebral artery.

There are several management differences for SAH due to AVM vs. aneurysm. Definitive therapy for the AVM usually is delayed 3 to 4 weeks to allow the brain to recover from acute injury. There is less risk of devastating early rebleeding from AVMs, and vasospasm is less relevant. Adjacent brain may be hyperemic after removal of the high-flow arteriovenous shunt, making hypertension and hypervolemia harmful rather than beneficial. Three therapeutic modalities for AVMs are currently in common use: microsurgical excision, endovascular glue embolization, and stereotactic radiosurgery (SRS). AVMs that are large, near eloquent cortex, or that drain to deep venous structures are considered high grade and more difficult to surgically resect without causing significant neurologic deficit. Radiosurgery can treat these lesions, although it is limited to lesions <3 cm in diameter and has a 2-year lag time (i.e., the AVM may bleed in the interval). Embolization reduces flow through the AVM. It is usually considered adjunctive therapy, but it may serve as the sole treatment for deep, inaccessible lesions.

TUMORS OF THE CENTRAL NERVOUS SYSTEM

A wide variety of tumors affect the brain and spine. Primary benign and malignant tumors arise from the various elements of the CNS, including neurons, glia, and meninges. Tumors metastasize to the CNS from many primary sources. Presentation varies widely depending on relevant neuroanatomy. Prognosis depends on histology and anatomy. Modern brain tumor centers use team approaches to CNS tumors, as patients may require a combination of surgery, radiation therapy, chemotherapy, SRS, and research protocol enrollment. Tumors affecting the peripheral nervous system are discussed in the Peripheral Nerve section.

Intracranial Tumors

Intracranial tumors can cause brain injury from mass effect, dysfunction or destruction of adjacent neural structures, swelling, or abnormal electrical activity (seizures). Supratentorial tumors commonly present with focal neurologic deficit, such as contralateral limb weakness, visual field deficit, headache, or seizure. Infratentorial tumors often cause increased ICP due to hydrocephalus from compression of the fourth ventricle, leading to headache, nausea, vomiting, or diplopia. Cerebellar hemisphere or brain stem dysfunction can result in ataxia, nystagmus,

or cranial nerve palsies. Infratentorial tumors rarely cause seizures.

All patients with symptoms concerning for brain tumor should undergo MRI with and without gadolinium. Initial management of a patient with a symptomatic brain tumor generally includes dexamethasone for reduction of vasogenic edema and phenytoin if the patient has seized. Patients with significant weakness, lethargy, or hydrocephalus should be admitted for observation until definitive care is administered.

Metastatic Tumors

Prolonged cancer patient survival and improved CNS imaging have increased the likelihood of diagnosing cerebral metastases. The sources of most cerebral metastases are (in decreasing frequency): lung, breast, kidney, GI tract, and melanoma. Lung and breast cancers account for more than half of cerebral metastases. Metastatic cells usually travel to the brain hematogenously and frequently seed the gray-white junction. Other common locations are the cerebellum and the meninges. Meningeal involvement may result in carcinomatous meningitis, also known as *leptomeningeal carcinomatosis*. MRI pre- and postcontrast administration is the study of choice for evaluation. Figure 42-19 demonstrates bilateral cerebellar metastases. These lesions are typically well circumscribed, round, and multiple. Such findings should prompt a metastatic work-up, including CT scan of the chest, abdomen, and pelvis, and a bone scan.

Fig. 42-19.

A. Precontrast T1-weighted axial magnetic resonance imaging demonstrating bilateral hemorrhagic cerebellar metastases. Patient presented with ataxia and then lethargy progressing to deep coma. This patient has total effacement of the fourth ventricle and severe brain stem compression. The fourth ventricle cerebrospinal fluid space should be at the tip of the *arrowhead*. Patient recovered to normal mental status after emergent posterior fossa craniotomy. **B.** Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a ring-enhancing lesion in the lateral left temporal lobe with moderate edema. The uncus (*U*) is compressing the left cerebral peduncle (*CP*) and displacing the brain stem to the right.

Management largely depends upon the primary tumor, overall tumor burden, patient's medical condition, and location and number of metastases. The patient's and family's beliefs regarding aggressive care must be considered. Craniotomy plus whole-brain radiation therapy (WBRT) has been shown to benefit patients with a single surgically accessible metastatic lesion, compared to radiation therapy alone. Median survival increased from 15 to 40 weeks in one randomized trial.³⁰ Postoperative radiotherapy may not increase overall survival but it does significantly reduce original lesion recurrence.³¹ Studies do not support craniotomy unless all detectable metastases can be resected. Recent data suggest that SRS (e.g., gamma knife) may be applied to multiple metastases in one session with improved outcome.³²

Glial Tumors

Glial cells provide the anatomic and physiologic support for neurons and their processes in the brain. The several types of glial cells give rise to distinct primary CNS neoplasms.

ASTROCYTOMA

Astrocytoma is the most common primary CNS neoplasm. The term *glioma* often is used to refer to astrocytomas specifically, excluding other glial tumors. Astrocytomas are graded from I to IV. Grades I and II are referred to as low-grade astrocytoma, grade III as anaplastic astrocytoma, and grade IV as glioblastoma multiforme (GBM). Prognosis varies significantly between grades I/II, III, and IV, but not between I and II. Median survival is 8 years after diagnosis with a low-grade tumor, 2 to 3 years with an anaplastic astrocytoma, and roughly 1 year with a GBM. GBMs account for almost two thirds of all astrocytomas, anaplastic astrocytomas account for two thirds of the rest, and low-grade astrocytomas the remainder. Figure 42-20 demonstrates the typical appearance of a GBM.

Fig. 42-20.

A. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a ring-enhancing lesion in the anteromedial right temporal lobe with central necrosis (*dark area*) consistent with glioblastoma multiforme. **B.** T2-weighted axial magnetic resonance imaging with extensive bright signal signifying peritumoral edema seen with glioblastoma multiformes.

The great majority of astrocytomas infiltrate adjacent brain. Juvenile pilocytic astrocytomas and pleomorphic xanthoastrocytomas are exceptions.

These tumors are circumscribed, low grade, and associated with a good prognosis. Histologic features associated with higher grade include hypercellularity, nuclear atypia, and endovascular hyperplasia. Necrosis is present only with GBMs; it is required for the diagnosis.

Gross total resection should be attempted for suspected astrocytomas. Motor cortex, language centers, deep or midline structures, or brain stem location may make this impossible without unacceptable, devastating neurologic deficit. Such lesions may be limited to stereotactic needle biopsy. Gross total resection followed by radiation therapy improves survival for all grades, although radiation therapy may be delayed until recurrence in low-grade tumors. Chemotherapy such as temozolomide is of limited efficacy and typically is reserved for GBM. There are various ongoing research studies for GBM adjuvant therapy; these should be discussed with the patient and family. Other options include Irtrex-containing balloons for conformal radiation brachytherapy (Glia-Site), placed in the resection cavity at the time of surgery for recurrence. Adjuvant therapy remains marginally effective; survival has changed little over the last several decades.

OLIGODENDROGLIOMA

Oligodendroglioma accounts for approximately 10% of gliomas. They often present with seizures. Calcifications and hemorrhage on CT or MRI suggest the diagnosis. Oligodendrogliomas are also graded from I to IV; grade portends prognosis. Prognosis is better overall than for astrocytomas. Median survival ranges from 2 to 7 years for highest and lowest grade tumors, respectively. Aggressive resection improves survival. Many oligodendrogliomas will respond to procarbazine, lomustine (CCNU), vincristine (PCV) chemotherapy. A particular chromosomal deletion, 1p19q, has been associated with robust response to the chemotherapeutic agent temozolomide. Radiation has not been clearly shown to prolong survival.

EPENDYMOMA

The lining of the ventricular system consists of cuboidal/columnar ependymal cells from which ependymomas may arise. Although most pediatric ependymomas are supratentorial, two thirds of adult ependymomas are infratentorial. Supratentorial ependymomas arise from the lateral or third ventricles. The infratentorial tumors arise from the floor of the fourth ventricle (i.e., off the posterior brain stem). The most common symptoms are headache, nausea, vomiting, or vertigo, secondary to increased ICP from obstruction of CSF flow through the fourth ventricle. The tumors may grow out the foramina of Luschka to form a cerebellopontine angle mass. They may also spread through the CSF to form "drop mets" in the spinal canal. The two main histologic subtypes are papillary and anaplastic, the latter characterized by increased mitotic activity and areas of necrosis. Gross total resection often is impossible because the tumor arises from the brain stem. The goal of surgery is to achieve maximal resection without injuring the very delicate brain stem. Suboccipital craniotomy and midline separation of the cerebellar hemispheres allows access to tumors in the fourth ventricle. Postoperative radiation therapy significantly improves survival. Patients with CSF spread documented by LP or contrast MRI should also have whole-spine radiation plus focused doses to visualized metastases.

CHOROID PLEXUS PAPILLOMA

The choroid plexus is composed of many small vascular tufts covered with cuboidal epithelium. It represents part of the interface between blood and brain. The choroid cells create CSF from blood and release it into the ventricular system. Choroid plexus papillomas and choroid plexus carcinomas (rare, mostly pediatric) may arise from these cells. Papillomas usually occur in infants (typically supratentorial in the lateral ventricle) but also occur in adults (usually infratentorial in the fourth ventricle). Papillomas are well circumscribed and vividly enhance due to extensive vasculature. Like ependymomas, adult choroid plexus papillomas usually present with symptoms of increased ICP. Treatment is surgical excision. Total surgical excision is curative; recurrent papillomas should be re-resected. Radiation or chemotherapy are not indicated for papillomas. Radiation is adjunctive to aggressive surgery for carcinomas, but the results are generally poor.

Neural Tumors and Mixed Tumors

Neural and mixed tumors are a diverse group that includes tumors variously containing normal or abnormal neurons and/or normal or abnormal glial cells. Primitive neuroectodermal tumors arise from bipotential cells, capable of differentiating into neurons or glial cells.

MEDULLOBLASTOMA

Primitive neuroectodermal tumor is the most common type of medulloblastoma. Most occur in the first decade of life, but there is a second peak around age 30. Medulloblastoma is the most common malignant pediatric brain tumor. They are usually midline. Most occur in the cerebellum and present with symptoms of increased ICP. Histologic characteristics include densely packed small round cells with large nuclei and scant

cytoplasm. They are generally not encapsulated, frequently disseminate within the CNS, and should undergo surgical resection followed by radiation therapy and chemotherapy.

GANGLIOGLIOMA

Ganglioglioma is a mixed tumor in which both neurons and glial cells are neoplastic. They occur in the first three decades of life, often in the medial temporal lobe, as circumscribed masses that may contain cysts or calcium and may enhance. The presenting symptom is usually a seizure, due to the medial temporal location. Patients have a good prognosis after complete surgical resection.

Neural Crest Tumors

Multipotent neural crest cells develop into a variety of disparate cell types, including smooth muscle cells, sympathetic and parasympathetic neurons, melanocytes, Schwann cells, and arachnoid cap cells. They migrate in early development from the primitive neural tube throughout the body.

Miscellaneous Tumors

MENINGIOMA

Meningiomas are derived from arachnoid cap cells of the arachnoidea mater. They appear to arise from the dura mater grossly and on MRI and are commonly referred to as *dural-based tumors*. The most common intracranial locations are along the falx (Fig. 42-21), the convexities (i.e., over the cerebral hemispheres), and the sphenoid wing. Less common locations include the foramen magnum, olfactory groove, and inside the lateral ventricle. Most are slow growing, encapsulated, benign tumors. Aggressive atypical or malignant meningiomas may invade adjacent bone or cerebral cortex. Previous cranial irradiation increases the incidence of meningiomas. Approximately 10% of patients with a meningioma have multiple meningiomas. Total resection is curative, although involvement with small perforating arteries or cranial nerves may make total resection of skull base tumors impossible without significant neurologic deficit. Small, asymptomatic meningiomas can be followed until symptomatic or until significant growth is documented on serial imaging studies. Atypical and malignant meningiomas may require postoperative radiation. Patients may develop recurrences from the surgical bed or distant de novo tumors.

Fig. 42-21.

Postcontrast T1-weighted coronal magnetic resonance imaging demonstrating a brightly enhancing lesion arising from the falx cerebri with moderate edema and mass effect on the right lateral ventricle. This is a falcine meningioma. Note also the small separate meningioma arising from the dura over the cerebral convexity.

VESTIBULAR SCHWANNOMA (ACOUSTIC NEUROMA)

Vestibular schwannomas arise predominantly from the superior half of the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII) (Fig. 42-22). Commonly, patients present with progressive hearing loss, tinnitus, or balance difficulty. Large tumors may cause brain stem compression and obstructive hydrocephalus. Bilateral acoustic neuromas are pathognomonic for neurofibromatosis type 2 (NF2), a syndrome resulting from a chromosome 22 mutation. NF2 patients have an increased incidence of spinal and cranial meningiomas and gliomas.

A. Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a brightly enhancing mass on the right vestibular nerve with an enhancing tail going into the internal auditory canal (*arrowhead*). Pathology demonstrated vestibular schwannoma. **B.** Postcontrast T1-weighted sagittal magnetic resonance imaging of the same lesion, indicated by the *arrowhead*. Note small incidental meningioma at the top of the scan.

Vestibular schwannomas may be treated with microsurgical resection or conformal SRS (gamma knife or linear accelerator technology). The main

complication with treatment is damage to the facial nerve (cranial nerve VII), which runs through the internal auditory canal with the vestibulocochlear nerve. Risk of facial nerve dysfunction increases with increasing tumor diameter.

PITUITARY ADENOMA

Pituitary adenomas arise from the anterior pituitary gland (adenohypophysis). Tumors <1 cm diameter are considered microadenomas; larger tumors are macroadenomas. Pituitary tumors may be functional (i.e., secrete endocrinologically active compounds at pathologic levels) or nonfunctional (i.e., secrete nothing or inactive compounds). Functional tumors are often diagnosed when quite small, due to endocrine dysfunction. The most common endocrine syndromes are Cushing's disease, due to adrenocorticotrophic hormone secretion, Forbes-Albright syndrome, due to prolactin secretion, and acromegaly, due to growth hormone secretion. Nonfunctional tumors are typically diagnosed as larger lesions causing mass effects such as visual field deficits due to compression of the optic chiasm or panhypopituitarism due to compression of the gland. Figure 42-23 demonstrates a large pituitary adenoma. Hemorrhage into a pituitary tumor causes abrupt symptoms of headache, visual disturbance, decreased mental status, and endocrine dysfunction. This is known as *pituitary apoplexy*.

Fig. 42-23.

Postcontrast T1-weighted sagittal magnetic resonance imaging demonstrating a large sellar/suprasellar lesion (*arrowheads*) involving the third ventricle superiorly and abutting the midbrain and pons posteriorly. The patient presented with progressive visual field and acuity loss. Pathology and lab work revealed a nonfunctioning pituitary adenoma.

Symptomatic pituitary tumors should be decompressed surgically to eliminate mass effect and/or to attempt an endocrine cure. However, prolactin-secreting tumors (prolactinomas) usually shrink with dopaminergic therapy alone, namely bromocriptine, which inhibits production and secretion of prolactin. Consider surgery for prolactinomas with persistent mass effect or endocrinologic dysfunction in spite of adequate dopamine agonist therapy. Most pituitary tumors are approached through the nose via the transsphenoidal approach. Minimally invasive endoscopic sinus surgery techniques are being used increasingly.

HEMANGIOBLASTOMA

Hemangioblastomas occur almost exclusively in the posterior fossa. Twenty percent occur in patients with von Hippel-Lindau (VHL) disease, a multisystem neoplastic disorder. Other tumors associated with VHL are renal cell carcinoma, pheochromocytoma, and retinal angiomas. Many

appear as cystic tumors with an enhancing tumor on the cyst wall known as the *mural nodule* . Surgical resection is curative for sporadic (non-VHL associated) tumors. Pathology reveals abundant thin-walled vascular channels; internal debulking may be bloody. En bloc resection of the mural nodule alone, leaving the cyst wall, is sufficient.

LYMPHOMA

CNS lymphoma may arise either primarily in the CNS or secondarily from systemic disease. Recent rising incidence may be due to growing transplant and AIDS populations. Presenting symptoms include mental status changes, headache due to increased ICP, and cranial nerve palsy due to lymphomatous meningitis (analogous to carcinomatous meningitis). Often, lymphoma appears hyperdense on CT due to dense cellularity, and most lesions typically enhance with contrast. Surgical excision is not indicated. Stereotactic needle biopsy usually confirms the diagnosis. Subsequent treatment includes steroids, whole-brain radiation, and chemotherapy. Intrathecal methotrexate is an option.

Embryologic Tumors

Embryologic tumors result from embryonal remnants that fail to involute completely or differentiate properly during development.

CRANIOPHARYNGIOMA

Craniopharyngiomas are benign cystic lesions that occur most frequently in children. There is a second peak of incidence around 50 years of age. Calcification occurs in all pediatric and roughly half of adult craniopharyngiomas. Symptoms result from compression of adjacent structures, especially the optic chiasm. Pituitary or hypothalamic dysfunction or hydrocephalus may develop. Treatment is primarily surgical. Excision is somewhat easier in children, as the tumor is often soft and easily suctioned. Adult tumors are often firm and adherent to adjacent vital structures. Visual loss, pituitary endocrine hypofunction, diabetes insipidus, and cognitive impairment from basal frontal injury are common complications.

EPIDERMOID

Epidermoid tumors are cystic lesions with stratified squamous epithelial walls from trapped ectodermal cell rests that grow slowly and linearly by desquamation into the cyst cavity. The cysts contain keratin, cholesterol, and cellular debris (Fig. 42-24). They occur most frequently in the cerebellopontine angle and may cause symptoms due to brain stem compression. Recurrent bouts of aseptic meningitis may occur due to release of irritative cyst contents into the subarachnoid space (Mollaret's meningitis). Treatment is surgical drainage and removal of the cyst wall. Intraoperative spillage of cyst contents can lead to severe chemical meningitis and must be avoided by containment and aspiration.

Postcontrast T1-weighted axial magnetic resonance imaging demonstrating a nonenhancing mass in the left cerebellopontine angle with brain stem compression. *White arrowhead* indicates interface of tumor and brain stem. *Black arrowhead* indicates deformed fourth ventricle. Pathology revealed epidermoid tumor.

DERMOID

Dermoids are less common than epidermoid tumors. They contain hair follicles and sebaceous glands in addition to a squamous epithelium. Dermoids may be found anywhere along the craniospinal axis. They are more commonly midline structures and are associated with more anomalies than epidermoids. They may be traumatic, as from a LP that drags skin structures into the CNS. Bacterial meningitis may occur when associated with a dermal sinus tract to the skin along the spine. Treatment of symptomatic lesions is surgical resection, again with care to control cyst contents.

TERATOMA

Teratomas are germ cell tumors that arise in the midline, often in the pineal region (the area behind the third ventricle, above the midbrain and cerebellum). They contain elements from all three embryonal layers: ectoderm, mesoderm, and endoderm. Teratomas may contain skin, cartilage, GI glands, and teeth. Teratomas with more primitive features are more malignant, while those with more differentiated tissues are more benign. Surgical excision may be attempted. However, prognosis for malignant teratoma is very poor.

Spinal Tumors

A wide variety of tumors affect the spine. Approximately 20% of CNS tumors occur in the spine. Unlike cranial tumors, the majority of spinal tumors are histologically benign. Understanding two major spinal concepts—stability and neural compression—facilitates an understanding of the effects of spinal tumors. Destruction of bones or ligaments can cause spinal instability, leading to deformities such as kyphosis, subluxation, or possible subsequent neural compression. Tumor growth in the spinal canal or neural foramina can cause direct compression of the spinal cord or nerve roots and cause pain and loss of function. Classically, the pain is worse at night. Anatomic categorization provides the most logical approach to these tumors. Certain tumors present in characteristic locations. An understanding of the anatomy leads to an understanding of the clinical presentation and possible therapeutic options.

EXTRADURAL TUMORS

Extradural tumors account for approximately 55% of spinal tumors. This category includes tumors arising within the bony vertebral structures and from within the epidural space. Destruction of the bone can lead to instability and fractures, causing pain and/or deformity. Epidural expansion can lead to spinal cord or nerve root compression with myelopathy, radiculopathy, or a combination thereof.

Metastatic Tumors

Metastatic tumors are the most common extradural tumors. Spinal metastases most commonly occur in the thoracic and lumbar vertebral bodies because the greatest volume of red bone marrow is found in these regions. The most common primary sources of spine metastasis are lymphoma, lung, breast, and prostate. Other sources include renal, colon, thyroid, sarcoma, and melanoma. Most spinal metastases create osteolytic lesions. Osteoblastic, sclerotic lesions suggest prostate cancer in men and breast cancer in women.

Patients with progressive neurologic dysfunction due to a metastatic lesion should undergo urgent surgery followed by radiation therapy.³³ Patients with debilitating pain may undergo radiation therapy with close observation for neurologic deterioration. Preoperative neurologic function correlates with postoperative function. Patients may lose function over hours. These patients should be given high-dose IV dexamethasone, taken immediately to MRI, and then to the OR or radiation therapy suite. Indications for surgery include failure of radiation therapy, spinal instability, recurrence after radiation therapy, and the need for diagnosis in cases of unknown primary tumors. Most cases with significant bone involvement require both decompression and fusion. Bony fusion usually takes 2 to 3 months. Prognosis governs operative decisions. Surgery is unlikely to improve quality of life for patients with a life expectancy of 3 months or less, but it is likely to improve quality of life for patients with life expectancy of 6 months or more. Benefit for patients with 3- to 6-months life expectancy is unclear and requires frank discussion with the patient and family. Patients who are unlikely to tolerate general anesthesia, are already completely paralyzed, or who have very radiosensitive tumors such as multiple myeloma and lymphoma, should not generally undergo surgery.

Primary Tumors

Hemangiomas are benign tumors found in 10% of people at autopsy. They occur in the vertebral bodies of the thoracolumbar spine and are frequently asymptomatic. They are often vascular and may hemorrhage, causing pain or neurologic deficit. Large hemangiomas can destabilize the spine and predispose to fracture. Osteoblastic lesions include osteoid osteoma and osteoblastoma. The latter tends to be larger and more destructive. Aneurysmal bone cysts are non-neoplastic, expansile, lytic lesions containing thin-walled blood cavities that usually occur in the lamina or spinous processes of the cervicothoracic spine. They may cause pain or sufficiently weaken the bone to cause a fracture. Cancers arising primarily in the bony spine include Ewing’s sarcoma, osteosarcoma, chondrosarcoma, and plasmacytoma.

INTRADURAL EXTRAMEDULLARY TUMORS

Intradural extramedullary tumors constitute approximately 40% of spinal tumors and arise from the meninges or nerve root elements. They may compress the spinal cord, causing myelopathy, or the nerve roots, causing radiculopathy. The most common intradural extramedullary tumors are typically benign, slow growing, and well circumscribed. Rare benign epidural masses include arachnoid cysts, dermoids, and epidermoids. Rare malignant epidural tumors include metastases and high-grade gliomas, or "drop" metastases from posterior fossa gliomas.

Meningioma

Meningiomas arise from the arachnoidea mater. They appear to be dural based and enhance on MRI. An enhancing "dural tail" may be seen. They occur most commonly in the thoracic spine (Fig. 42-25) but also arise in the cervical and lumbar regions. Some spinal meningiomas grow into the epidural space. Growth causes cord compression and progressive myelopathy with hyperreflexia, spasticity, and gait difficulties. Surgical excision is the treatment of choice. The surgeon often finds a clean margin between the tumor, dura, and spinal cord, allowing en bloc resection without damage to the cord.

T2-weighted sagittal magnetic resonance imaging of the midthoracic spine demonstrating a well-encapsulated tumor arising from the dura posteriorly and compressing the spinal cord. *Arrowhead* points to dorsal location of the mass. The patient presented with worsening gait and lower extremity spasticity. Pathology demonstrated meningioma.

Schwannoma

Schwannomas are derived from peripheral nerve sheath Schwann cells. They are benign, encapsulated tumors that rarely undergo malignant degeneration. Two thirds are entirely intradural, one sixth are entirely extradural, and one sixth have a classic "dumbbell" shape from intradural and extradural components. Symptoms result from radiculopathy, often presenting as pain or myelopathy. Symptomatic lesions should be surgically resected. The parent nerve root usually can be preserved. Patients with multiple schwannomas likely have NF2. In these patients, a careful neurologic examination is needed to determine which lesions are symptomatic and require resection.

Neurofibroma

In contrast to schwannomas, neurofibromas tend to appear more fusiform and to grow within the parent nerve, rather than forming an encapsulated mass branching off the nerve. Neurofibromas are benign but not encapsulated. They present similarly to schwannomas, and the two may be difficult to differentiate on imaging. Salvage of the parent nerve is more challenging with neurofibromas. To improve the likelihood of total resection, thoracic and high cervical nerve roots may be sacrificed with minimal deficit. Patients with multiple neurofibromas likely have NF1, also known as *von Recklinghausen's neurofibromatosis*. Resection for symptomatic lesions should be offered.

INTRAMEDULLARY TUMORS

Intramedullary tumors constitute approximately 5% of spinal tumors. They arise from within the parenchyma of the spinal cord. Common presenting symptoms are local dysesthesia, burning pain, radicular pain, sensory loss, weakness, or sphincter dysfunction. Patients with such symptoms should undergo MRI of the entire spine with and without enhancement.

Ependymoma

Ependymomas are the most common intramedullary tumors in adults. There are several histologic variants. The myxopapillary type occurs in the conus medullaris or the filum terminale in the lumbar region and has the best prognosis after resection. The cellular type occurs more frequently in the cervical cord. Many spinal ependymomas have cystic areas and may contain hemorrhage. Surgical removal can improve function. A

distinct tumor margin often exists, allowing safer excision. Postoperative radiation therapy after subtotal resection may prolong disease control.

Astrocytoma

Astrocytomas are the most common intramedullary tumors in children, although they also occur in adults. They may occur at all levels, although more often in the cervical cord. The tumor may interfere with the CSF-containing central canal of the spinal cord, leading to a dilated central canal, referred to as *syringomyelia* (*syrinx*). Spinal astrocytomas are usually low grade, but complete excision is rarely possible due to the nonencapsulated, infiltrative nature of the tumor. As a result, patients with astrocytomas fare worse overall than patients with ependymomas.

OTHER TUMORS

Other types of rare tumors include high-grade astrocytomas, dermoids, epidermoids, teratomas, hemangiomas, hemangioblastomas, and metastases. Patients usually present with pain. Prognosis generally depends on preoperative function and the histologic characteristics of the lesion.

SPINE: BASIC CONCEPTS

The spine is a complex structure and is subject to an extensive array of pathologic processes, including degeneration, inflammation, infection, neoplasia, and trauma. Discussions of spine trauma, tumor, and infection are addressed separately in this chapter in the Infection—Spine, Spinal Tumors, and Spine Trauma sections. General concepts, common patterns of disease, and basic operative interventions are presented here.

The spine consists of a series of stacked vertebrae, intervening discs, and longitudinal ligaments. The vertebrae consist of the vertebral body anteriorly and the pedicles, articular facets, laminae, and spinous processes posteriorly. The intervertebral discs have two components. The tough, fibrous ring that runs around the outer diameter of the two adjacent vertebral bodies is known as the annulus fibrosus. The spongy material inside the ring of the annulus is known as the *nucleus pulposus*. The annulus and the nucleus provide a cushion between adjacent vertebral bodies, absorb forces transmitted to the spine, and allow some movement between the vertebral bodies. The ligaments stabilize the spine by limiting the motion of adjacent vertebrae.

Stability and neural compression are the two concepts critical to understanding the mechanics and pathologic processes affecting the spine.

Stability

The spinal column is the principal structural component of the axial spine, and it must bear significant loads. The vertebrae increase in size from the top to the bottom of the spine, correlating with the increased total loads that the more caudal elements must bear. The cervical spine is the most mobile. Cervical stability depends greatly on the integrity of the ligaments that run from level to level. The thoracic spine is the least mobile, due to the stabilizing effect of the rib cage. The lumbar spine has relatively massive vertebrae, supports heavy loads, and has intermediate mobility. The sacral spine is fused together and has no intrinsic mobility. The load borne by the lumbar spine is transmitted to the sacrum, and then the pelvis through the sacroiliac joints. The coccyx is the most inferior segment of the spine and has no significant contribution to load bearing or mobility.

A stable spine is one that can bear normally experienced forces resulting from body mass, movement, and muscle contraction, while maintaining normal structure and alignment. An unstable spine will shift or sublux under these forces. The determinants of spinal stability vary throughout the cervical, thoracic, and lumbar portions. In elementary form, stability depends on the structural integrity of the hard, bony elements of the vertebral column, as well as the tensile integrity and security of the supporting ligamentous attachments. Plain x-rays and CT scans are sensitive for detecting bony defects such as fractures or subluxation, while MRI better detects disruptions of the soft tissues, including ligaments and intervertebral discs. Specific patterns of abnormalities seen on imaging studies may suggest or diagnose spinal instability.

A common form of nontraumatic spinal instability is lumbar spondylolisthesis, which is typically a forward slippage of a lumbar vertebra relative to the lower vertebra on which it rests. This results from congenital or degenerative disruption of the pars interarticularis, the critical bridge of bone that spans adjacent facet joints. In the setting of a pars defect, there is no solid bony connection between the adjacent vertebrae. The spine is unstable and anterior listhesis (slippage) may result. Patients typically present with severe low back pain that is exacerbated with movement and load bearing (mechanical low back pain). Radiculopathy in this setting indicates neuroforaminal compression. Figure 42-26 demonstrates an L4 and L5 spondylolisthesis.

Fig. 42-26.

Lateral lumbar spine x-ray demonstrates a 25% anterior slippage of L4 on L5 due to a defect in the L4 pars interarticularis. This is called *spondylolisthesis*.

Neural Compression

Besides providing a stable central element of the body's support structure, the spine also must protect the spinal cord as it descends in the central canal and the nerve roots as they pass from the central canal out the neural foramina to form the peripheral nervous system. In a healthy spine, the spinal cord and nerve roots are suspended in CSF, free of mechanical compression. Pathologic processes that can lead to CSF space impingement and neural compression include: hypertrophic degenerative changes in the intervertebral discs and facet joints, expansion of epidural masses such as tumors or abscesses, and subluxation (i.e., slippage) of adjacent vertebral bodies. Subluxation may be due to trauma that exceeds the spine's load-bearing capabilities and leads to structural failure, or chronic structural degradation by degenerative disease, infection, or tumor. Subluxation reduces the cross-sectional area of the central canal and the neural foramina (see Fig. 42-10B). Reduced central canal area can lead to myelopathy. Reduced neural foraminal area can lead to radiculopathy.

MYELOPATHY

Compression of the spinal cord can cause a disturbance of function known as *myelopathy*. This dysfunction may be secondary to the direct effects of compression, cord ischemia due to reduced perfusion, or pathologic changes due to repeated cord trauma. These mechanisms lead to demyelination of the corticospinal tracts, which are long descending motor tracts. Corticospinal tract damage leads to upper motor neuron signs and symptoms, including hyperreflexia, spasticity, and weakness. These mechanisms also cause damage to the dorsal columns, which carry ascending proprioception, vibration, and two-point discrimination information. Loss of proprioception makes fine motor tasks and ambulation difficult.

RADICULOPATHY

Compression of the nerve roots causes disturbance of root function, known as *radiculopathy*. Characteristic features of radiculopathy include lower motor neuron signs and symptoms (hyporeflexia, atrophy, and weakness) and sensory disturbances such as numbness or tingling

sensations (paresthesias), burning sensations (dysesthesias), and shooting (radicular) pain. Myelopathy and radiculopathy often present together in diseases that involve the central canal and the neural foramina. This combination can lead to lower motor neuron dysfunction at the level of disease, and upper motor neuron dysfunction below that level.

Patterns of Disease

CERVICAL RADICULOPATHY

The cervical nerve roots exit the central canal above the pedicle of the same-numbered vertebra and at the level of the higher adjacent intervertebral disc. For example, the C6 nerve root passes above the C6 pedicle at the level of the C5–C6 discs. The cervical nerve roots may be compressed acutely by disc herniation, or chronically by hypertrophic degenerative changes of the discs, facets, and ligaments. Table 42-6 summarizes the effects of various disc herniations. Most patients with acute disc herniations will improve without surgery. NSAIDs or cervical traction may help alleviate symptoms. Patients whose symptoms do not resolve or who have significant weakness should undergo decompressive surgery. The two main options for nerve root decompression are anterior cervical discectomy and fusion (ACDF) and posterior cervical foraminotomy (keyhole foraminotomy). ACDF allows more direct access to and removal of the pathology (anterior to the nerve root). However, the procedure requires fusion because discectomy causes a collapse of the interbody space and instability will likely occur. Figure 42-27 demonstrates a C6–C7 ACDF with the typical interposed graft and plating system. Keyhole foraminotomy allows for decompression without requiring fusion, but it is less effective for removing centrally located canal pathology.

Table 42-6 Cervical Disc Herniations and Symptoms by Level					
Level	Frequency (%)	Root Injured	Reflex	Weakness	Numbness
C4–C5	2	C5	—	Deltoid	Shoulder
C5–C6	19	C6	Biceps	Biceps brachii	Thumb
C6–C7	69	C7	Triceps	Wrist extensors (wrist drop)	Second and third digits
C7–T1	10	C8	—	Hand intrinsic	Fourth and fifth digits

A. Anteroposterior cervical spine x-ray showing the position of an anterior cervical plate used for stabilization after C6–C7 discectomy. Patient presented with right triceps weakness and dysesthesias in the right fifth digit. Magnetic resonance imaging revealed a right paracentral C6–C7 herniated disc compressing the exiting C7 nerve root. **B.** Lateral cervical spine x-ray of the same patient clearly demonstrates the position of the plate and screws. The allograft bone spacer placed in the drilled-out disc space is also apparent.

CERVICAL SPONDYLOTIC MYELOPATHY

The term *spondylosis* refers to diffuse degenerative and hypertrophic changes of the discs, intervertebral joints, and ligaments, which collectively result in spinal stenosis. Spinal cord dysfunction (myelopathy) due to cord compression from cervical spinal degenerative disease is therefore referred to as cervical spondylotic myelopathy (CSM). CSM classically presents with spasticity and hyperreflexia due to corticospinal tract dysfunction, upper extremity weakness and atrophy from degeneration of the motor neurons in the anterior horns of the spinal gray matter, and loss of lower extremity proprioception due to dorsal column injury. Figure 42-28 demonstrates typical findings. Patients complain of difficulty buttoning shirts, using utensils, and ambulating. Spondylosis is usually diffuse, so the usual treatment for CSM is multilevel (usually C3–C7) cervical laminectomy, although patients with disease localized over one to three levels may be candidates for anterior decompression and fusion. Figure 42-29 demonstrates the postoperative appearance of a vertebral corpectomy and fusion for CSM. Thorough cervical laminectomy decompresses the cord posteriorly. Patients often have slow recovery due to the extensive chronic changes in the cervical cord and may benefit from rehabilitation programs. The other disease that classically presents with combined upper and lower motor neuron symptoms is amyotrophic lateral sclerosis (ALS). Care must be taken to avoid offering cervical laminectomy to a patient with undiagnosed ALS. Two findings help differentiate CSM from ALS: cranial nerve dysfunction such as dysphagia (not typically caused by cervical spine disease) and sensory disturbance (not found in ALS).

Lateral cervical spine x-ray status post C5 corpectomy for cervical spondylotic myelopathy. This involves removal of the C4–C5 disc, C5 vertebral body, and C5–C6 disc, decompressing at two levels. A bone strut is visible bridging C4 to C6. The plate and screws stabilize the segments.

THORACIC DISC HERNIATION

Thoracic disc herniation accounts for <1% of herniated discs. A patient may present with radicular pain or sensorimotor changes in the lower extremities due to cord compression. A posterior approach via midline incision and laminectomy should be avoided because of the high incidence of cord injury from manipulation and retraction. Anterior approaches via thoracotomy minimize risk to the cord and allow excellent access to the disc. The radicular arteries running from the aorta to the thoracic cord should be spared, when possible, to avoid ischemia. Alternatively, a posterolateral approach is possible via resection of the rib head and facet joint. Finally, a transpedicular approach may be attempted for lateral disc herniations.³⁴

LUMBAR RADICULOPATHY

Lumbar nerve roots exit the thecal sac, pass over the higher adjacent disc space, and exit the canal under the pedicle of the same-numbered vertebra. Therefore, the L5 nerve root passes over the L4–L5 disc space and exits under the L5 pedicle (Fig. 42-30). Lumbar discs may herniate with or without a history of trauma or straining. They normally cause lancinating (radicular) pain down the leg (Table 42-7). Most acute herniated lumbar discs improve symptomatically without surgery. Surgery is indicated for symptoms persisting more than 6 to 8 weeks, progressive motor deficit (e.g., foot drop), or for patients with incapacitating pain not manageable with analgesics. Discectomy is performed using a midline incision, partial removal of the overlying laminae (hemilaminectomy or laminotomy), identification of the thecal sac and nerve root, and extraction of disc fragments. Free-floating disc fragments may be found. Often, however, the herniated disc material is still contained within the annulus, requiring incision of the posterior longitudinal ligament and curettage of the disc space. After lumbar discectomy, approximately two thirds of patients will have complete relief of pain, and up to 85% will have significant improvement.

Fig. 42-30.

NEUROGENIC CLAUDICATION

Neurogenic claudication is characterized by low back and leg pain that occurs while walking and is relieved by stopping, leaning forward, or sitting. It is normally caused by degenerative lumbar stenosis causing compression of the cauda equina. Neurogenic claudication must be distinguished from vascular claudication, which tends to resolve quickly with cessation of walking. There is typically no need to change position, and the pain follows a stocking distribution rather than a dermatomal distribution. Pallor and coldness of the feet, and normal neurologic examination are also typical, though diabetic patients may present a challenge with microvascular neuropathy. Patients with neurogenic claudication have a slowly progressive course and may be surgical candidates when their pain interferes with their lifestyle. The usual surgery is an L3 to L5 lumbar laminectomy to decompress the nerve roots.

CAUDA EQUINA SYNDROME

Cauda equina syndrome is due to compression of the cauda equina and may result from massive disc herniation, EDH, epidural abscess, tumor, or subluxation from trauma. Patients with cauda equina compression often present with urinary retention, saddle anesthesia, or progressing leg weakness. Saddle anesthesia is numbness in the perineum, genitals, buttocks, and upper inner thighs. Patients with suspected cauda equina syndrome should undergo immediate MRI of the lumbar spine to evaluate for a surgical lesion. Mass lesions should be removed urgently via laminectomy to preserve sphincter function and ambulation.

Spine Fusion Surgery

Fusion surgery is often required for patients with spinal instability resulting from disease, surgical intervention, or both. Fusion procedures lock adjacent vertebrae together. Fusion occurs when the body forms a solid mass of bone incorporating the adjacent vertebrae, eliminating normal intervertebral movement. Stabilization and immobilization promote bony fusion. Internal instrumentation and external orthoses are often used to stabilize and immobilize the fused spinal segments.

Spinal Instrumentation

Internal fixation devices for spinal segmental immobilization have been developed for all levels of the spine. Most spinal instrumentation constructs have two elements. The first element is a device that solidly attaches to the vertebral bodies. Options include wires wrapped around laminae or spinous processes, hooks placed under the lamina or around the pedicles, or screws placed in the pedicles or the vertebral bodies. The second element is a device that traverses vertebral segments. Options include rods and plates that lock directly to the wires, hooks, or screws at each vertebral level. Spinal instrumentation devices are available for anterior and posterior fusion in the cervical, thoracic, and lumbar regions. Most modern spinal instrumentation devices are made of titanium to minimize problems with future MRI scanning (Fig. 42-31). All spinal instrumentation constructs will eventually fail by loosening or breaking if bony fusion does not occur.

A. Lateral lumbar spine x-ray showing pedicle screws and connecting rods used to stabilize L4 with respect to L5. This instrumentation was placed as part of a fusion operation to stabilize progressive L4–L5 spondylolisthesis with intractable low back pain. **B.** Anteroposterior lumbar spine x-ray showing L3 to L5 instrumentation with pedicle screws and connecting rods. The patient had previously sustained an L4 burst fracture. Note the significant loss of height of the L4 body compared to adjacent levels. The small row of staples to the right delineates the incision over the iliac crest used to harvest cancellous bone as a nonstructural osteoinductive autograft fusion designed to induce formation of a solid bone bridge from L3 to L5 (arthrodesis).

Arthrodesis

Arthrodesis refers to the obliteration of motion or instability by incorporating the relevant components into a solid mass of bone. Arthrodesis must occur in any fused segment to have long-term stability. Failure of arthrodesis results in failed fusion, often in the form of a fibrous nonunion. The rates of successful fusion are higher in the cervical spine than the lumbar spine. Arthrodesis requires ingrowth of new bone formed by the patient's osteoblasts across the unstable defect. Inserting graft material, such as autograft or allograft, into the defect provides a bridge for osteoblasts and promotes fusion. The term *autograft* refers to the patient's own bone, often harvested from the iliac crest. Iliac crest bone graft is a source of both cortical and cancellous bone. Cortical bone provides structural support, while cancellous bone provides a matrix for bony ingrowth. The term *allograft* refers to sterilized bone from human tissue banks. Allografts also may be cortical, cancellous, or both. Allograft lacks the array of osteoinductive endogenous compounds intrinsic to autograft, although supplemental products such as demineralized bone matrix paste can be added to encourage new bone formation. Other techniques for increasing the rates of successful fusion are being developed, including the integration of osteoinductive bone morphogenetic proteins, known as *BMPs*, into the fusion constructs.

Dynamic stabilization refers to the creation of spinal stability without achieving a bony fusion. The concept applies to both cervical and lumbar motion segments. Artificial lumbar and cervical disc replacement therapies are recent developments in degenerative spine disease that address this concept. However, their use is limited to very select cases. Another motion preservation technique that may hold promise is segmental "soft" stabilization.³⁵ In cases of degenerative spondylolisthesis, such systems in the lumbar spine allow for decompressive laminectomy without increasing slippage. In theory, adjacent level facets and discs are spared the stresses of a neighboring bony fusion moment arm.

PERIPHERAL NERVE

Common pathologic processes that compromise function of the peripheral nervous system include mechanical compression, ischemia, inflammation, and neoplasia.

Peripheral Nerve Tumors

Most peripheral nerve tumors are benign and grow slowly. Significant pain increases the likelihood that the patient has a malignant tumor. Treatment for peripheral nerve tumors is surgical resection to establish diagnosis and evaluate for signs of malignancy. These tumors have various degrees of involvement with the parent nerve. Some can be resected with minimal or no damage to the nerve. Tumors that grow within the nerve often contain functioning fascicles. Total excision of these tumors requires sacrifice of the parent nerve. The choice of subtotal resection, nerve preservation, and observation, vs. total resection with nerve sacrifice depends on tumor histology and the function of the parent nerve.

SCHWANNOMA

Schwannomas are the most common peripheral nerve tumors, also referred to as *neurilemmas* or *neurinomas*. Most occur in the third decade of life. These benign tumors arise from Schwann cells, which form myelin in peripheral nerves. The most characteristic presentation is a mass lesion with point tenderness and shooting pains on direct palpation. Spontaneous or continuous pain suggests malignancy. Schwannomas tend to grow slowly and eccentrically on parent nerves. The eccentric location and discrete encapsulated nature of these tumors often allow total resection without significant damage to the parent nerve. Subtotal resection and observation is reasonable for schwannomas entwined in important nerves, as the incidence of malignant transformation is extremely low.

NEUROFIBROMA

Neurofibromas arise within the nerve and tend to be fusiform masses, unlike schwannomas, which tend to grow out of the nerve. Neurofibromas often present as a mass that is tender to palpation. They usually lack the shooting pains characteristic of schwannomas. Neurofibromas are often difficult to resect completely without sacrifice of the parent nerve. Neurofibromas have a higher incidence of malignant transformation; therefore, patients with known residual tumors require close observation. Patients with NF1 often have multiple neurofibromas. These patients should be offered resection for symptomatic tumors. Risk of malignant degeneration is up to 10%. Malignant neurofibromas have the histologic characteristics of sarcoma.

MALIGNANT NERVE SHEATH TUMORS

Malignant nerve sheath tumors include solitary sarcomas, degenerated neurofibromas, and neuroepitheliomas. Patients with malignant peripheral nerve tumors typically complain of constant pain, rather than pain only on palpation, and are more likely to have motor and sensory deficits in the distribution of the parent nerve. Treatment for these tumors is radical excision. This often requires sacrifice of the parent nerve. Invasion of nearby soft tissues may occur and necessitate wide resection or amputation in an attempt to prevent systemic metastasis.

Entrapment Neuropathies

Entrapment neuropathy is neurologic dysfunction in nerves passing through a pathologically small, fixed space. Nerve dysfunction may result directly from chronic, repetitive pressure on the nerve, or from ischemic damage due to impaired perfusion.³⁶ Entrapment causing dysfunction of nerve signaling may cause numbness, paresthesias, weakness, or muscle atrophy. By far the two most common sites of entrapment neuropathy are the ulnar nerve at the medial aspect of the elbow and the median nerve at the wrist. EMG/NCS usually demonstrate slowing across the entrapped segment of nerve. Mechanical peripheral nerve disorders resulting from trauma (brachial plexus disruption, radial nerve damage from humerus fractures, and common peroneal nerve crush injuries) are discussed in the section on Trauma.

ULNAR NEUROPATHY

The ulnar nerve has contributions from the C7, C8, and T1 nerve roots, arises from the medial cord of the brachial plexus, and supplies most of the intrinsic hand muscles (interossei and third and fourth lumbricals), and sensation to the fourth and fifth digits. It passes posteriorly to the medial epicondyle at the elbow in the condylar groove. This segment is superficial and subject to external compression and repetitive minor impacts. Patients with ulnar entrapment at the elbow present with numbness and tingling in the medial palm, as well as the fourth and fifth digits. Motor deficits include weakness and wasting of the intrinsic hand muscles. Treatment for symptomatic ulnar entrapment neuropathy is surgical exploration and incision of the fibrous aponeurotic arch that overlies the nerve. A 6-cm curvilinear incision centered between the medial epicondyle and the olecranon allows exploration of up to 10 cm of nerve and lysis of compressive tissues.

CARPAL TUNNEL SYNDROME

The median nerve has contributions from the C5 to T1 nerve roots, arises from the medial and lateral cords of the brachial plexus, and supplies the muscles of wrist and finger flexion and sensation to the palmar aspect of the first, second, and third digits. The median nerve passes through the carpal tunnel in the wrist, lying superficial to the four deep and four superficial flexor tendons. The transverse carpal ligament is a tough, fibrous band that forms the roof of the carpal tunnel. The ligament attaches to the pisiform and hamate medially and the trapezium and scaphoid laterally. Patients complain of numbness and tingling in the supplied digits, clumsiness, and worsening with sleep or repetitive wrist movement. Patients may notice wasting of the thenar eminence. Treatment for symptomatic carpal tunnel syndrome unresponsive to splinting, analgesics, and rest is surgical division of the flexor retinaculum. This often provides prompt relief of pain symptoms and slow recovery of numbness and strength.

Autoimmune and Inflammatory Disorders

These are not surgical diseases, but merit brief mention as they are included in the differential diagnosis for new-onset weakness. Their characteristic presentations help distinguish them from weakness due to structural lesions.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute inflammatory demyelinating polyradiculopathy often occurring after viral infection, surgery, inoculations, or mycoplasma infections. Patients classically present with weakness ascending from the legs to the body, arms, and even cranial nerves. Symptoms usually progress over 2 to 4 weeks and then resolve. Care is supportive. Respiratory weakness may require ventilatory support.

MYASTHENIA GRAVIS

Myasthenia gravis is an autoimmune process in which antibodies form to the acetylcholine receptors of muscles, leading to fluctuating weakness. Most patients have either thymic hyperplasia or thymoma. The most common symptoms are diplopia, ptosis, dysarthria, and dysphagia. More severe cases have limb or respiratory involvement. Weakness worsens with repetitive movement. Treatment is with acetylcholinesterase inhibitors and possible thymectomy.

EATON-LAMBERT SYNDROME

Eaton-Lambert syndrome is an autoimmune process with antibodies to the presynaptic calcium channels. This is a paraneoplastic syndrome most commonly associated with oat cell carcinoma. Patients have weakness of proximal limb muscles that improves with repetitive movement. This diagnosis must prompt oncologic evaluation.

INFECTION

CNS infections of interest to neurosurgeons include those that cause focal neurologic deficit due to mass effect, require surgical aspiration or drainage because antibiotic therapy alone is insufficient, cause mechanical instability of the spine, or occur after neurosurgical procedures.

Cranial

OSTEOMYELITIS

The skull is highly vascular and resistant to infections. Osteomyelitis of the skull may develop by contiguous spread from pyogenic sinus disease or from contamination by penetrating trauma. *Staphylococcus aureus* and *S. epidermidis* are the most frequent causative organisms. Patients usually present with redness, swelling, and pain. Contrast head CT aids diagnosis and shows the extent of involved bone, along with associated abscesses or empyema. Osteomyelitis treatment entails surgical débridement of involved bone followed by 2 to 4 months of antibiotics. Craniotomy wound infections are a special concern because performing a craniotomy creates a devascularized free bone flap susceptible to infection and not penetrated by antibiotics. These wounds must be débrided and the bone flaps removed and discarded. Subsequent care involves appropriate antibiotic therapy, observation for signs of recurrent infection off antibiotics, and return to the OR for titanium or methylmethacrylate cranioplasty 6 to 12 months later.

SUBDURAL EMPYEMA

Subdural empyema is a rapidly progressive pyogenic infection. The subdural space lacks significant barriers to the spread of the infection, such

as compartmentalization or septations. Subdural empyema usually occurs over the cerebral convexities. Potential infectious sources include sinus disease, penetrating trauma, and otitis. Streptococci and staphylococci are the most frequently found organisms. Presenting symptoms include fever, headache, neck stiffness, seizures, or focal neurologic deficit. Neurologic deficit results from inflammation of cortical blood vessels, leading to thrombosis and stroke. The most common deficit is contralateral hemiparesis. Patients with suggestive symptoms should undergo rapid contrast CT scan. LP frequently fails to yield the offending organism and risks herniation due to mass effect. Typical treatment is wide hemicraniectomy, dural opening, and lavage. The pus may be thick or septated, making burr hole drainage or small craniotomy insufficient. Patients then require 1 to 2 months of antibiotics. Subdural empyema has 10 to 20% mortality risk and common chronic sequelae, including seizure disorder and residual hemiparesis. However, many patients make a good recovery.

BRAIN ABSCESS

Brain abscess is encapsulated infection within the brain parenchyma. It may spread hematogenously in patients with endocarditis or intracardiac or intrapulmonary right-to-left shunts, by migration from the sinuses or ear, or via direct seeding by penetrating trauma. Disorganized cerebritis often precedes formation of the organized, walled-off abscess. Patients may present with nonspecific symptoms such as headache, nausea, or lethargy, or with focal neurologic deficit such as hemiparesis. Alternatively, patients may present in extremis if the abscess ruptures into the ventricular system. Abscesses appear as well-demarcated, ring-enhancing, thin-walled lesions on CT scan and MRI, and often have associated edema and mass effect. Patients require antibiotic therapy after needle aspiration or surgical evacuation. Antibiotic therapy without surgical evacuation may be considered for patients with small, multiple, or critically located abscesses. Abscesses that are large, cause mass effect, decreased mental status, or that fail to decrease in size after 1 week of antibiotics, should be evacuated. Nonsurgical management still requires aspiration or biopsy for organism culture and sensitivities. Blood and CSF cultures rarely give definitive diagnosis. Removal of an encapsulated abscess significantly shortens the length of antibiotic therapy required to eliminate all organisms. Common chronic sequelae after successful treatment include seizures or focal neurologic deficit.

Spine

PYOGENIC VERTEBRAL OSTEOMYELITIS

Pyogenic vertebral osteomyelitis is a destructive bacterial infection of the vertebrae, usually of the vertebral body. Vertebral osteomyelitis frequently results from hematogenous spread of distant disease, but may occur as an extension of adjacent disease, such as psoas abscess or perinephric abscess. *S. aureus* and *Enterobacter* spp. are the most frequent etiologic organisms. Patients usually present with fever and back pain. Diabetics, IV drug abusers, and dialysis patients have increased incidence of vertebral osteomyelitis. Epidural extension may lead to compression of the spinal cord or nerve roots with resultant neurologic deficit. Osteomyelitis presents a lytic picture on imaging and must be distinguished from neoplastic disease. Adjacent intervertebral disc involvement occurs frequently with pyogenic osteomyelitis, but rarely with neoplasia. Plain films and CT help assess the extent of bony destruction or deformity such as kyphosis. MRI shows adjacent soft tissue or epidural disease. Most cases can be treated successfully with antibiotics alone, although the organism must be isolated to steer antibiotic choice. Blood cultures may be positive. Surgical intervention may be required for débridement when antibiotics alone fail, or for stabilization and fusion in the setting of instability and deformity.

TUBERCULOUS VERTEBRAL OSTEOMYELITIS

Tuberculous vertebral osteomyelitis, also known as *Pott's disease*, occurs most commonly in underdeveloped countries and in immunocompromised people. Several features differentiate tuberculous osteomyelitis from bacterial osteomyelitis. The infection is indolent and symptoms often progress slowly over months. Tuberculosis rarely involves the intervertebral disc. The involved bodies may have sclerotic rather than lytic changes. Multiple nonadjacent vertebrae may be involved. The upper lumbar and lower thoracic vertebrae are most commonly affected. Diagnosis requires documentation of acid-fast bacilli. Treatment involves long-term antimycobacterial drugs. Patients with spinal instability or neural compression from epidural inflammatory tissue should undergo débridement and fusion as needed.

DISCITIS

Primary infection of the intervertebral disc space, or discitis, is most commonly secondary to postoperative infections. Spontaneous discitis occurs more commonly in children. *S. epidermidis* and *S. aureus* account for most cases. The primary symptom is back pain. Other signs and symptoms include radicular pain, fevers, paraspinal muscle spasm, and localized tenderness to palpation. Many cases will resolve without

antibiotics, which generally are given for positive blood or biopsy cultures or persistent constitutional symptoms. Most patients will have spontaneous fusion across the involved disc and do not need débridement or fusion.

EPIDURAL ABSCESS

Epidural abscesses may arise from or spread to the adjacent bone or disc, so distinguishing between vertebral osteomyelitis or discitis and a spinal epidural abscess may be difficult. The most common presenting signs and symptoms are back pain, fever, and tenderness to palpation of the spine. The most significant risk of epidural abscess is weakness progressing to paralysis due to spinal cord or nerve root damage. Cord and root damage may be due to direct compression or to inflammatory thrombosis resulting in venous infarction. *S. aureus* and *Streptococcus* spp. are the most common organisms. Methicillin-resistant *S. aureus* now constitutes a significant proportion of these infections, as high as 40%.³⁷ The source may be hematogenous spread, local extension, or operative contamination. MRI best demonstrates the epidural space and degree of neural compromise. Patients with spinal epidural abscess and neurologic compromise should undergo surgical débridement for decompression and diagnosis, followed by culture-directed antibiotic therapy. Relative contraindications to surgery include prohibitive comorbidities or total lack of neurologic function below the involved level. Patients with no neurologic deficits and an identified organism may be treated with antibiotics alone and very close observation. However, this management strategy remains somewhat controversial because these patients can undergo rapid and irreversible neurologic decline. Most epidural abscesses can be accessed via laminectomy without fusion. Collections predominantly anterior to the cervical or thoracic cord may require anterior approach and fusion.

FUNCTIONAL NEUROSURGERY

Epilepsy Surgery

Seizures result from uncontrolled neuronal electrical activity. Seizures may result from irritative lesions in the brain, such as tumors or hematomas, or from physiologic or structural abnormalities. Seizures may involve a part of the brain (focal) or the entire brain (generalized). Focal seizures may be associated with normal consciousness (simple) or decreased consciousness (complex). All generalized seizures cause loss of consciousness. Focal seizures may secondarily generalize. Patients with multiple unprovoked seizures over time are considered to have epilepsy. The type of epilepsy depends on such factors as type of seizures, electroencephalographic (EEG) findings, associated syndromes, and identifiable etiologies. All patients with unexplained seizures (i.e., no obvious cause such as head trauma or alcohol withdrawal) require thorough neurologic evaluation, including imaging to evaluate for a mass lesion. Antiepileptic drugs (AEDs) form the first line of therapy for epilepsy, initially as monotherapy, then as combination therapy. Epilepsy patients who have failed satisfactory trials of several AED combination regimens may be candidates for surgical intervention. Lack of seizure control or patient intolerance of the medications may constitute failure. Epilepsy surgery can decrease the frequency of seizures by resection of the electrical source of the seizures, or decrease the severity of seizures by disconnecting white matter tracts through which the abnormal electrical activity spreads. Three types of epilepsy surgery are discussed. Epilepsy surgery appears to be extremely underused, given the relatively low risk of the procedures, and the crippling social and economic effects of uncontrolled or partially controlled epilepsy.³⁸ Patients with symptoms, imaging abnormalities, and EEG analysis compatible with a specific seizure focus are most likely to have good results from epilepsy surgery.

ANTERIOR TEMPORAL LOBECTOMY

Medial temporal lobe structural abnormalities can lead to complex partial seizures (CPS). Many patients with CPS have poor seizure control on medications. Patients with CPS may have significant reduction in seizure frequency or cessation of seizures after resection of the anterior temporal lobe. The amygdala and the head of the hippocampus are removed as part of the lobectomy. Resection may be taken back approximately 4.5 cm from the temporal tip in the language-dominant hemisphere, and 6 cm from the temporal tip in the language nondominant hemisphere, with low risk of significant deficits.³⁹ Two main risks of anterior temporal lobectomy are memory problems and visual problems. Removal of the hippocampus in a patient with an atrophied or nonfunctional contralateral hippocampus causes a global memory deficit. Interruption of the optic radiations, which carry visual signals from the contralateral superior visual quadrants of both eyes, causes a contralateral superior quadrantanopia, known as a *pie in the sky* field deficit.

CORPUS CALLOSOTOMY

Patients with generalized seizures, atonic seizures associated with drop attacks, or absence seizures, who are found to have bilaterally coordinated pathologic cortical discharges on EEG and who fail AED therapy, may be candidates for corpus callosotomy. The corpus callosum is a

large white matter tract that connects the cerebral hemispheres. Loss of consciousness requires simultaneous seizure activity in both hemispheres. Focal or partial seizures may spread via the corpus callosum to the contralateral hemisphere, causing generalization and loss of consciousness. Division of the corpus callosum can interrupt this spread. Patients may have decreased numbers of seizures and/or fewer episodes of lost consciousness. Usually only the anterior half or two thirds of the corpus callosum is divided, as more extensive division increases the risk of disconnection syndrome. Patients with disconnection syndrome are unable to match objects in the opposite visual hemifields, to identify objects held in one hand with the other hemifield, and to write with the left hand or name objects held in the left hand (in left hemisphere–dominant patients).

HEMISPHERECTOMY

Children with intractable epilepsy, structural anomalies in one hemisphere, and contralateral hemiplegia, may have improved seizure control after resection of the hemisphere (anatomic hemispherectomy) or disruption of all connections to the hemisphere (functional hemispherectomy). Functional hemispherectomy often is preferred over anatomic hemispherectomy because of the high incidence of complications such as hematoma formation and ventriculoperitoneal shunt dependence associated with the latter.

Deep Brain Stimulation

Patients with essential tremor and medically refractory Parkinson's disease have abnormal activity in the nuclei of the basal ganglia. The basal ganglia are extrapyramidal structures that modulate and regulate signals in the corticospinal (pyramidal) tracts. Abnormal extrapyramidal activity leads to the loss of the normal modulation of movement and thus the clinical manifestations of the diseases. Fine electrical leads placed in these deep basal ganglia nuclei and connected to pulse generators modify the pathologic signals. The pulse generators are usually placed in the chest in a manner similar to cardiac pacemakers. Connector wires travel from the generators in the subcutaneous space up the neck and in the subgaleal space in the head, to connect the pulse generators to the electrical leads. Proper lead placement is accomplished with stereotactic guidance. A frame is rigidly fixed to the patient's head, and an MRI is obtained with the frame in place. Calculation of the coordinates of the millimeter-sized deep brain nuclei is performed in relation to the three-dimensional space defined by the fixed frame, allowing for accurate targeting of the fine electrical leads (Fig. 42-32). Postoperatively, the pulse generators can be interrogated and adjusted with hand-held, transcutaneous, noninvasive devices as needed for symptom control.

Fig. 42-32.

Fast spin echo coronal magnetic resonance imaging demonstrating position of deep brain stimulator leads in the subthalamic nuclei bilaterally. The electrodes appear thick and wavy due to magnetic susceptibility artifact.

ESSENTIAL TREMOR

Essential tremors are action tremors of 4 to 8 Hz rhythmic oscillation that often affect one arm or the head. Essential tremor often starts in the third or fourth decade of life, and increases in frequency and amplitude with age. Beta blockers decrease symptoms. Patients with poor medical control and significant functional impairment can benefit significantly from placement of a deep brain stimulator in the contralateral ventralis intermediate nucleus of the thalamus. Placement of ventralis intermediate nucleus stimulators for essential tremor appears to result in durable symptom control with good postoperative neuropsychologic outcomes in properly selected patients.^{40,41}

PARKINSON'S DISEASE

Parkinson's disease is a progressive disorder characterized by rigidity, bradykinesia, and resting tremor, due to loss of dopamine-secreting neurons in the substantia nigra and locus ceruleus. It is also known as *paralysis agitans*. Dopaminergic agents such as levodopa/carbidopa and anticholinergic agents such as amantadine and selegiline form the basis of medical therapy. Patients with poor medical control or significant drug side effects may benefit significantly from placement of bilateral deep brain stimulators in the subthalamic nuclei. Although the globus pallidus interna has also been a widely targeted area, the subthalamic nuclei is now the most accepted target in deep brain stimulation for Parkinson's disease.⁴² Deep brain stimulation provides durable symptom relief with good postoperative neuropsychologic function in properly selected patients.⁴³

Trigeminal Neuralgia

Trigeminal neuralgia, also known as *tic douloureux*, is characterized by repetitive, unilateral, sharp, and lancinating pains in the distribution of, typically, the second, but sometimes third, branch of cranial nerve V, the trigeminal nerve. The patient may describe a "trigger point," an area on the face that elicits the pain when touched. A current leading etiologic hypothesis for trigeminal neuralgia is irritation and pulsatile compression of the root entry zone of the nerve by an artery in the posterior fossa, usually a loop of the superior cerebellar artery. The pain is excruciating and can be debilitating. Medical therapy, including carbamazepine and amitriptyline, may reduce the frequency of events. Options for medically refractory cases include percutaneous injection of glycerol into the path of the nerve, peripheral transection of the nerve branches, SRS, and microvascular decompression (MVD).

MVD involves performing a small posterior fossa craniotomy on the side of the symptoms, retraction of the cerebellar hemisphere, and exploration of cranial nerve V. If an artery is found near the nerve, the vessel is freed of any adhesions and nonabsorbable material is placed between the nerve root and the artery. MVD remains the first definitive management option because SRS is associated with a substantial incidence of facial numbness.^{44,45}

STEREOTACTIC RADIOSURGERY

The term *stereotactic radiosurgery* (SRS) refers to techniques that allow delivery of high-dose radiation that conforms to the shape of the target and has rapid isodose fall-off, minimizing damage to adjacent neural structures. The two most common devices used for conformal SRS for intracranial lesions are the LINAC (linear accelerator) and the gamma knife. LINAC delivers a focused beam of x-ray radiation from a port that arcs part way around the patient's head. Linear accelerators are commonly used to provide fractionated radiation for lesions outside the CNS. They are found in most radiation oncology departments. SRS can be performed with these existing units, after upgrades to the software and collimators. The gamma knife delivers 201 focused beams of gamma radiation from cobalt sources through a specially designed colander-like helmet. Gamma knife units are used only for intracranial disease and cost up to \$5 million; thus, they are most appropriate in high patient-volume centers. There is ongoing debate in the literature regarding the two technologies.^{46–48} Both continue to evolve, allowing more precise and complex isodose conformation to complex lesions. Most lesions can be treated equally well with either technology. Lesions abutting the medulla or the spinal cord should not be treated with SRS, because these structures do not tolerate the radiation dose delivered to structures within millimeters of the target. Also, medullary or spinal cord compression can result from swelling of the lesion after the radiosurgery dose, resulting in devastating neurologic deficit.

Proton beam is an evolving SRS technology that may play a specialized role in treatment of lesions where posttarget exiting radiation limits photon-based therapies.⁴⁹ For example, the physical properties of photons cause destruction upon entry and exit from tissue, which can be

particularly harmful to skull-base or clival lesions such as chordoma, in which the exiting pathway travels through the brain stem. Proton beam therapy uses accelerated protons, which dissipate energy upon impact and do not cause additional exiting damage. Currently, there are very few centers using this technology.

CyberKnife is another radiosurgery system that has neurosurgical application. It is a frameless, robotic, LINAC-based system that allows for targeting of spinal neoplasms with higher resolution than conventional external beam radiotherapy.⁵⁰ Using imaging tracking in real time, the CyberKnife is able to adjust to breathing artifact and patient movement. The application of this technology is rapidly growing.

Arteriovenous Malformations

SRS has been found to be an effective stand-alone therapy for AVMs up to 3 cm in diameter. SRS is best for lesions that are difficult to access surgically due to high likelihood of postoperative neurologic deficit. SRS is not effective for lesions >3 cm. Effective obliteration and elimination of the risk of hemorrhage takes 2 to 3 years. Overall, there is an approximately 2% annual incidence of AVM hemorrhage,⁵¹ although one study found a 50% decrease in hemorrhage rate during the latency period before angiographic obliteration.⁵² Nonetheless, surgical excision remains the preferred therapeutic modality, while SRS is reserved for cases deemed very high-risk for surgery due to location or patient factors.⁵³ Some patients with large AVMs who undergo surgery will have unresectable residual lesions. SRS may be used as an effective adjunctive therapy in these patients.

Vestibular Schwannomas

SRS has been introduced as a therapeutic alternative to microsurgical resection for vestibular schwannomas up to 2.5 cm in maximum diameter. SRS provides high rates of tumor growth arrest and possible reduction in size with low rates of facial nerve palsy. Patients with functional ipsilateral preprocedure hearing may be more likely to retain functional hearing postprocedure than with microsurgery. The limitations of SRS include inability to treat tumors >2.5 cm, the possibility of radiation-induced malignant transformation of these benign tumors, and lack of long-term follow-up. SRS centers are accumulating experience with these tumors and accumulating data on long-term results.^{54,55} The indications for microsurgery and SRS will continue to evolve. Either approach should be undertaken at a high-volume center, as studies show the patient outcomes improve with increased surgeon experience.⁵⁶

Intracranial Metastases

Patients with solitary or multiple intracranial metastases may be treated primarily with SRS.⁵⁷ Patients have improved survival after SRS compared to no treatment or WBRT, and similar survival to patients undergoing total surgical resection. Patients with lesions >3 cm in diameter or evidence of ICH should undergo surgical decompression rather than SRS. Some studies show improved survival with up to seven intracranial masses. Patients with multiple intracranial masses have almost zero long-term survival, and most will die of their intracranial disease. Patients with intracranial metastases live 3 to 6 months on average with medical care and WBRT. This can be extended to 9 to 16 months with SRS or surgery, depending on tumor type, age, and patient condition.⁵⁸

CONGENITAL AND DEVELOPMENTAL ANOMALIES

Dysraphism

Dysraphism describes defects of fusion of the neural tube involving the neural tube itself, or overlying bone or skin. Dysraphism may occur in the spine or the head. Neural tube defects are among the most common congenital abnormalities. Prenatal vitamins, especially folic acid, reduce the incidence of neural tube defects.

Spina Bifida Occulta

Spina bifida occulta is congenital absence of posterior vertebral elements. The spinous process is always missing, the laminae may be missing to various degrees, but the underlying neural tissues are not involved. Spina bifida occulta is found in 25% of the general population, and is asymptomatic unless associated with other developmental abnormalities.

Spina Bifida with Myelomeningocele

Spina bifida with myelomeningocele describes the congenital absence of posterior vertebral elements with protrusion of the meninges through

the defect, with underlying neural structural abnormalities. Common findings include weakness and atrophy of the lower extremities, gait disturbance, urinary incontinence, constipation, and deformities of the foot. Myelomeningoceles arising from the high lumbar cord usually cause total paralysis and incontinence, while those arising from the sacral cord may have only clawing of the foot and partial urinary function loss. Myelomeningocele patients often have hydrocephalus and a Chiari II malformation, an abnormal downward herniation of the cerebellum and brain stem through the foramen magnum. Patients with abnormal protrusion of meninges through the bony defect without abnormalities of the underlying neural tissue have a meningocele. Most of these patients are neurologically normal.

Encephalocele

Herniation of brain encased in meninges through the skull that forms an intracranial mass is referred to as *encephalocele*. Herniation of meninges without brain tissue is referred to as a *meningocele*. Most occur over the convexity of the skull. More rarely, the tissue protrudes through the skull base into the sinuses. Treatment involves excision of the herniated tissue and closure of the defect. Most patients with encephaloceles and meningoceles have impaired cognitive development. Patients with greater amounts of herniated neural tissue tend to have more severe cognitive deficits.

Craniosynostosis

Craniosynostosis is the abnormal early fusion of a cranial suture line with resultant restriction of skull growth in the affected area and compensatory bulging at the other sutures. Skull growth occurs at the cranial sutures for the first 2 years of life, at the end of which the skull has achieved >90% of its eventual adult size. Fusion of the sagittal suture, or sagittal synostosis, results in a boat-shaped head, known as *scaphocephaly*. Unilateral coronal synostosis results in ipsilateral forehead flattening and outward deviation of the orbit, known as *plagiocephaly*. The contralateral normal forehead appears to bulge by comparison. Bilateral coronal synostosis results in a broad, flattened forehead, known as *brachycephaly*, and is often associated with maxillary hypoplasia and proptosis. Unilateral or bilateral lambdoid synostosis results in flattening of the occiput. Occipital flattening can result from abnormal suture fusion (synostosis), or from physical remolding of the skull caused by always placing the baby in the supine position for sleep (known as *positional plagiocephaly*). Placing the baby in the prone position or tilted onto the contralateral side may restore near-normal skull shape in most cases of lambdoid synostosis, avoiding surgery. Treatment for synostoses in general is surgical, involving resection of the fused suture, or more complex reconstructive techniques for severe or refractory cases.

Hydrocephalus

Excess CSF in the brain that results in enlarged ventricles is known as *hydrocephalus*. The adult forms approximately 500 mL of CSF per day, much of it in the lateral ventricles. CSF flows from the ventricles to the subarachnoid space and is then absorbed into the venous blood through the arachnoid granulations. Hydrocephalus may be classified as communicating or obstructive (outlined in the next two sections), and congenital or acquired. Congenital lesions associated with or causing hydrocephalus include stenosis of the cerebral aqueduct, Chiari malformation, myelomeningocele, and intrauterine infection. Acquired hydrocephalus may result from occlusion of arachnoid granulations by meningitis, germinal matrix hemorrhage, or SAH. CSF pathways may be occluded by adjacent tumors (Fig. 42-33).

A. Axial head computed tomography scan revealing dilated ventricular system. Note dilated atria of the lateral ventricles (*arrowheads*) and rounded third ventricle (*arrow*). The large size of the ventricles and lack of transependymal flow indicate a chronic process (contrast to Fig. 42-2). The patient had normal-pressure hydrocephalus and had improved ambulation after placement of a ventriculoperitoneal shunt. **B.** Higher cut from same scan showing ventricular catheter in place in the frontal horn of the right lateral ventricle.

COMMUNICATING HYDROCEPHALUS

Obstruction at the level of the arachnoid granulations constitutes communicating hydrocephalus. This usually causes dilation of the lateral, third, and fourth ventricles equally. The most common causes in adults are meningitis and SAH. Hydrocephalus may be transient after SAH, with re-

establishment of normal CSF absorption after the protein content of the CSF returns to normal and the granulations reopen.

OBSTRUCTIVE HYDROCEPHALUS

Obstruction of CSF pathways is known as *obstructive hydrocephalus*. Ventricles proximal to the obstruction dilate, while those distal to the obstruction remain normal in size. Typical patterns include dilation of the lateral ventricles due to a colloid cyst occluding the foramen of Monro, dilation of the lateral and third ventricles due to a tectal (midbrain) glioma or pineal region tumor occluding the cerebral aqueduct, or dilation of the lateral and third ventricles with obliteration of the fourth ventricle by an intraventricular tumor of the fourth ventricle. Obstructive hydrocephalus may present precipitously and require urgent shunting to prevent herniation.

Chiari I Malformation

Chiari I malformation is the caudal displacement of the cerebellar tonsils below the foramen magnum. It may be seen as an incidental finding on MRI scans in asymptomatic patients. Symptomatic patients usually present with headache, neck pain, or symptoms of myelopathy, including numbness or weakness in the extremities. A syrinx may be associated, but the brain stem and lower cranial nerves are normal in Chiari I malformations. Chiari II malformations are more severe and involve caudal displacement of the lower brain stem and stretching of the lower cranial nerves. Symptomatic patients may be treated with suboccipital craniectomy to remove the posterior arch of the foramen magnum, along with removal of the posterior ring of C1. Removal of these bony structures relieves the compression of the cerebellar tonsils and cervicomedullary junction, and may allow re-establishment of normal CSF flow patterns. Figure 42-34 demonstrates typical MRI appearance of a Chiari I malformation.

Fig. 42-34.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 43. Orthopedic Surgery >

KEY POINTS

1. The assessment of any patient with a musculoskeletal complaint or injury must include a careful history and a physical examination that includes the neurologic, vascular, and muscular bony assessment.
2. Fractures frequently involve significant soft tissue as well as bony injury.
3. Open fractures (fractures where the fracture hematoma extends to a wound in the skin) require urgent operative irrigation and débridement.
4. The majority of fractures can be managed nonoperatively, with a cast or a brace.
5. Orthopedic injuries in pediatric patients are managed differently than in adults. Injury to the physis (growth plate) are common and require special management. Bone injury in young patients heal so quickly that prompt treatment and close follow-up is critical.

GROWING SPECIALTY

Orthopedic surgery is a broad and actively growing surgical specialty. It concerns the nonoperative and operative treatment of disorders of the musculoskeletal system including bones, joints, muscles, tendons, ligaments, and nerves. The orthopedic surgeon must be familiar with the normal growth and development of the musculoskeletal system, as well as disorders that can arise from genetic or developmental abnormalities, trauma, infection, inflammatory processes, the degenerative process, and neoplasm. In every patient, the orthopedic surgeon will work hard to find nonsurgical solutions for the patient's condition. However, surgical treatments are often necessary to preserve or restore musculoskeletal function, assist in healing, or palliate pain.

Anatomy of Long Bones

Much of an orthopedic surgeon's practice concerns treatment of the "long bones." Long bones generally consist of an epiphysis (the portion of the bone on either end which usually contains an articular surface). The *epiphysis* is formed from an epiphyseal ossification center at either end of most long bones separated from the *metaphysis* of the long bone by the growth plate (Fig. 43-1). After skeletal maturity, the ends of bones continue to be referred to as the *epiphyseal region*. The metaphysis of a long bone is the region immediately below the growth plate or its remnant. The metaphysis tapers to become the shaft or *diaphysis* of the long bone.

Fig. 43-1.

 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Long bones have three sections. The end is the epiphysis or secondary ossification center, the adjacent area is the metaphysis, and the middle of the bone is the diaphysis. The metaphysis is broader than the diaphysis, has a thin cortex, and is composed of primarily cancellous bone.

Long bones are composed of one or more articular surfaces, covered with hyaline cartilage, thick durable cortex of dense bone, and an interior region of trabecular bone and marrow. It is important to know that all bone is subject to turnover with resorption and new bone formation, occurring in both the trabecular bone and the cortex. Cortical bone does turn over considerably slower than trabecular bone, however, by a factor of approximately seven or eight (Fig. 43-2). Another major function of the bone, in addition to its mechanical function, is the regulation of serum calcium levels. Hematopoiesis also occurs in the marrow.

Fig. 43-2.

The cells that synthesize bone matrix (osteoid) are the *osteoblasts*. Essentially all surfaces of the bone are covered with osteoblasts or osteocytes. Osteoblasts, which are active in bone synthesis, are noted histologically to be large with abundant cytoplasm. Quiescent osteoblasts are thin and "flat."

Joint Anatomy

Mobile joints are called *diarthrodial joints*. In such joints, there is no direct bone to bone contact. Instead, weight bearing and motion are accomplished through intervening surfaces or hyaline (articular) cartilage. Stability of the joints is accomplished through musculotendinous action and limited and guided by the presence of ligaments and the joint capsule itself. The joint capsule also serves to enclose the lubricating synovial fluid, which provides nutrition to the chondrocytes in the articular cartilage and facilitates gliding motions between the two cartilage surfaces.

Muscle Anatomy

Skeletal muscle is, by weight, the single largest tissue in the body. The structure of skeletal muscle is indicated in Fig. 43-3. Muscle contraction is accomplished by adenosine triphosphate driven sliding motions between actin and myosin filaments, driven by the adenosine triphosphatase of the myosin molecule. Precisely arranged, actin and myosin containing sarcomeres form the basic contractile apparatus, the *myofiber*. Multiple myofibers compose a muscle fiber and multiple muscle fibers compose the *fascicle*. In turn, multiple fascicles form a muscle.

Basic Biomechanics

An understanding of basic biomechanics is critical to an orthopedic surgeon. Bone generally is considered to be a rather static rigid structure; however, this is a misconception. Not only are the cells and matrix of the bone subject to regular turnover, the bone itself normally flexes and bends to a surprising degree.

Biomechanical engineers use the words *stress* and *strain* to describe the material properties of bone, and tissue, as well as orthopedic implants. The word *stress* refers to force exerted per unit area. The word *strain* is used to define deformation of a material when placed under stress. The mechanical properties of most materials can be displayed in a stress/strain curve. The *stiffness* of a material is expressed by the slope of such a curve. Strain in a bone or other material is usually elastic (or completely reversible) under low levels of stress. When the exerted force causes reversible changes to the material, plastic deformation or mechanical failure (fracture) is said to occur.

The mechanical behaviors of a substance can be changed substantially by the presence of focal defects in the material. For example, a bone will break much more easily at or near a small defect of the bone. This is due to concentration of stress forces in this area, a so-called *stress riser*. This can occur at the site of a destructive lesion, such as a tumor, or more importantly, can result from surgical intervention with the creation of screw holes (Fig. 43-4).

Fig. 43-4.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

A stress riser is a hole or defect in a material that produces a concentration of forces. This increases the risk of the material failing under conditions that, without the stress riser, would not lead to failure of the material.

Biomechanics of Skeletal Motion

The joints move by the action of muscles on the bone through their tendinous attachments. The effect of a muscle contraction depends on its origin and insertion and on the constraints and geometry of the intervening joint or joints. The effect of most muscles can be usefully viewed as a *lever arm*. The amount of force needed to move an object is heavily influenced by the length of the level arm (Fig. 43-5). Contraction of a muscle unit with a short lever arm results in a large application of force, generally at a low speed. A longer lever arm will diminish the amount of effective force that can be exerted, but can result in a great rapidity of motion. Thus, because of the lever arms present at the elbow and shoulder, one can move the hand and throw an object at a rate many times faster than the maximal rate of muscle contraction.

Fig. 43-5.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

The biceps muscle with its insertion to the bicipital tuberosity of the radius has a short lever arm compared to the length of the forearm that is the lever arm for the weight in the hand. The biceps force must be much greater than the weight of the ball because of the difference between the two lever arms.

TRAUMATIC BONE LESIONS

Fracture Repair

The biologic and histologic events in fracture repair can be divided into three general stages. The duration and classification of each stage is variable based on age, general health, and other factors. Additionally, these stages can overlap, as there are no definitive features to suggest progression of one stage to another. The three stages are (a) circulatory, which includes closure of any wound and primary callus formation, (b) metabolic, the stage where the primary callus is reinforced leading to clinical union, and (c) mechanical, the stage in which the united bone is remodeled along the lines of stress.

Once a fracture has occurred, the surrounding muscle, vessels, and other soft tissues are damaged as well. A cellular response, with inflammatory cells and undifferentiated mesenchymal cells, is prominent in the first 3 to 5 days.

The biologic events that lead to fracture healing are complex, and as yet, incompletely understood. Most fractures heal by way of callus formation. In some unusual instances, when fractured fragments are in close physical contact, bone healing involves direct osteonal penetration from across the fracture site, a process called *primary bone healing*. In normal long-bone fracture healing, the clinical process has been described in four stages: inflammation, soft callus, hard callus, and bone remodeling.

These mesenchymal cells are the hallmark of the circulatory stage of fracture repair and lead to the appearance of chondrocytic, osteoblastic, and vascular cells. These components form the structure of the primary callus. The hematoma is invaded from the periphery by granulation tissue that adds to and aids in the callus formation.

The cellular phase is followed by the vascular phase. The hematoma gradually is replaced by a cellular and vascular bed. With this comes a passive hyperemia and decreased oxygen tension that is conducive for cartilage formation. While this occurs, there is an osteoclastic response to remove the previously damaged bone and make way for the newly formed bone. With enough cartilage formation and the subsequent endochondral ossification, the primary callus is formed. Changes also occur in the periosteum adjacent to the fracture. The periosteal cells adjacent to the fracture become active and produce a matrix that elevates the periosteum and adds to the primary callus. This brings the *circulatory stage* to a close.

The second stage is primarily concerned with reinforcement of the callus. The initial callus is remodeled by the removal and replacement of the woven bone into a more mature lamellar bone. The lamellar bone provides the strength and support at this stage. The necrotic debris and inflammation is gone by this point, and the callus is primarily defined by the bone formation and remodeling.

The metabolic phase leads into the mechanical stage with remodeling and realignment of bone and callus along the lines of stress. This process continues and will last up to 2 years, depending on a number of factors.

As this process continues, a defined cortex will emerge with a lamellar Haversian structure. The healed area of the fracture itself also will have a cancellous interior with normal marrow contents including fat and hematopoietic elements.

Early in the healing process, the cartilage initially synthesized by chondrocytes within the callus is reflected by the presence of significant amounts of chondroitin sulfate and dermatan sulfate as well as type II cartilage. As healing continues, synthesis of type I collagen will predominate over other types, and the amounts of collagen matrix proteins also will decrease.

Growth Factors

Since the original description of bone morphogenic proteins by Marshall Urist in 1974, the existence of several small protein and polypeptide growth factors have been identified. At present, these growth factors are under intense study because of their potential application to the manipulation of the bone healing process. It is likely that the normal biologic functions of these proteins control and regulate the bone formation and resorption. Bone morphogenic protein is a low molecular weight protein that can influence the differentiation of mesenchymal cells into mature osteoblasts.

Other protein factors that can affect fracture healing include insulin-like growth factor, transforming growth factor beta, and platelet-derived growth factor (PDGF). Insulin-like growth factor stimulates bone cell proliferation and the production of cartilage matrix. Transforming growth factor beta induces the synthesis of cartilage, proteoglycans, and type II collagen. PDGF stimulates proliferation of osteoblasts and increases the rate of synthesis of type I collagen. PDGF is also known to be a chemotactic agent and induces the migration of inflammatory cells into the callus. This process is distinct from the process of primary bone healing in long bones with the extension of cutting cones across areas of firm bony contact with direct extension of new Haversian canals that span the two opposed surfaces. Osteoclasts at the front of such a cutting cone resorb cylindrical channels from the bone that are subsequently filled in by concentric layers of lamellar bone with a central vascular channel.

TREATMENT OF FRACTURES AND DISLOCATIONS

The majority of fractures are managed nonsurgically. Optimal treatment depends on multiple factors, including the location and type of fracture. In some instances (such as a minimally displaced fracture of the middle phalanx of one of the lesser toes) no treatment at all other than those for symptoms of

pain generally are necessary (Fig. 43-6). In most other fractures, some form of immobilization is the treatment of choice, this might involve a simple sling (as for a midshaft clavicle fracture) or a more robust splint or brace. When more complete immobilization is desired, immobilization in a circumferential plaster or fiberglass cast is often ideal.

Fig. 43-6.

Types of fracture. *Top row*: segmental, comminuted, and spiral. *Bottom row*: oblique and transverse.

The technical aspects of creating a cast often are underestimated. A proper cast is carefully constructed to immobilize the fractured bone in question and avoid the complications of loss of reduction, neurovascular compromise, pressure ulceration of skin, or the creation of joint contractures. Nondisplaced fractures generally are treated by simple casting. Should the fracture be unacceptably displaced, a closed reduction (applying force by direct pressure, traction, or other maneuvers) to realign the bones precedes the application of the cast. This often requires local, regional, or systemic anesthesia. To construct a cast, the affected limb is often, but not always, first covered with a cloth sleeve or stocking. Critically, the limb is then covered with a generous amount of cast padding. Those inexperienced with casting almost always apply far too little padding. Insufficient padding, particularly overlying a bony prominence, can cause skin erosion within the immobilizing cast, a potentially devastating complication.

After adequate padding is in place, plaster or fiberglass is gently rolled on to the limb. The cast material is applied wet and will generate heat while hardening. This exothermic reaction is sometimes underestimated. Patients can sustain burns during application of thick casts or splints. Several minutes are required, and for this reason, it is applied in layers while maintaining reduction of the fracture. The process can be both technically demanding and tiring.

An alternative to plaster is fiberglass cast tape. This is superior to plaster in terms of strength to weight ratio and has largely replaced plaster for many

casting applications. Fiberglass tape itself, however, is a bit elastic and creates an extra potential hazard of creating a cast too tight. This can lead to excessive compression to the limb.

Finally, swelling of the injured limb beneath the plaster cast can be a significant and dangerous issue. In many minimally displaced fractures, a circumferential plaster or fiberglass cast can be safely applied immediately. For many other injuries, definitive casts are applied 24 to 72 hours after the acute injury because of the potential for ongoing swelling beneath the cast, which all too frequently results in skin problems or neurovascular compromise.

Generally, the cast application, particularly if the casting involves reduction maneuvers, are followed by immediate postprocedure x-ray imaging, to verify a satisfactory alignment of the fracture fragments. It also is customary to repeat imaging through the cast during the course of healing to ensure that the cast is successfully maintaining a satisfactory reduction.

Internal Fixation

Internal fixation refers to any device placed surgically to directly hold bones in position. These can include sutures, wires and screws, plates, rods, or nails. General principles of internal fixation, however, will be detailed below in Simple Screw Fixation and Intramedullary Internal Fixation.

SIMPLE SCREW FIXATION

Many times simply fixing two fractured bones together using individual screws can be effective. The technical challenge of screw fixation often is underestimated. The surgeon must choose an appropriate sized screw and place it correctly with good purchase on the bone. Bone screws come in a variety of designs to address specific fracture fixation problems. A *cortical screw* is a screw with a large inner diameter and shallow screw threads. This screw is designed to have a high breaking strength for its total diameter, and the screws threads are intended to engage cortical bone. Purchase of shallow screw threads in cortical bone can be excellent.

Cancellous screws have a deeper thread pattern and a smaller inner shaft diameter. They are designed to obtain fixation in less dense cancellous bone. *Lag screws* also are commonly used. These are screws in which only the distal portion of the screw length is threaded. These screws penetrate one bone fragment without thread fixation. When a second fracture fragment is engaged by the threaded portion of the screw, turning the screw head tight down to the cortex of the first bony fragment will pull or "lag" the distal fragment toward the screw head. Compression of the fractured bones is the result.

INTRAMEDULLARY INTERNAL FIXATION

Fractures of the shaft of long bones often are managed by intramedullary rods or nails. A metal rod is inserted into the medullary canal to obtain a tight and secure fit to immobilize the fracture. Often, as in the femur, the medullary canal is sequentially reamed over a guidewire to allow insertion of a stout rod. Frequently, the rod is further stabilized by inserting "locking screws" that transfix the bone cortex and pass through appropriate holes in the rod either distal, proximal, or both.

Open Fractures

Fortunately, fractures of the bone usually do not occur with penetration of the skin. When a fracture occurs, and the fracture hematoma is not in continuity with a wound of the skin, the fracture is said to be closed. Such a fracture hematoma may become secondarily infected, but such events are uncommon.

A more serious condition exists when the fracture hematoma communicated with a wound of the skin. Such injuries are called *open fractures*. The fractured ends of the bone are frequently driven through the skin at the moment of injury, often leaving deceptively small wounds. Penetrating trauma also can lead to open fractures, and bacterial contamination must be assumed to be present in all such cases. All such injuries carry a serious risk of infection and osteomyelitis.

Except in unusual circumstances, all open fractures are initially treated by a formal irrigation and débridement procedure performed in the operating room.¹ Depending on the circumstances of each individual injury, the initial débridement can be followed by simple splinting, or external fixation (with definitive operative treatment performed at a later date), or by definitive internal fixation. In severe injuries, with extensive soft tissue injury, the fracture treatment usually is performed in stages.² It must be stressed, however, that urgent débridement of open fractures is a critical step in the treatment of these patients.

Compartment Syndrome

A compartment syndrome is a clinical emergency and describes a clinical situation where muscle tissue compartment edema constrained by the investing muscle fascia results in increased muscle compartment pressures sufficient to stop small vessel flow of blood. Severe problems arise when the perfusion pressure in the capillary bed is approached or exceeded by the intracompartmental pressure. In this situation, perfusion of the muscle is compromised

and muscle necrosis results. The diagnosis of a compartment syndrome is a clinical one, based on complaints of local pain out of proportion to the apparent injury, in association with pain, on passive stretch of the involved muscles. This situation can arise after a period of ischemia, after local blunt trauma, and, frequently, in the presence of an acute fracture. Measurement of compartment pressures, using one of a number of commercially available devices, involves inserting a needle into the suspected muscle compartments to measure pressure. Pressure measurements alone are not reliable to absolutely rule in or rule out the diagnosis, but they can be a useful adjunct to clinical assessment, particularly valuable in obtunded or unconscious patients. Pressure measurements that are greater than 30 mmHg or within 30 mmHg of the diastolic blood pressure are consistent, but not absolutely diagnostic with the presence of a compartment syndrome. The diagnosis is a clinical one. Treatment of a compartment syndrome is always surgical and involves extensive skin incisions and fascial release of all suspected muscle compartments.

An untreated compartment syndrome will result in necrosis of involved muscle compartments with subsequent contracture and severe loss of function in the affected limb.

FRACTURES OF THE CALCANEUS

Fractures of the calcaneus are common and frequently are associated with falls from a height. In assessing patients presenting with a fractured calcaneus, the orthopedist should always consider a possible concurrent fracture of the spine, as these injuries frequently occur together (Fig. 43-7).

Fig. 43-7.

Multiple enchondromas of the hand.

Fractures of the calcaneus can be extra-articular. More frequently, calcaneal fractures involve the subtalar joint or the calcaneal cuboid, and sometimes, calcaneal navicular joints. Often, a practitioner will need computed tomography (CT) scan imaging as well as plain x-ray images to fully document the extent of injury in a calcaneal fracture.

Extra-Articular Calcaneal Fractures

Fracture of the posterior third of the calcaneus without articular involvement can result from falls or crush injuries. Other extra-articular calcaneal fractures are avulsion injuries to the insertional area of the Achilles tendon. In all such cases, final clinical judgment and experience are important, but in general, if fragments are large and displaced, internal fixation using screws is often a consideration (Fig. 43-8). Screw fixation within the calcaneus can be technically challenging, as unfortunately the cortex of this bone often is surprisingly thin and the trabecular bone often is disappointingly porous.

Fig. 43-8.

X-ray images of a comminuted intra-articular calcaneus fracture, before and after open reduction and internal fixation.

Calcaneal Fractures Involving the Subtalar Joint

Calcaneal fractures involving the subtalar joint usually are best assessed by CT scan as well as plain x-ray images. Displaced fractures of the calcaneus involving the subtalar joint usually are best managed by open reduction and internal fixation, using screws and screw-plate devices.

Fractures of the Talus

Fractures of the talus are common and frequently the result of forced dorsal flexion of the foot and ankle. As with most fractures of the tarsal bones, complete assessment of the injury often requires the use of CT scan images as well as plain x-ray views. The surface of the talus itself is covered by large areas of articular cartilage from the tibiotalar articulation to the talocalcaneal articulation (the subtalar joint) and the talonavicular joints. The blood supply to the bone is, therefore, a bit tenuous. Accordingly, many fractures of the talus are complicated by avascular necrosis. The main vascular supply to the bone of the talar neck is through the branches of the dorsalis pedis and of the peroneal arteries. The arteries of the tarsal canal are the main source of blood for the talar body. Displaced fractures of the talus are, therefore, at very high risk of avascular necrosis. Avascular necrosis osteonecrosis also can occur from nondisplaced fractures. Nondisplaced fractures of the body of the talus usually are treated nonoperatively through bracing or casting. Displaced fractures of the talar body generally are treated by open reduction and internal fixation.

Fractures of the Talar Neck

Fractures of the talar neck also may be managed nonoperatively with casting or bracing and strict nonweightbearing. Nondisplaced fractures of the talar neck carry approximately 14% of the incidents of avascular necrosis. Displaced talar neck fractures are essentially always treated by careful open reduction followed by internal fixation.³ Reported avascular necrosis rates for displaced talar neck fractures range from 30 to 100%.

Midfoot Trauma Fractures of the Tarsal Bones

The tarsal bones (the navicular, the cuboid, and the three cuneiform bones) link the hind foot to the metatarsals. The precise arrangements of these bones provide mechanical stability to the arch of the foot. The large articular surfaces of these bones, however, also make avascular necrosis a potential complication with any fracture. Isolated fractures of the tarsal bones are uncommon. The force needed to fracture these bones is usually quite high. Such injuries are associated with trauma to adjacent structures, frequently including dislocations of the tarsometatarsal joints. The articulation between the tarsal bones and the metatarsals is referred to as *Lisfranc's joint*. Fracture dislocations in this area of the foot are generally the results of large torsional forces delivered to the foot while the foot is held in dorsiflexion. Such dislocations can be associated with multiple fractures and can involve any number

of the metatarsals. Displaced dislocations to any of these joints almost always are managed operatively by internal fixation (Fig. 43-9).

Fig. 43-9.

X-ray images of a patient with a fracture dislocation of the tarsometatarsal joints of the foot, before and after reduction and internal fixation.

Fractures of the Metatarsals

Fracture of the base of the metatarsals can occur by similar mechanisms to the Lisfranc fracture/dislocation, but are not associated with significant joint deformities. These usually are successfully managed by simple immobilization. Distal fractures of the metatarsal shaft, particularly the first metatarsal, are more often treated directly by internal fixation to ensure proper alignment of the weightbearing portion of these bones.

Fractures of the Fifth Metatarsal

Fractures of the fifth metatarsal merit special discussion. The very proximal fracture of the posterolateral tuberosity of the fifth metatarsal is usually the result of an avulsion mechanism. Such fractures do not traverse the shaft of the metatarsal and are successfully treated by simple immobilization. Slightly more distal fractures of the proximal metatarsal, however, require closer follow-up because malunions and nonunions are frequently a result and sometimes require internal fixation.

Fractures of the Metatarsal-Phalangeal Joints

Fractures of the metatarsal-phalangeal joints are common and usually are the result of direct trauma. Injuries to the metatarsal-phalangeal joints and the proximal phalanx frequently are managed by "buddy taping" of the involved digit to an uninjured neighboring toe. Injuries to the first metatarsal-phalangeal joint often are best treated with a rigid-soled shoe. Injuries to the first metatarsal-phalangeal joint that involve injury to the articular surfaces are sometimes best treated by open reduction and internal fixation.

Fractures of the Ankle

Fractures of the ankle are extremely common. These fractures are always intra-articular. Because the ankle joint is a major weight-bearing joint subject to large rotational loads, precise reconstruction of the joint is a very high priority.⁴

ANATOMY OF THE ANKLE

The ankle joint is comprised of the talus, tibia, and fibula. The talus normally fits immediately beneath the distal tibia and is restrained medially by the

buttress that the medial malleolus provides. Laterally, the talus is restrained by the articular surface of the fibula which, in precise alignment with the distal tibia, allows for flexion and extension of the ankle. Ligamentous stability of the medial ankle is provided by the "deltoid" ligament that attaches to the medial malleolus of the tibia and talus. Stability of the talofibular joint is provided by the anterior talofibular ligament (a common site for sprains of the ankle), the calcaneal-fibular ligament, and the posterior talofibular ligaments.

DISLOCATIONS OF THE ANKLE

Dislocations of the ankle are common. They usually occur in combination with significant fractures of the tibia or fibula. A much more rare injury would be a purely ligamentous injury that may allow either an anterior or posterior dislocation.

With or without an associated fracture, a dislocation of the ankle joint threatens the blood supply to the foot and requires prompt neurovascular evaluation. Whether or not an acute neurologic deficit or vascular compromise is identified, prompt relocation of the talus in its anatomic position beneath the tibia should be done as soon as possible. An ankle joint that remains dislocated puts the patient at risk for an evolving neurovascular injury and a possible compartment syndrome.

Ankle dislocation without associated fracture can be managed either operatively (with primary repair of the major stabilizing ligaments), or nonoperatively by immobilization as determined by physical examination, imaging, and the demonstrated stability of the talus beneath the tibia after relocation.

LATERAL MALLEOLUS FRACTURES

An isolated distal fibula fracture, often referred to as a *lateral malleolus fracture*, should be anatomically reduced whenever possible. This often can be accomplished by closed reduction and casting (Figs. 43-10 and 43-11).

Fig. 43-10.

Anteroposterior radiograph of a patient who has an open reduction and internal fixation of the bimalleolar ankle fracture.

If closed reduction maneuvers do not result in an anatomic or near-anatomic restoration of the anatomy of the ankle, precise open reduction and internal fixation is indicated. Even a disruption of as little as 1 mm in the position of the lateral malleolus can result in a lateral shift of the talus and a decreased contact area between the tibia and talus of almost 50% and can markedly accelerate degenerative arthritis. Surgical exposure of the distal fibula is by a lateral incision. Fracture fragments are precisely aligned and fixed in place generally using a screw and plate device. With accurate reduction and internal fixation, excellent function can result.

Isolated Medial Malleolar Fractures

An isolated fracture of the medial malleolus is caused in most cases by an avulsion of the malleolus. If the fracture is not displaced, or if it can be anatomically reduced by closed means, casting or bracing may be adequate and appropriate treatment. Surgical treatment of an isolated medial malleolus generally consists of exposure of the bones through a medial approach, precise anatomical alignment, and fixation using screws inserted from distal to proximal. Postoperative management will generally include postoperative casting or bracing.

Bimalleolar Fractures

The bimalleolar fracture is an injury that includes fracture of both the distal fibula and distal tibia. Such injuries often are accompanied by significant subluxation or even complete dislocation of the tibiotalar joint. Prompt reduction of the dislocation is indicated. Almost all such fractures are treated operatively to allow the best possible realignment of the fracture fragments and the joint anatomy.⁵

Posterior Malleolus Fracture

The posterior portion of the distal tibia (the posterior third of the tibiotalar articular surface) often is referred to as the *posterior malleolus*. Isolated fractures of the posterior malleolus are rare, but fractures of this weightbearing surface of the tibiotalar joint are frequently found in patients with fracture of both malleoli. This injury can be called a *trimalleolar fracture*. If the fracture comprises more than one third of the tibiotalar joint or if such fractures have significant displacement, internal fixation of this posterior malleolar fracture fragment may be indicated.

Ankle Syndesmosis

The precise alignment of the tibia and the fibula are important to the function of the ankle joint. A robust ligamentous attachment of the two bones, the *ankle syndesmosis* is an important stabilizer of the ankle and generally extends at least 4 cm above the joint. Quite frequently, injuries to the tibiotalar joint also disrupt the syndesmosis, causing a splaying or widening of the tibia and fibula. Such injuries generally are managed with a "syndesmotic screw"

inserted from lateral to medial, transfixing both fibula and tibia. Ligamentous healing generally is slower than bone healing, and such screws are, therefore, usually left in place for 8 to 12 weeks. Elective screw removal at that time is common, but the consequence of leaving the screw in place beyond 3 months is screw breakage. The possible morbidity caused by a broken screw in this area is minimal.

Acute Rupture of the Achilles Tendon

The gastrocnemius muscle complex acting on the calcaneus through the Achilles tendon can result in very high forces, particularly with sporting activities that involve jumping or rapid changes of direction while running. The Achilles tendon can rupture.⁶ This is apparent clinically as weakness in plantar flexion. The patient often notes an audible "pop" at the time of injury. Open reconstruction of the tendon is frequently performed, often using augmenting material (cadaver tendon or the autologous plantaris tendon). Operative reconstruction of this tendon does, however, have a significant and troublesome rate of wound complication such as local infection or skin necrosis. Accordingly, many practitioners manage this injury nonoperatively with casting or bracing. Either approach is reasonable.

Fractures of the Tibial Plafond: Pilon Fractures

High-energy fractures of the distal tibia and fibula that involve both the distal shaft of the tibia and the weightbearing surface are called *tibial plafond fractures* or, more commonly, *pilon fractures*. Due to the subcutaneous nature of these high energy fractures, skin complications, compartment syndromes, wound healing problems, and nonunions frequently complicate the care of patients with pilon fractures, which represent one of the most difficult challenges in the entire field of orthopedic trauma (Fig. 43-12).

Fig. 43-12.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Radiographs of a severe fracture of the distal tibia and fibula, before and after open reduction and internal fixation. High-energy trauma to the distal leg can frequently lead to neurovascular injury, compartment syndrome, and wound healing problems.

Pilon fractures almost always are displaced and are almost universally associated with significant soft tissue damage. Treatment nearly always involves open reduction and internal fixation of the bone fragments with as meticulous reconstruction of the ankle joint as possible. Immediate reconstructive surgery rarely is undertaken, however, because of the extremely high incidence of soft tissue complications. In most cases, the lower limb is stabilized by external fixation often with limited open reduction and internal fixation of the fibula to help establish and maintain anatomic length. A definitive reconstruction procedure on the tibia often is postponed until the acute swelling has resolved. This approach has been shown to lessen the incidence of soft tissue complications. With or without appropriate stabilization and timing, wound complications are common. Wound breakdown is seen in >10% of such injuries. The incidence of wound infection is high as are nonunion of the distal fragments. Posttraumatic arthritic joints are distressingly common.

Fractures of the Tibial Shaft

Fractures of the tibial shaft usually result from direct blows or torsional mechanisms.⁷ The nearly subcutaneous position of the bone means that open fractures are commonly seen. Thus, inspection of the skin, particularly the anterior leg, is critically important. Fractures that result from a direct blow usually result in a transverse or oblique tibia injury often sparing the fibula. Torsional injury (frequent in skiers) will often lead to a spiral fracture of the tibia, often with associated fibular injury at the knee or the ankle. High-energy trauma to the limb can lead to comminuted fracture and extensive soft

tissue injury.

Management of tibial shaft fracture can be accomplished by a simple closed reduction and long leg cast immobilization. Advancing the patient to a functional brace within 4 to 6 weeks often is recommended. Nonunion of fractures managed closed is a significant problem, and cast immobilization, when used, usually is necessary for approximately 3 to 4 months. Intramedullary nailing of the tibia is now commonly performed and, indeed, is the preferred form of treatment more often than not. An intramedullary nail is inserted across the fracture site, proceeding proximal to distal. Small diameter nails ("nonreamed nails") can be impacted across the fracture site directly. Another alternative, particularly with more unstable fractures, is a rigid intramedullary nail where reaming devices of graduated diameter are passed across the fracture site, before inserting a larger nail. These larger nails often are manufactured with screw holes positioned distal and proximal to accept transfixing distal and proximal interlocking screws to assist in controlling length and rotation.

Fractures of the Tibia Plateau

The upper surface of the tibia, which articulates with the condyles of the femur, has a relatively flat surface and is usually referred to as the *tibia plateau*.⁸ Fractures of this large articular surface can represent a challenge. The weightbearing demands of this surface are high, and the fractures are often accompanied by crushing and impaction of the cartilage menisci and the underlying cancellous bone, making reconstruction particularly challenging as several of the many pieces of this three dimensional puzzle can be partially crushed (Fig. 43-13). Fractures can involve the medial or the lateral plateau or both and often are accompanied by a significant angular deformity. Minimally displaced fractures can be managed nonoperatively with a cast or a brace. Criteria for nonoperative treatment include <3 mm of documented articular step-off and ligamentous stability of the knee when held in extension. More severe fractures with displaced articular fragments generally are managed operatively by anterior, medial, lateral, or combined surgical approaches and direct internal fixation of the fracture fragments. This can be done by transfixing screws or screw-plate devices or, most often, a combination. Because of crushing of the metaphyseal bone, bone grafting (local, iliac crest, or allograft) often is necessary to reconstruct the original anatomy. Reconstruction of ligaments and menisci also sometimes is indicated.

Fig. 43-13.

Computed tomography image of a proximal tibial fracture. The details of the fracture are more easily seen with a computed tomography scan. This improves preoperative surgical planning.

Fracture involving this large articular weightbearing surface often leads to chronic stiffness of the joint or early arthritis. The treating surgeon must be alert for associated injuries such as compartment syndrome of the leg or associated peroneal nerve injury.

Dislocation of the Knee

A dislocation of the knee (dislocation of the joint between the femur and the tibia should not to be confused with a dislocation of the patella) is a devastating injury, and is nearly always the result of a high-energy injury mechanism. Massive ligamentous injury is necessary to allow a dislocation, which can happen in any direction (anterior, posterior, medial, lateral, or rotatory). This injury often is initially unappreciated as after a knee dislocation a

spontaneous reduction, or relocation by the initial treating personnel may delay the diagnosis. Nonetheless, immediate prompt relocation of the knee is a high priority in the emergency management of this condition. Dislocation of the knee has a high associated incidence of neurovascular injury and compartment syndrome. Even if a frank arterial injury is not present, kinking or compression of the vessel and intimal flap tears due to the dislocation can limit the blood flow to the limb. After relocation, immediate assessment of pulses is necessary. Prompt radiographic visualization of the arterial supply to the lower limb is indicated when pulses are deficient. Close attention to the possibility of an evolving compartment syndrome is necessary as well. Depending on clinical assessment and on the extent of the ligamentous injuries, on some occasions, nonoperative management using immobilization is reasonable. In most cases, however, repair of the ligamentous structures with special attention to the posterior capsule is undertaken.

Late stiffness of the knee, and, occasionally, late instability of the knee, are potential complications of this devastating injury. If close attention is not paid to the strong possibility of arterial injury or compartment syndrome, death of the limb can result.

Dislocation of the Patella

Dislocation of the patella, usually in the lateral direction, is a relatively common injury in adolescents, particularly adolescent athletes. Treatment consists of manual reduction of the patella, generally performed with the knee in full extension. Initial treatment is immobilization in extension for an approximate 6-week interval. The most common complication of this injury is recurrent dislocation.

Fractures of the Patella

Fractures of the patella can result from failure of the patella under tension, which usually leads to a nondisplaced or mildly displaced simple transverse fracture. Avulsion fractures of the upper pole also are possible. Direct blows to the knee as from a dashboard to a nonrestrained automobile passenger often lead to comminuted fractures that can involve large areas of the articular surface. Minimally displaced fractures can be managed nonoperatively with a brace in extension. Comminuted fractures, particularly with displaced fragments, may be best managed by open reduction and internal fixation.

Fractures of the Distal Femur

Fractures of the distal femur can present a variety of challenges to the orthopedic trauma surgeon. Simple transverse fractures of the metaphysis do occur without intra-articular involvement (Fig. 43-14). These are less common, however, than are injuries that involve one or both condyles of the femur. As with all intra-articular fractures, great effort is extended to anatomically reduce the fracture fragments and precisely reconstruct and realign the joint surfaces. In most such injuries, fractures are managed with internal fixation, most commonly with transfixing screws combined with either medial or lateral plate fixation. As with all intra-articular fractures, complications can include loss of reduction, nonunion, or malunion. The most common late complication is osteoarthritis.

Fig. 43-14.

Radiographic images of a supracondylar femur fracture, before and after open reduction and internal fixation. Note that the fracture cleaved the femoral condyle apart, requiring reconstruction of the distal articular surface.

Fractures of the Femoral Shaft

Fractures of the femoral shaft more frequently are caused by high-energy trauma. It is common for such patients to have associated injuries. Almost all femoral shaft injuries are managed surgically, usually by intramedullary nailing.⁹ Intramedullary nails are inserted usually after sequential reaming. They usually are inserted proximal to distal through an entry point immediately medial to the greater trochanter or the proximal femur (Fig. 43-15). In some situations, it is preferable to use a "retrograde" approach where a similar rod is inserted distal to proximal with an entry point within the knee joint (this procedure requires a knee arthrotomy). Intramedullary nails often are sufficient to control length and rotation. In severely comminuted fractures, another situation where additional stability is desired, many available intramedullary rod systems have proximal and distal holes to allow transfixing "locking" screws to be inserted in a bicortical manner to transfix the whole intramedullary rod. This provides outstanding rotational and axial control.

Fig. 43-15.

An oblique fracture of the shaft of the femur, before and after reamed intramedullary fixation with a stout nail and interlocking screws. This treatment allows near immediate ambulation for the patient.

In some unusual cases, the use of an external fixator may be indicated in treating a femoral shaft fracture. The usual indication for this is a polytrauma patient with other severe life-threatening injuries where stability of the limb is of lesser priority than other surgical procedures. External fixation may also be a good treatment choice for patients with severe open fractures of the femoral shaft that require wound care or access. Finally, external fixation also is considered in patients who have major ipsilateral vascular injuries.

Fractures of the Hip

Fractures of the hip (proximal femur) are extremely common. They are major injuries with significant risk of morbidity and mortality. It is important for all of the physicians involved in treating a patient with an acute hip fracture that the severity of the injury not be underestimated. The acute survival rate from this injury is approximately 90%. Various authors have reported that the mortality rate for patients sustaining a hip fracture can be as high as 25 to 50% when assessed 1-year postinjury.

As is well known, hip fractures are strongly associated with antecedent osteoporosis. Osteoporosis, the advanced age of many of the patients, and associated medical comorbidities make survival from this injury a concern for every such patient. Physicians taking care of these patients must include careful medical assessment and follow-up on medical comorbidities. Such concerns must also extend to the social welfare of the patient after hospital discharge. Decreased mobility, pain, and disruption of routine can lead to deep vein thrombosis, pneumonia, pressure ulcers, and depression. It is also important to understand that a hip fracture is often a precipitating life event, in that a patient so afflicted may transition from independent living to assisted living or nursing home situations.

Although not necessarily part of the immediate acute management, essentially all patients sustaining a hip fracture should be evaluated for osteoporosis and treated appropriately for their mineral densities postoperatively.

CLASSIFICATION OF FRACTURES OF THE HIP

Fractures of the hip generally are classified as three distinct types: femoral neck fractures, intertrochanteric fractures, and subtrochanteric fractures.

Femoral Neck Fractures

Fractures of the femoral neck comprise approximately one half of all fractures of the proximal femur. They are most common in elderly patients. The anatomy of the hip joint is an important consideration in the management of this fracture. The hip joint capsule extends from the rim of the acetabulum to the base of the neck of the femur. Fractures of the femoral neck are, therefore, entirely intracapsular. The blood supply to the femoral neck is accordingly quite precarious. In some adult patients, there is a limited blood supply from the ligamentum teres of the acetabulum, which contains a small branch of the obturator artery. The major route for blood supply to the femoral head in all patients (the only blood supply to the femoral head in most patients) is derived from vessels within and along the surface of the bone of the femoral neck.

Femoral neck fractures, as they are entirely within the joint capsule, usually are not associated with hemodynamically significant blood loss. Fracture hematomas are contained within the hip capsule. When the femoral neck fracture is displaced, disruption of the blood flow to the femoral head is virtually certain. Accordingly, osteonecrosis of the femoral head in displaced fractures is nearly inevitable.¹⁰ It is often better for the patient to proceed directly to prosthetic replacement of the femoral head. This operation is called a *hemiarthroplasty* and involves replacing the femoral neck and head with a metal and plastic prosthesis that will fit within the native acetabulum. This generally is done by a posterior approach to the hip, exposure and entry into the joint capsule, removal of the doomed femoral head, resection of the residual femoral neck to allow reaming of the proximal medullary canal, and insertion of an appropriately sized prosthesis. After placement of the prosthesis, the artificial head is relocated into the native acetabulum, tissues are opposed, and the skin closed. Although this technique allows near immediate weightbearing on the involved limb, it has a significant physiologic stress for the patients. The secure placement of the femoral component within the proximal shaft of the femur can be done using polymethylmethacrylate bone cement that creates a mantle about the shaft of the prosthesis. This has the advantage of immediate, secure fixation of the femoral component. A disadvantage of this technique is that the polymethylmethacrylate cement is an attractive substrate for bacterial biofilms should the patient acquire a perioperative infection. An alternative to the use of polymethylmethacrylate cement is the use of a "press fit" prosthesis. In such noncemented techniques, more precisely shaped prostheses are impacted into the proximal femur to obtain a tight interference fit. One disadvantage of this prosthesis type in treatment of a hip fracture is that obtaining a tight "press fit" of the prosthesis does involve some risk of an iatrogenic femur fracture (Fig. 43-16).

Fig. 43-16.

A displaced fracture of the femoral neck. This injury so predictably leads to osteonecrosis of the femoral head that it is best managed (as shown) by hemiarthroplasty. In this case, a noncemented implant was selected.

The placement of the arthroplasty prosthesis to replace the proximal femur is a good option for the patient only if the acetabular side of the joint is healthy. If the acetabular side of the joint is severely arthritic, wear of the prosthetic femoral head on the acetabulum is predicted to be unacceptably painful. Accordingly, in patients with significant osteoarthritic change that preceded their femoral neck fracture event, proceeding directly to a total hip arthroplasty with replacement of both the femoral and acetabular sides of the joint may be the best choice for the patient. Discussion of the technique is found in the Total Hip Arthroplasty section of this chapter.

Nondisplaced or impacted fractures of the femoral head can occur without critical disruption of the blood supply to the femoral head. Accordingly, such fractures most frequently are managed by internal fixation in situ using three or four screws (Fig. 43-17) inserted through the cortex of the lateral proximal femur, which transfix the fracture site and engage the femoral head. Placement of such screws can be done through very small skin incisions and, in most cases, do not require any direct exposure of the bone. These procedures result in minimal blood loss and often can lead to a very rapid postoperative recovery.

Pre- and postoperative radiographs of a patient with a displaced fracture of the femoral neck and pre-existing severe arthritic change in the acetabulum. The patient was managed by performing a total hip replacement, with replacement of both the acetabular surface and the femoral head and neck.

Intertrochanteric Fractures of the Hip

Fractures of the hip also frequently occur in the region between the greater and the lesser trochanters. Such fractures are referred to as *intertrochanteric fractures of the hip*. They may represent a single fracture line, or several discrete fragments may be created. A discrete fragment representing the lesser trochanter is a common result. Unlike femoral neck fractures, fractures of the trochanteric region of the femur usually result in substantial blood loss that may have hemodynamic consequences for the patient. Monitoring the patient's hemodynamic indices and hematocrit are important in any patient with an intertrochanteric fracture. Like fractures of the femoral neck, almost all fractures of the intertrochanteric region are managed operatively, because nonoperative treatment has an extremely high incidence of complication. Treatment of the intertrochanteric fracture essentially always involves internal fixation. This can be done using a fracture table whereby the alignment of the lower limb can be mechanically held in a reduced position while surgery is performed. Alternatively, it can be performed in a supine position on a radiolucent table using manual reduction methods.

In most cases, a lateral approach to the hip is made and fixation of the fracture is achieved by transfixing the trochanter and the femoral neck and head with a large screw. This can be placed in conjunction with a screw and plate device (together called a *sliding hip screw*). Another alternative is a cephalomedullary device where fixed angle screws engage a short intramedullary nail inserted proximal to distal through the proximal region of the trochanter or through the piriformis fossa. With placement of either device (the choice of which usually is dictated by the fracture morphology), the

patient is capable of near immediate postoperative weightbearing.

Subtrochanteric Fractures and Femoral Shaft Fractures

Subtrochanteric fractures of the hip are generally the result of higher-energy injury mechanisms than femoral neck or intertrochanteric fractures. They are, accordingly, more likely to occur with other bone or soft tissue injuries. In most cases, subtrochanteric fractures are managed by an intramedullary device, which may be inserted with or without reaming. As muscle attachments to the proximal fragments result in forceful displacement of the fragments, open resection often is necessary. Almost all fractures of the diaphysis of the femur are managed with the use of an intramedullary rod. These are placed after sequential reaming. In many cases, the intramedullary device is augmented by either locking screws or a transfixing screw that engages the femoral neck. In most cases, immediate postoperative weightbearing is possible.

Hip Dislocation

Hip dislocation is a severe, high-energy injury that frequently is associated with multitrauma patients. Most dislocations of the hip occur in the posterior direction. Such injuries frequently result in neurovascular compromise. Indeed, an isolated hip dislocation may represent a life-threatening injury. Emergent reduction is strongly indicated. This usually can be accomplished closed. If this is unsuccessful, prompt open reduction is recommended.

Hip dislocations often are associated with acetabular fractures and, less commonly but significantly, with fractures of the femoral head (Fig. 43-18). Obviously, a fracture of the femoral head with associated acetabular injury and/or femoral head fracture is a very serious injury indeed. Common complications with any of these injuries are posttraumatic arthritis, osteonecrosis, and recurrent dislocation. Associated neurovascular injuries are common.¹¹ Acetabular fractures can occur with or without frank hip dislocation. Acetabular fractures frequently are seen in association with other fractures of the pelvis (Fig. 43-19). Significant blood loss from bone bleeding is a major concern with these injuries.

X-ray images of a patient with a right acetabulum fracture, before and after operative reconstruction. Note the protrusion of the head of the femur into the pelvis before surgery.

Operative treatment of the acetabular fracture is directed at reconstruction and internal fixation of the original acetabular anatomy and the creation of a stable hip joint.¹² The acetabulum can be exposed through an anterior, lateral, or posterior approach depending on the osseous injury. Surgical treatment of an acetabular fracture is a major undertaking, requiring special training and experience.

PELVIC TRAUMA

Pubic Ramus Fractures

Pubic ramus fractures usually are seen after minor trauma in older patients with osteoporosis. Such fractures usually present with diffuse anterior pelvic pain and may or may not occur with an identifiable traumatic event. Tenderness to gentle lateral compression can be a useful physical examination maneuver. Pubic ramus fractures are frequently associated with concurrent sacral fractures. Vertical fractures through the sacral ala often involving multiple sacral foramina frequently occur with this injury. Interestingly, the sacral fractures are often quite nondisplaced and may be difficult or impossible to see on plain x-ray images. Nondisplaced fractures of the sacrum and minimally displaced fractures of the pelvic rami usually are managed with analgesics and mobilization. These injuries are compatible with full weightbearing. An apparent slight pelvic fracture in a young patient without osteoporosis, however, should trigger a more robust search for associated injuries or malignancy.

Fractures of the Pelvic Ring

Fractures of the pelvic ring are an unfortunate but frequent consequence of high-energy trauma.^{13,14} Vertical fractures through the posterior elements of the pelvis or sacrum associated with anterior ring injury may result in "open booking" of the pelvis. Vertical translation of large portions of the pelvis with such injuries are all too often associated with major visceral injury and potentially catastrophic blood loss. Injuries to the bladder, ureter, urethra, and kidney also frequently occur in association with these injuries. Any associated hematuria must be aggressively investigated. Unfortunately, patients with such injuries frequently present with hemodynamic difficulties due to hypovolemia and blood loss. Sometimes, this can be improved by the urgent application of an external fixator to engage the ilia bilaterally. Compression and stabilization of the pelvis can help limit bone bleeding. Reconstruction of major pelvic disruption of this kind is a major undertaking and usually is performed 3 to 10 days after the initial injury to allow bone bleeding to stabilize.¹⁵ These reconstructive procedures are clinically challenging and must be extremely well planned. They should only be undertaken by orthopedic surgeons with special training and experience with this injury (Fig. 43-20).

Pre- and postoperative image of a patient with displaced fractures of the pubis and the sacroiliac joint. Such injuries are the result of high-energy trauma and are frequently associated with visceral injury and severe blood loss.

FRACTURES OF THE SHOULDER

Fractures of the Clavicle

Fractures of the medial third of the clavicle are rare. Often what appears to be a fracture of the medial clavicle is actually a dislocation of the sternoclavicular joint. When anteriorly displaced, this injury, while painful, requires only symptomatic treatment. In contrast, posterior dislocation of the sternoclavicular joint can impinge the great vessels and may be managed by closed reduction. With general anesthesia, the arm is abducted and a lateral force is applied, and a towel, clip, or bone holding clamp can be used to apply anterior forces on the clavicle that can relocate this joint. These maneuvers should be undertaken only when a surgeon is available for any associated great vessel injury. Fortunately, such injuries are rare (Fig. 43-21).

Fig. 43-21.

Anteroposterior radiograph of a patient with a fractured clavicle. As usual, there is elevation of the medial fragment and shortening of the clavicle. This fracture will heal, and the function will be excellent with closed treatment. The patient can be treated with a sling.

Fractures of the middle third of the clavicle are quite common. Indeed, they are one of the most commonly seen fractures in an orthopedic practice. A fracture of the clavicle often is apparent on visual inspection, as the middle third of the clavicle is virtually subcutaneous. Fortunately, such injuries are rarely associated with skin penetration. Nonunions of the midshaft of the clavicle do occur, although they are rare. Accordingly, symptomatic treatment

with mild analgesic medication and a sling is usually sufficient treatment.

Fractures of the Distal Clavicle

Fractures of the distal third of the clavicle can be more troublesome. When such fractures are displaced, it is frequently the result of concomitant rupture of the coracoclavicular ligaments. A significantly displaced clavicle may impinge the shoulder musculature and interposed soft tissue may result in nonunion. Accordingly, closed reduction, pinning, and/or open reduction and internal fixation of distal clavicle fractures often is recommended. In any surgical treatment of the clavicle, the proximity of the lung, the great vessel, and the brachial plexus must be kept in mind.

Fractures of the Scapula

Fractures of the scapula can result from direct blows to the shoulder or from falls onto the arm. Most scapula fractures are managed conservatively with exceptions made for those that have significant involvement of the glenoid. In such cases, open reduction and internal fixation using screws and small plates generally is recommended. These procedures usually are performed through a posterior approach.

Fractures of the Proximal Humerus

Fractures of the proximal humerus are common.¹⁶ This is a frequent event in older individuals with osteoporosis but can result from significant trauma to younger individuals as well.

Minimally displaced fracture or impacted fractures of the femoral neck are best managed by immobilization with a shoulder immobilizer brace, a sling, or a sling and swath. Displaced fractures of the neck and humerus without a great deal of comminution often are managed by intramedullary internal fixation inserted from distal to proximal. This approach can be difficult in patients with osteoporosis, as the metaphyseal bone of the humerus is often quite porous.

Fractures of the proximal humerus, which involve the humeral head, are a particularly difficult problem. A large portion of the humeral head is covered with articular cartilage, and fracture events often will lead to up to four discrete fragments as classified by Dr. Neer.¹⁷ When there is significant displacement of these fragments, leaving large pieces of articular bone without blood supply, avascular necrosis (osteonecrosis) is likely to occur. Accordingly, such fractures with displaced interarticular fragments are usually most appropriately managed by hemiarthroplasty; the humeral head is replaced with a prosthesis affixed to the humeral shaft with an intramedullary extension. Unfortunately, hemiarthroplasty procedures do not completely restore normal strength and range of motion to the shoulder; however, it generally gives a very functional result and is certainly preferable to the complications that ensue from an osteonecrosis of the humeral head.

Fractures of the Humeral Shaft

Fractures of the humeral shaft can result from falls or from direct trauma. They are most usually managed by open reduction and internal fixation with a stout screw-plate device. Intramedullary fixation is also an option, but insertion of an intramedullary device is more challenging in the humerus than in other long bones because of the specific anatomy of the elbow and shoulder (Fig. 43-22).

X-ray images of a comminuted spiral fracture of the shaft of the humerus, before and after open reduction and internal fixation using a plate and screws. This injury is frequently associated with neurovascular compromise; particularly at risk is the radial nerve.

Any treatment plan for a diaphyseal fracture of the humerus must take into consideration the anatomy of the radial nerve that spirals down the arm in contact with the humerus. Thus, the radial nerve is at great risk for injury both at the time of the injury and at the time of surgical treatment.¹⁸ Careful attention to the neurovascular status of the limb, particularly of the radial nerve, is a strong concern in the management of these injuries.¹⁹

FRACTURES OF THE ELBOW AND FOREARM

Fractures of the Distal Humerus

Fractures of the distal humerus in adult patients thankfully do not involve the articular surface of the humerus nearly as often as those seen in pediatric practice. An extra-articular supracondylar humeral fracture in favorable cases can be managed by immobilization, although, to ensure good control of these fracture fragments and to prevent subsequent displacement, such fractures most often are managed by internal fixation. This can be accomplished by either a posterior medial or lateral surgical approach, depending on fracture morphology. With extensive comminution, combined approaches may be considered. When such fractures have an intra-articular component, precise reconstruction of the joints is, of course, a high priority. The elbow joint, formed by three long bones, the radius, ulna, and humerus, can present the surgeon with a difficult reconstructive problem. In most cases, it is useful to reconstruct the articular surface by separately and precisely placing screws to restore the articular anatomy. Once this is done, the distal fragments can then be affixed to the humeral shaft by appropriate screw-plate devices.

It should be noted that, in some difficult cases of articular fractures of the distal humerus, an olecranon osteotomy (deliberate creation of an olecranon fracture) can be a good way to visualize the trochlea to assist the surgeon in reconstructing an intra-articular fracture of the distal humerus. When this is accomplished, the olecranon then can be fixed as discussed in Fractures of the Olecranon below.

Fractures of the Olecranon

The proximal ulna and the olecranon fossa articulate with the trochlea of the distal humerus. This joint provides much of the bony stability of the joint. Fractures of the olecranon are common and may result from avulsion mechanisms, falls, or in rare cases, blows to the elbow. Very small and minimally displaced fracture fragments of the olecranon may be successfully managed by immobilization alone. In many cases, reconstruction of the joint can be accomplished with a single leg screw inserted from proximal to distal or a cerclage wire and with pins. In some cases with severe comminution, simple

excision of the fracture fragment may also yield a highly functional elbow. Even where properly placed, the olecranon fixation devices are often symptomatic due to its subcutaneous location. Accordingly, hardware removal procedures after fractures have healed is often a consideration.

Fractures of the Radial Head

Fractures of the radial head are common injuries. In many cases, a single fracture line is present, and one or two transfixing screws inserted through a lateral approach can provide adequate fixation. Where reconstruction is difficult, excision of the radial head can be considered. Removal of the radial head may, in some individuals, lead to proximal migration of the radius. In some unfortunate patients, wrist symptoms can develop as a result. Reconstruction of the radial head and/or replacement with one of a number of prosthetic devices is now receiving more attention. Some controversy does surround this specific issue.

Fractures of the Ulnar Shaft

Fractures of either the radius or the ulna within the forearm can represent significant diagnostic and treatment challenges. Careful evaluation of both the elbow and the wrist is essential when assessing these injuries. It must be kept in mind that the precise anatomy of the shafts of these bones also is necessary for pronation and supination of the forearm. It is very common for a radial or an ulnar fracture to be associated with a concomitant wrist or elbow injury or a subtle fracture or dislocation of its neighboring long bone.

Fractures of the ulnar shaft are common and usually result from a direct blow to the ulnar forearm. The ulna in the forearm is subcutaneous and vulnerable to blows. The name *night stick fracture* is applied to the diaphyseal fractures of the ulna that result from a direct blow. They are due to one common mechanism, that of a direct blow by a club or night stick.

Such fractures in the ulna shaft usually are managed nonsurgically with the use of a cast. Proximal ulnar shaft fractures or those with significant angulation may be managed by open reduction and internal fixation.

Fracture of the Ulna and the Radius (Fracture of Both Bones of the Forearm)

Fractures of the shafts of both bones of the forearm are common injuries, sometimes associated with high-energy mechanisms (Fig. 43-23). In pediatric patients, the high potential for bony remodeling nonoperative treatment often is appropriate in very young individuals. In adults, however, precise reconstruction of the alignment and contour of the shafts of these bones is important to maintain pronation and supination function. Accordingly, fractures of both bones of the forearm within the shaft are most commonly treated by open reduction and internal fixation using screw-plate devices for each bone.

Fig. 43-23.

X-ray images of a patient with fractures of both bones of the forearm before and after open reduction and internal fixation. Note that the ulna fracture is segmental. Precise alignment of the radial and ulnar shafts is important for pronation and supination.

Fractures of the Proximal Ulna with Radial Head Dislocation (Monteggia Fracture Dislocation)

This particular injury pattern is relatively common, and unfortunately, the dislocation of the radial head sometimes is unrecognized.²⁰ In almost every case, an internal fixation of the ulna is indicated with closed reduction of the radial head. The treating surgeon must be alert to possible neurovascular injury and compartment syndrome. Late complications to this injury can include heterotopic ossification and redislocation of the radial head.

Fractures of the Shaft of the Radius with Radial Ulnar Dislocation (Galeazzi Fracture or Piedmont Fracture)

Radial shaft fractures often are associated with ligamentous injury to the distal radioulnar joint.²¹ This injury, which may escape detection of the unwary, could lead to instability of the wrist. The radioulnar joint injury may be purely ligamentous or may be accompanied by a fracture of the ulnar styloid. The treating surgeon must be alert for widening of the distal radioulnar joint. The stability of this joint may need to be addressed surgically to avoid a chronically painful wrist.

Fractures of the Wrist and Hand

Fractures of the distal radius and ulna, and fractures of the wrist and hand are discussed in Chap. 44.

MUSCULOSKELETAL INFECTIONS

Infections of the Bone

Infections of the bone (osteomyelitis) frequently can represent diagnostic challenges. Infections of the bone can occur to a wide variety of organisms, ranging from gram-positive and gram-negative bacteria to microbacteria and even fungi. Immunocompromised patients (particularly those on immunosuppressive medications, corticosteroids, or suffering from HIV infection) can present with bone infections caused by very unusual pathogens. Accordingly, when a bone infection is suspected, biopsy for culture is nearly always necessary. Indeed, bony changes caused by bone infection quite often mimic the appearance of tumor. Accordingly, it is recommended during any biopsy procedure of a presumptive infection that tissue samples be sent for

histopathology. Likewise, it is strongly recommended that anytime a suspected tumor of the bone is biopsied, specimens also are obtained and sent for culture.

Osteomyelitis is an inflammation of the bone, usually the result of infection, which involves both the local bone tissue and the surrounding marrow and is located in the intramedullary canal. Infections of the subperiosteal space are termed *periostitis*. The morphologic features are similar to infections occurring in other organ systems and the same cells are involved.

Although osteomyelitis is similar to infections in other organs, the process is unique in that the cortical bone prevents release of the increased local pressure that normally accompanies inflammations. In soft tissues, this pressure can be dissipated into the surrounding tissue, but in the intramedullary canal, the pressure change produces infarction of the marrow fat by compressing the capillary and sinusoidal beds that supply it. This marrow infarction results in coagulative necrosis initially and then is replaced by a myxofibrous stroma. Cancellous trabeculae also are infarcted by the collapse of the vessels and also undergo necrosis. These necrotic segments of bone often are not resorbed and are termed *sequestrae*. These will calcify and remain centrally located, and they appear radiologically as very dense areas within the lytic portion of the process. Reactive, viable bone often will form around a sequestrum; this bone is called an *involucrum*.

Given the increased pressure, there is an increased osteoclastic response with resorption at the endosteal surfaces and within the necrotic trabeculae. However, the pressure, if the underlying infection is left untreated or undiagnosed, often will outstrip the ability of the osteoclasts to effectively remodel the intramedullary space. This leads to a penetration of the cortex (via Volkmann's canals) by the inflammation that reached the periosteum. This will result in new bone formation by the periosteal disruption that will be noted radiologically. The periosteal reaction can be quite dramatic radiographically and can mimic a malignancy, especially in children.

In patients with acute osteomyelitis, the radiologic features do not appear until 1 to 14 days after the onset of symptoms. The initial x-ray appearance is a vague, localized osteoporosis as a result of the removal of the dead trabecular bone and initial stages of endosteal resorption. This transforms to a mottled appearance on the plain film as more bone is resorbed, with the end result of a lytic area with or without a sequestrum.

As the infection progresses, the radiologic and morphologic features transform as the inflammation becomes chronic. The marrow gradually is replaced by fibrous tissue, and the inflammatory cells are composed of mononuclear cells (i.e., lymphocytes and plasma cells). Radiologically, this appears as patchy sclerosis in the intramedullary space. A sinus tract may be appreciated especially on CT and magnetic resonance imaging (MRI). The periosteal reaction becomes more compact and often can appear lamellated.

The causative organisms on biopsy often are not visualized histologically, even with special stains. Microbiologic culture is the preferred method for demonstrating the causative agent.

Hematogenous Osteomyelitis

Hematogenous spread of bacteria to the bone is a common event.²² It is seen most frequently in children, likely due to the vascular anatomy at the epiphyseal growth plate, although it is also commonly seen in patients after illnesses involving bacteremias. It may also arise, apparently spontaneously, after incidental seeding of the bone without identifiable antecedent illness. Bone infections are frequently painful, and indeed, usually cause severe pain. Afflicted pediatric patients may be less likely to express the symptom clearly.

Focal Osteomyelitis of the Bone

Antibiotic treatment for severe bone infections generally is not nearly as successful as antibiotic treatment for most soft tissue infections. Thus, prolonged IV therapy often is indicated (6 weeks or more), and most severe bone infections also are débrided surgically. When possible, the sequestrum is removed entirely. Bone infections in children are almost all due to *Staphylococcus aureus* and, on many occasions, pediatric patients are well treated by antibiotics specifically directed to this organism. In contrast, in adult patients with osteomyelitis, a huge variety of infective organisms have been identified, and it is strongly recommended that, whenever possible, antibiotic treatment be postponed until after tissue biopsy from the infected focus is obtained for culture and sensitivity analysis.

Many patients are immunocompromised due to various causes, which can include chronic corticosteroid use, HIV infection, chemotherapy for cancers, and immunosuppression after organ transplant. In any patient, particularly those who are immunocompromised, the variety of organisms causing osteomyelitis is wide indeed. It is imperative to culture for aerobic organisms, anaerobic organisms, acid microbacteria, and fungus in all such cases. It is speculated that the frequent presentation of pediatric patients with metaphyseal osteomyelitis may be due to the anatomy of the metaphyseal growth plate. Large vessels, particularly veins, supply the growth plate as a site of high metabolic activity and bone synthesis. These large vessels frequently demonstrate a "hairpin turn" at the physis, and studies have shown that the flow of blood, particularly in these veins, may be slow. It is speculated that bacteria may lodge here due to low flow rates. The possibility that local transient thrombosis of these veins may provide a focus for infection also has

been raised. At any event, the area of bone immediately adjacent to the physis is a frequent focus for infection.

Chronic osteomyelitis may lead to a fistula or chronically draining sinus. This is a commonly seen problem in diabetic patients, but may arise in any incompletely treated osteomyelitis. Successful treatment of this problem is challenging. Once the chronic infection is established, it is then amply demonstrated that culture of the sinus itself is very unreliable at revealing the causative organism in the deep tissues. When definitive treatment is undertaken, an adequate culture from the deep tissues is mandatory.

An interesting, if unfortunate observation in patients with chronic osteomyelitis with draining sinuses is that malignancy, particularly squamous cell carcinomas, can arise within the chronically inflamed tissue. This possibility must be kept in mind when treating patients with chronic osteomyelitis.

Granulomatous Osteomyelitis

A *granuloma* is a chronic inflammatory process with central giant cells and macrophages with a peripheral cuff of lymphocytes and plasma cells. Plain radiographs generally are notable for ossification and calcification with variable degrees of lucency. The histology demonstrates granuloma formation that is identical to that seen in other locations. The most common granulomatous condition in the skeletal system is due to tuberculosis.

Tuberculosis more commonly manifests as an arthritis rather than osteomyelitis. However, when it does manifest in bone, typically it occurs in the spine. Deformity as a result of the infection may be severe due to the destruction of the vertebra or vertebrae. In the adult, the infection more often begins beneath the periosteum and may spread under the anterior longitudinal ligament and involve the vertebrae some distance away. The histologic features are those of chronic osteomyelitis, with fibrosis, bone destruction, and prominent caseous necrosis.

Septic Arthritis

Septic arthritis, as the name implies, is an infection of a diarthrodial joint. Organisms, usually bacteria, proliferate within the joint cavity, and in almost every case, cause marked limitation of joint motion, and severe pain with joint loading or motion. Patients with septic arthritis often demonstrate high fever, leukocytosis, and severe malaise. The involved joint typically becomes tensely swollen, warm, and exquisitely tender. Spontaneous septic arthritis can and does occur in all age groups, but it is most common in children. It generally is believed that most cases of acute septic arthritis in children derive from foci of acute osteomyelitis of the metaphysis that "breaks through" into the joint. Joints where the growth plate is enclosed by the joint capsule are common sites for this event (humerus, proximal femur). An infection in the joint typically puts the articular cartilage at risk for irreversible damage. Accordingly, prompt recognition of this entity and initiation of treatment is essential. It also must be recognized that some noninfectious processes can mimic the presentation of an infected joint. Such common clinical entities include acute gouty arthritis, an acute flare of an inflammatory arthritis such as rheumatoid arthritis, or an acute hemarthrosis. Generally, the first step in the evaluation of a patient suspected of septic arthritis is aspiration of the joint. The joint fluid is examined for cells, blood, and the presence of uric acid or calcium pyrophosphate crystals.

In the presence of a leucocytosis and no other firm diagnosis, treatment involves prompt irrigation and débridement of the joint. In some easily accessible joints, such as the knee, the irrigation and débridement can be carried out with an arthroscope. In many other joints, there is a need for an open arthrotomy with surgical exploration débridement and aggressive irrigation of the joint. After such procedure, the selection of the antibiotic regimen and its duration generally are decided after consultation with an infectious disease specialist. The antibiotic regimen is tailored to the infective organism and clinical situation of the individual patient.

DISORDERS OF THE FOOT AND ANKLE

Osseous Anatomy

The distal tibia and fibula combine with the talus to form the ankle joint. Primary motion of the ankle joint is flexion and extension and a normal arch of motion is approximately 60°, 20° of dorsiflexion, and 40° of plantar flexion. This tibiotalar joint bears very large loads during gait and especially during vigorous activity. Underneath the talus, the talocalcaneal joint, also called the *subtalar joint*, is the site of significant inversion and eversion (normally between 5° and 20°). The metatarsal-phalangeal joints normally move very little. Metatarsal-phalangeal joints and interphalangeal joints principally move in flexion and extension.

Evaluation of the Patient

PHYSICAL EXAMINATION

Gait abnormalities should be noted. The presence of edema or skin lesions should be recorded as signs of vascular insufficiency or inflammatory disease.

The dorsalis pedis and the tibialis anterior pulses usually are readily located. Scars, consistent with previous wound healing problems, can indicate chronic disease.

Tenderness of the joints can indicate degenerative arthritis or inflammatory disease. Significant joint deformity often is characteristic of inflammatory joint disease such as rheumatoid arthritis. The major ligaments of the ankle can be palpated; frequently of specific interest is the anterior talofibular ligament and the tibial calcaneal ligaments. Both are frequently injured during ankle sprains. The range of motion of the joints should be assessed. Chronic talofibular ligament injuries are common and can be demonstrated by an anterior drawer sign by drawing the hind foot forward at the tibiotalar joint. In acute sprains, this maneuver will be acutely painful, in the chronic sprain it will not.

RADIOGRAPHIC EXAMINATIONS

A study of the foot would include specific views including the anteroposterior (AP) lateral and oblique as well as AP lateral and mortis views of the ankle. The mortis view is a particularly useful view of the ankle that is taken in a slightly oblique AP direction to display the ankle joint space with the talus in alignment with the ankle joint. This allows assessment of the joint space of the tibiotalar and fibulotalar joints. In the diagnosis and treatment of many foot and ankle disorders, CT scans, MRI scans, bone scans, venous and arterial vascular studies, and other radiographic techniques are used with a specific purpose.

Common Degenerative Conditions of the Ankle

Hallux valgus is a common deformity in the foot characterized by valgus angulation to the first metatarsal-phalangeal joint. There are numerous factors that influence the development of hallux valgus, but overwhelmingly, the most common culprit is tight shoe wear that puts extra pressure on the first toe in a valgus direction. A lifetime of narrow, high-heeled shoe wear can create substantial, painful, and unsightly first toe deformities. Once hallux valgus is present, angulation of the first ray is such that eventually bowstringing the tendons crossing the joint acts to increase the deformity. Most notable is a plantar and lateral shift of the abductor hallucis tendon. Lesser toe deformities frequently accompany this condition, usually with identical risk factors. Frequently, skin problems develop due to contact between adjacent rays.

Treatment

Conservative treatment for degenerative arthritis and associated deformities will often suffice. This generally consists of shoe modifications. Such measures are always the first choice of treatment.

Surgical treatment of hallux valgus generally is satisfying in the relief of cosmetic issues and pain.²³ A successful operation must address several issues that contribute to the problem. Specifically, valgus deviation of the great toe must be corrected, and frequently, a varus deviation of the first metatarsal also must be addressed. Reconstruction of the flexor apparatus and relocation of the sesamoid bones is also important (to relieve deforming forces and prevent recurring deformity). Usually excision or resection of the medial bony eminence (medial osteophytes from the metatarsal-phalangeal joint) also is performed. The reconstruction often consists of reefing the capsule and adjusting the position of tendons that cross the joint. Often, a metatarsal osteotomy is performed, which can be done by a variety of means.

Hallux Rigidus

Hallux rigidus is a common condition that frequently affects athletes or patients who are accustomed to wearing high-heeled shoes. The condition is a painful loss of motion, particularly in dorsal flexion of the metatarsal-phalangeal joint of the first toe, usually accompanied by exuberant osteophytes on the dorsal surfaces of both joints. When accompanied by significant degenerative change, this condition is sometimes addressed by fusion and bone grafting of the involved joint.

Deformities of the Lesser Toes

Angular deformities of the lesser toes generally are categorized as "crossover toe" deformities. The causes are usually shoe wear related to the pathophysiology of hallux valgus. Such angular deformities often also present in hallux valgus patients and are often concurrent. Also commonly symptomatic are the mallet toe, the hammer toe, and the claw toe deformities, all of which are related to flexion deformities of the individual digits. Multiple claw toe deformities are frequently seen in neurologic disease and their presence may indicate more significant systemic neurologic pathology. In general, conservative treatments centering on appropriate footwear generally are helpful. In severe intractable cases, surgical treatment generally involves resection of the extensor digitorum brevis or lengthening of the extensor digitorum brevis tendon, occasionally accompanied by lengthening or tenotomy of the extensor digitorum longus. On rare occasion, surgical resection or ablation of the interphalangeal joints can be effective treatment.

Nerve Entrapment Syndromes

Morton's neuroma is a common and painful condition of the common digital nerve of the foot, most frequently in the first, second, or third web space. Although the word *neuroma* is commonly used, it may be better described as degenerative disease of the nerve. Repetitive microtrauma and chronic compression may be contributing factors. Morton's neuroma is most common in females. Diagnosis is by physical examination, specifically, reproduction

pain with mediolateral compression of the foot and local tenderness. Conservative treatment consists of wide-toed shoes with a firm sole. A metatarsal pad worn inside the shoe to support the more proximal metatarsals can be useful. When conservative treatments fail, excision of the nerve (leaving the patient with some small sensory deficits) can be appropriate treatment.

Tarsal Tunnel Syndrome

The space between the medial malleolus and adjacent surface of the calcaneus is referred to as the *tarsal tunnel*. Beneath the dense layer of ligaments, the tarsal tunnel contains the tendons of the flexor hallucis longus and flexor digitorum longus, as well as the tibialis posterior tendon and a neurovascular bundle. Rather analogous to carpal tunnel syndrome, nerve compression can cause significant discomfort. The symptoms often are felt distal to the site of compression and at times outside of the normal distribution of the posterior tibial nerve. This diagnosis almost always is associated with tenderness over the tarsal tunnel. Symptoms may be due to identifiable neuromas, inflammatory disease, or the effects of old trauma. The true etiology is often debated. Electrodiagnostic studies are occasionally used. Shoe modification including immobilization in a brace can be useful, but many of these patients do undergo surgical treatment, which involves exploration of the tunnel and release of the flexor retinaculum and of the fascia.

Rheumatoid Arthritis of the Foot

The foot and ankle frequently are involved in patients with systemic inflammatory diseases such as rheumatoid arthritis. As in the hand and wrist, the effects of inflammatory disease can manifest in erosive disease of the ligaments and tendons (including rupture) as well as erosive disease of the bones and joints.²⁴

The feet are the major source of disability for patients with rheumatoid arthritis. Indeed, with the incidents of rheumatoid arthritis known to be approximately 1% in North America, the orthopedic surgeon must be alert to the characteristic signs of inflammatory disease in the foot (exuberant articular enlargement, joint deformity, and synovitis), and often, it will be up to the orthopedic surgeon to make the initial diagnosis of rheumatoid arthritis.

Inflammatory disease in the foot most frequently begins in the metatarsal-phalangeal joints and leads to subluxation or even frank dislocation at the base of the proximal phalanges. Deformity and pain beneath the metatarsal heads also can be presenting complaints; often physical examination will reveal significant soft tissue reactions on the plantar surface of the hind foot. A valgus deformity of the hind foot is seen in inflammatory disease due to involvement of the talocalcaneal joints and ligaments. Valgus angulation and lateral subluxation of the joint result and may cause the loss of the longitudinal arch of the foot. Mild to moderate cases of rheumatoid disease of the foot can be managed by medications and modified shoe wear. Hindfoot valgus deformities often are treated by bony fusion (often a triple arthrodesis: a fusion of the talus, calcaneus, and navicular).

Heel Pain Syndrome—Plantar Fasciitis

Heel pain syndrome is a relatively common condition that can cause severe and sometimes near disabling pain. Pain generally is felt on the plantar surface of the foot immediately anterior to the calcaneus. This area of the foot is tender to palpation, and the patient will report severe pain upon first arising from a bed or a chair with the first few minutes of weightbearing on the foot being extremely painful. In general, the severe pain with the initiation of weightbearing abates with continued weightbearing but will return after any short interval of rest. There is controversy over the exact pathophysiology underlying the symptoms. Irritation and inflammation of the plantar fascia generally is agreed to be the underlying cause. In some patients, entrapment of the first branch of the lateral plantar nerve can be identified. On such an occasion, release of the deep fascia adjacent to this nerve can provide substantial relief.

Posterior Heel Pain

Pain in the region of the Achilles tendon insertion on the calcaneus is common. This can be due to a bursitis, either posterior or anterior to the Achilles tendon, which most commonly presents with local posterior heel pain exacerbated by exertion. Physical examination will reveal tenderness anterior to the Achilles tendon. This usually can be managed nonoperatively with immobilization (walking boot) and anti-inflammatory medications.

Insertional Achilles tendonitis (tendinosis) of the Achilles tendon most frequently is seen in patients >40 years of age, and often is associated with a tight heel cord. Tendinosis can be disabling and generally is treated with immobilization and rest, stretching of the gastrocnemius and Achilles region, and shoe modification. When severe and persistent, this condition is treated operatively by débridement of the tendon involved. If the tendon insertional area on the calcaneus is severely attenuated, operative reconstruction of the tendon may be necessary.

SPORTS MEDICINE

Athletic injury can, of course, encompass many areas in the musculoskeletal system. The orthopedic subspecialty of "sports medicine" has developed in response to a very high incidence of soft tissue injuries (ligament, tendon, and cartilage) in patients who are active in exercise and athletics. The most

problematic joints in this regard are the knee and the shoulder. Orthopedic treatment for such injuries involves careful history, physical examination, and close attention to the need and desires of the individual patient. Surgical intervention for ligament and cartilage injuries in such patients most frequently is done using arthroscopic technique.

Anatomy of the Knee

The principal mechanical function of the knee is that of a hinge joint, but the knee does bear tremendous axial loads as well as torsional and shear forces. The major stabilizing structures within the knee unfortunately are frequently injured. The anterior cruciate ligament (ACL) is a very stout ligament that is situated centrally within the knee. Its mechanical functions are complex, but the most important is to restrain the tibia from forward excursion below the femur. The posterior cruciate ligament (PCL) lies immediately behind the ACL. The PCL undoubtedly has multiple functions, the most important and most easily assessed is its function to restrain posterior sliding movements of the tibia beneath the femur. The medial collateral ligament (MCL) is located outside of the joint capsule and restrains the knee from bending in a valgus direction. The lateral collateral ligament is analogous to the MCL and joins the lateral femoral epicondyle to the fibular head. The function of the lateral collateral ligament is to restrain the joint from varus angulation. All of these ligaments are vulnerable to injury.

Menisci

Within the joint, the two large articular surfaces of the condyles articulate with the cartilage of the tibial plateau. Crescent-shaped fibrocartilage menisci lie medially and laterally within the joint and serve to guide the femoral condyles' motion and to more evenly distribute loads across the joint. The menisci are important stabilizing structures. The fibrocartilaginous menisci are vascularized only in their outer third. Because of their significant mechanical function, they are subject to both acute traumatic tears (acute tears) as well as progressive degeneration (degenerative tears).

The medial meniscus is torn more frequently than the lateral. Tears of either the medial or the lateral meniscus may be clinically silent or they may cause significantly disabling symptoms. Tears of the menisci have been reported in virtually all portions of the meniscus. Radial and longitudinal tears are common.²⁵ A special type of a longitudinal tear is the "bucket handle tear," which parallels the C-shaped contour of the meniscus and can create a significant and problematic flap if it displaces.

Symptoms caused by a meniscal tear can include local pain and intermittent swelling of the knee, as well as pain on weightbearing. Displaced meniscal tears may cause interference with joint motion and, on some occasions, can frankly prevent the knee from full extension, a so-called *locked knee*. The locked knee joint does occasionally yield to manipulation to reduce the meniscal tear. More frequently, such patients require timely surgery to excise or repair the flap.

Options for treatment of a meniscal tear include resection and reshaping of the torn area, generally preferred for small tears (Fig. 43-24).²⁶ Very large tears in young active patients usually are treated by primary meniscal repair, generally using arthroscopic technique (Fig. 43-25). Complete excision of a torn meniscus, once quite popular, is now recommended only rarely because of loss of the meniscal load distributing function that can accelerate osteoarthritic change in the knee.²⁷ On some occasions, badly injured menisci in young active patients can be successfully treated by allograft replacement of the meniscus from a cadaver source. The long-term results of this approach are not yet clear.

Arthroscopic images of a horizontal tear of the medial meniscus. The tear is repaired using a "buried suture" technique.

Ligamentous Injuries of the Knee

MCL injury will occur after excessive valgus stress of the knee. Unfortunately, it is sometimes associated with a meniscal injury. Nonoperative treatment is preferred for an isolated MCL injury. In most cases, full return of function is anticipated.

Lateral collateral ligament injuries are much less common than MCL ligament injuries. Similarly, however, they are most often managed nonoperatively. ACL injuries can be isolated injuries, but often are seen in combination with MCL rupture and medial or lateral meniscal tear. The triad of MCL, medial meniscus, and ACL tears is most common in contact sports (e.g., football) or jumping sports (e.g., basketball).

Anterior Cruciate Ligament Injury

A functioning ACL is not necessary for most individual's activities and daily living.²⁶ Indeed, many competitive athletes can function at a high level of competition with an ACL deficient knee as well, presumably due to secondary soft tissue constraints, muscle activities, and individual effort.

Unfortunately, many individuals with an ACL-deficient knee due to traumatic failure of the ligament find themselves unable to compete because of instabilities of the knee. Accordingly, in patients for whom athletic endeavor is an important part of their life, reconstruction of the intercruciate ligament is a useful procedure that has prolonged many patients' athletic participation (Fig. 43-26).²⁸

(Courtesy of Dr. David Green.)

Evaluation of the patient for possible ACL injury involves a Lachman test: manual passive assessment of the AP stability of the knee, which is held in slight extension. Diagnosis of the ACL rupture and other associated internal joints of the knee usually is confirmed by an MRI image of the affected joint. Various techniques for the reconstruction of the cruciate ligament are described, which generally involve autograft or allograft tissues placed through tunnels within the tibia and the femur.²⁹ A central slip of the patellar tendon, including a portion of the bony attachment from both the tibial eminence and of the patella itself, is popular, as are woven grafts from hamstring tendons. Other graft sources also have found favor. Accurate placement of the bony tunnels for the graft and proper tensioning of the graft are critical portions of this procedure. Following the procedure, a lengthy rehabilitation process generally is necessary.

The PCL is less frequently injured than the ACL. A rupture of the PCL is, in general, better tolerated than is an ACL-deficient knee. A useful examination

maneuver to test for PCL function is a posterior drawer test, which is essentially the reverse of the Lachman test where a slightly flexed knee is tested for the stability of the tibia beneath the femur by passive manipulation. PCL reconstruction is less commonly performed than ACL reconstruction, although, when functional deficits result from this injury, surgical treatment may be rewarding for athletic patients.³⁰ Chronic PCL-deficient knees are thought to have an increased incidence of osteoarthritis, particularly in the patellofemoral and medial knee compartments.

THE SHOULDER

Shoulder Dislocation and Shoulder Instability

The glenohumeral joint is a ball and socket joint. Some stability for the very shallow socket of the glenoid is provided by the glenoid labrum, but this very mobile large joint is the most frequently dislocated joint in the human body. Dislocations can result from major or minor trauma. Although the dislocation can occur in the posterior or inferior directions, the most common direction for dislocation is anterior. A patient with an anterior dislocation will complain of local pain and will present with an internally rotated shoulder. The anterior position of the humeral head in such dislocation can make the radiographic diagnosis challenging. An AP x-ray, a glenoid (axillary) view, and a Y view of the shoulder is recommended in assessing this injury. Associated neurovascular injury is possible but rare. When carefully assessed, it often is found to be a transient axillary nerve palsy ($\geq 30\%$). Relocation of the shoulder is generally accomplished with the patient supine by subjecting the arm to gentle traction in a position of slight abduction. Some sedation before the maneuver is helpful. After relocation of shoulder dislocation, the patient generally is provided a sling for comfort. Prolonged immobilization of the shoulder (as was done in years past) is not recommended.³¹ Prolonged immobilization will often lead to substantial stiffness in the shoulder and does not appreciably decrease the redislocation rate. Unfortunately, after an anterior dislocation, many patients will experience recurrent dislocations.³² When these become multiple events, surgical stabilization of the shoulder is considered. Numerous procedures for reconstructing and tightening the shoulder capsule are described, many of which now are accomplished arthroscopically.

Impingement Syndromes

After minor trauma, repetitive injury, and sometimes without an identifiable inciting event, many patients experience symptoms of shoulder pain. Pain from a shoulder impairment syndrome often is reported in the anterior shoulder and is exacerbated by abduction of the shoulder, which can be due to irritation of the tissues in the subacromial space.

Shoulder impingement syndromes represent a broad spectrum of disease ranging from simple bursitis to tendonitis of the long head of the biceps or supraspinatus tendon.³³ In many cases, this impingement syndrome can progress to a frank tear of the supraspinatus tendon, the most cephalad of the rotator cuff tendons. The diagnosis is confirmed by documenting leakage of contrast in a shoulder arthrogram. MRI imaging also can be definitive, and ultrasonography is readily available and quite accurate.

Interestingly, patients with rotator cuff tears frequently are asymptomatic, and many have excellent use of the shoulder without apparent pain or difficulty. On the other hand, many patients with such tears report with severe disabling pain, and many are unable to pursue sporting activities as a result. Accordingly, surgical repair of a rotator cuff injury is often indicated to restore function. Primary repair of the rotator cuff is accomplished, in most cases, arthroscopically.³⁴ The procedure sometimes is accompanied by a bony resection of the inferior portion of the acromion.

The Acromioclavicular Joint

The acromioclavicular joint is stout and not very mobile. This joint is vulnerable to ligament injuries (sprains), particularly in athletic endeavors where blows to the shoulder or falls onto the shoulder are common. Such injuries range from simple partial thickness injuries (grade 1 sprains) to frank tearing of the acromial-clavicular and acromioclavicular coracoacromial ligaments causing displacement of the joint. Such injuries are common in contact sports such as football, and are particularly common in athletes playing ice hockey. An acromioclavicular sprain is referred to as a *shoulder separation* and is not to be confused with a glenohumeral dislocation. Treatment for such a shoulder separation (acromial-clavicular sprain) usually is symptomatic. Significantly displaced injuries involving frank tearing of the coracoclavicular ligaments sometimes are reconstructed surgically.

THE SPINE

Spinal Trauma

The treatment of spinal trauma is one of the most challenging areas in orthopedic surgery. Situations at times are extremely challenging because many patients who have sustained significant spinal trauma also have concomitant visceral and other musculoskeletal injuries as well. Prioritizing treatment in these situations can be challenging. In patients with an isolated spinal cord injury, the major concerns for the treating orthopedic surgeon are the neurologic status of the patient, the possible presence of ongoing spinal cord compression, and the stability of the spine and the possible need for stabilization.³⁵

Assessment of the neurologic status of the patient is covered in Chap. 42 on Neurosurgery. A detailed physical examination in search for other injuries as well as the thorough assessment for any neurologic deficits should be done early in the evaluation of these patients.³⁶ Priorities of care follow the primary concerns of airway, ventilation, and circulation. If the patient is neurologically intact, then the primary concern is assessment of the spinal stability to know whether or not mobilization of the patient (often necessary for other treatments) is safe and whether successful healing of the spinal injury is likely without surgical intervention.

In patients with significant neurologic deficits, the immediate question is asked whether or not there is ongoing compression of the spinal cord or the nerve root for which a decompressive procedure would be indicated. In most spinal cord injury situations, prompt decompression of ongoing neural compression is performed whenever possible. Unfortunately, the true benefits of such interventions are very difficult to objectively assess. There is a growing body of evidence that suggests that prompt decompression in spinal cord injury can make a detectable and measurable difference in the acute and semiacute neurologic function. Whether patients so treated are truly better 6 months or a year after their injury is a question that is still debated.

Extensive laboratory investigation using animal models with spinal cord injury suggested that very prompt decompression of a localized spinal cord leads to objective and measurable differences in recovery. The optimal time for this decompression in humans is not yet known. A body of animal data suggests that early intervention is better than late intervention.

Occipital Cervical Dislocation

Dislocation of the occiput on the occipital condyles of the atlas (C1) is a common injury after high-energy trauma, particularly motor vehicle trauma. Unfortunately, only a tiny fraction of the patients with this injury survive, as it is almost always accompanied by a high cervical spine or brain stem injury. For the rare patients who survive this injury, traction on the spine is contraindicated. Definitive treatment consists of stabilization and fusion in situ using a screw-plate or rod screw device spanning from the occiput to the midcervical spine.³⁷

Fractures of C1 (Jefferson Fracture)

The Jefferson fracture, eloquently discussed by Dr. Jefferson in 1920, is a fracture of the C1 ring.³⁸ The C1 vertebra does not have a true anterior body as do all of the rest of the vertebrae. The rather thin anterior and posterior rings are subject to fracture, particularly with axial load injuries. The Jefferson fracture results in a lateral spread of the lateral masses of C1, which are visible on an AP (through the mouth) x-ray image of the upper cervical spine. This injury actually results in an increase in the size of the spinal canal, and thus, rarely is associated with neurologic injury. Fortunately, the bony fractures heal quite reliably. The treatment of choice in Jefferson fractures is bracing with either a cervicothoracic orthosis or a halo ring and vest.

Fractures of C2 (Odontoid Fracture)

The odontoid is a peg of bone that arises off the central body of the C2 vertebra and articulates with the anterior ring of the C1 vertebra. The articulation between the odontoid (or dens) in the C1 vertebra and the atlantoaxial facet joint is the site where half of normal cervical rotational movement occurs. The odontoid is a relatively small structure, however, and it is vulnerable to fracture. The types of odontoid fracture are eloquently discussed by Anderson and D'Alonzo in their classic paper, which describes a generally benign "type I" fracture that consists of an avulsion fracture off the very tip of the odontoid.³⁹ These type I fractures are thought to arise from the alar ligaments that span from the tip of the odontoid to the skull (bypassing the C1 vertebra). Such isolated avulsion fractures, although they may be painful, do not represent any danger to the patient. Type I fractures generally are managed symptomatically with expected satisfactory outcomes.

A fracture through the base of the odontoid, at the level of the articular surfaces of the facet joints, is classified as a "type II" injury in the Anderson and D'Alonzo classification scheme (Fig. 43-27). These fractures result from oblique or lateral loading forces on the odontoid. The rather small fracture surface created by this and the small surface of cancellous bone within the odontoid may be reasons why this particular variety of odontoid fracture heals poorly. When such fractures are immobilized in cervicothoracic orthosis or halo vest, nonunion rates ranging from 20 to 80% have been reported. Accordingly, treatment of a type II odontoid fracture is most usually operative. Stabilization of the fracture can be accomplished through an anterior approach by directly transfixing the odontoid with a screw initiated at the anterior/inferior border of the C2 body and inserted across the fracture site and up into the odontoid. This is a technically demanding screw placement and is only done with the availability of excellent intraoperative imaging techniques. An alternative to direct fixation of this fracture is a posterior stabilization and fusion of C1 on C2. This can be done by sublaminar wiring cable techniques or by posterior screw fixation. The anterior odontoid screw fixation does allow the potential for continued rotational movement between C1 and C2. The posterior fusion of C1 and C2, while restoring safety and stability, also results in a markedly diminished range of motion of the cervical spine.

X-ray images of a displaced fracture of the odontoid process of C2, before and after reduction and internal fixation. Transverse fracture at the base of the odontoid (type II) has a high nonunion rate when managed nonoperatively.

Anderson and D'Alonzo type III fractures are described as those that extend into the body of C2, below the base of the odontoid. The fractures' surfaces are large and well vascularized. Type III fractures heal reliably with halo brace, or other brace designs. Surgical intervention rarely is needed.

Hangman's Fractures of C2

Hangman's fractures or traumatic spondylolisthesis of C2 are fractures that occur through the pars interarticularis of C2 (the segment of the posterior elements between the superior and inferior facets of C2). This fracture results from sudden extension forces on the neck causing a fracture through this area of C2, which is one of the thinner portions of the posterior elements of this vertebra. This fracture, in most cases, does not result in any narrowing of the spinal canal. The overwhelming majority of patients with minimally displaced hangman's fractures are neurologically intact. Treatment for this injury is almost always nonoperative employing simple immobilization using a cervicothoracic orthosis or a halo vest. With higher-energy injuries (such as those intentionally created in judicial hangings), more severe extension forces can create dislocation of the C2–3 facet complex and injury of the C2–3 disc. Such displaced fractures can and do compromise the spinal canal. When significant displacement occurs, death can result due to compromise of respiration. Infrequently encountered are neurologically intact patients who have significantly displaced hangman's fractures. These patients are managed by internal fixation and bone grafting between C2 and C3 (Fig. 43-28).

Preoperative computed tomography images and a postoperative X-ray of a patient with a displaced hangman's fracture of C2 (traumatic spondylolisthesis). Most hangman's fractures are managed nonoperatively, but in severely displaced fractures, reduction and stabilization with bone grafting is indicated. This can be done with either an anterior or (as shown) posterior procedure.

Compression Fracture of the Cervical Spine

Compression fractures of the cervical spine refer to an axial load injury with failure of the end plate, but preservation of the posterior cortex of the vertebral body. This will occur in the vertebrae of C3 to C7 and may or may not be associated with a fracture of the anterior cortex. In either case, with the posterior cortex of the vertebral body intact, no compromise of the neural elements results. The healing potential for these fractures is very high, and such patients generally are managed nonoperatively. Analgesics are prescribed as is a cervical brace for comfort.

Burst Fractures of the Cervical Spine

Burst fractures of the cervical spine arise as a result of failure under axial loads. Unrestrained motor vehicle occupants striking a windshield and diving accidents are common injury mechanisms. The burst fracture is distinct from the compression fracture, however, in that the posterior cortex of the vertebral body is fractured. This frequently results in displacement (retropulsion) of bony fragments into the canal, which can cause neurologic injury and dysfunction. Very high-energy burst fractures can result in fractures of the posterior elements as well; however, this is less commonly seen. A burst fracture noted in the neurologically intact patient can be managed conservatively by bed rest and traction. This can be appropriate treatment for a cooperative teenage patient who has potential to heal a fracture within a very short interval. Far more commonly, these occur in adult patients, for whom prolonged bed rest is not only inconvenient but risky. Accordingly, the overwhelming majority of such patients are managed operatively by anterior débridement of the fracture (necessary should there be neurologic compromise) and reconstruction using a bone graft strut and the application of a screw and plate device. Plate fixation after strut grafting and decompression generally will allow immediate mobilization of the patient. Patients are restrained from rigorous activities until after fracture healing is confirmed in 6 to 15 weeks.

Unilateral and Bilateral Facet Dislocation

A forceful flexion with distraction forces (such as can happen in an automobile accident with a restrained driver) can result in forward subluxation of the cervical vertebrae on a subjacent neighbor with dislocation of one or both of the facet joints. Interestingly, the diagnosis usually can be made with confidence by examination of a lateral x-ray image, as dislocation of one facet joint predictably will result in an anterior displacement of precisely 50% of the AP diameter of the involved vertebral body.

Bilateral facet dislocation typically is caused by an anterior displacement of 50%. On occasion, fractures of the facet joint occur in association with the dislocation. A unilateral facet dislocation rarely results in spinal cord injury; however, bilateral facet dislocations frequently do. Radicular symptoms following unilateral or bilateral dislocation are common, as the dislocated facet can narrow the exit foramen and impinge the intervening nerve roots. Treatment for this injury consists of axial traction, usually exerted after placement of cranial tongs, followed by graduated application of weight and periodic x-rays. This always is done with the patient awake because of safety concerns. When successful reduction is attained, the risk of recurrent dislocation is so high that most patients are then taken to surgery for posterior fusion procedures of the involved vertebrae. This can be done with interspinous process wiring or by a screw-plate or screw-rod device, with screws inserted into the lateral masses. Postoperative stabilization with a cervical collar is at the discretion of the treating surgeon. Excellent long-term results are generally expected.

Clay Shoveler's Injury

Clay shoveler's injury is a common, but often missed injury to the spinous process of a lower cervical vertebra or the upper thoracic vertebrae. It is most common at the levels of C6, C7, T1, and T2, and is the result of avulsion fracture of the spinous process by the paraspinal muscle forces. The injury was originally described in convicts involved with shoveling clay and soil. This is most commonly seen today after motor vehicle trauma. These fractures are at times difficult to see on x-ray images (because of the density shadow cast by the patient's shoulder). The fracture itself generally requires only symptomatic treatment (analgesics with or without a soft collar for comfort); however, it behooves the treating physician to look for such injuries when they are suspected.

FRACTURES OF THE THORACIC AND LUMBAR SPINE

Thoracic Lumbar Spine Injury

Thoracic and lumbar fractures generally are discussed together because the mechanism fracture of these distinct anatomic areas is similar. Fractures of the thoracic spine are generally more stable than similar injuries in the lumbar spine because of the stability afforded by the ribs. Also, of course, neurologic injury patterns are different in the thoracic and proximal lumbar spine because of the presence of the spinal cord, which normally ends at the L2 level. Accordingly, injuries that compromise the spinal canal are more likely to cause neurologic deficits in the thoracic spine than in the lumbar spine. Nonetheless, general patterns of injury and their treatments are very similar.

Compression Fracture

Acute compression fracture in the thoracic and lumbar spine is a relatively common event. Traumatic compression fractures in patients with normal bone densities may involve a fracture of the superior or, less frequently, inferior end plate with or without associated posterior cortical failure. The zone of injury for the compression fracture is confined to the "anterior column" as defined by Dr. Francis Denis⁴⁰ in his classic paper in 1983 (Fig. 43-29). Isolated injuries to the anterior column do not result in neurologic deficit, because the posterior cortex of the vertebral body, and thus, the borders of the spinal canal remain intact; these injuries are not at all likely to lead to instability. Treatment is generally symptomatic with the use of braces for comfort and analgesics. In most cases, the fracture is noted to have successfully healed with resolution of pain within 4 to 10 weeks.

The spine can be thought of as three columns. Two of three can maintain stability.

Burst Fracture

Burst fracture, caused by more severe axial load forces, is common following falls and motor vehicle trauma. A burst fracture involves fracture of one or both end plates and the anterior cortex of a thoracic lumbar vertebra with an associated failure of the posterior cortex. Frequently, the posterior cortical fracture results in retropulsion of bone into the canal, which can cause compromise of the neural elements and acute neurologic deficit. The retropulsed fragment in a burst fracture injury typically has a trapezoidal shape, which reflects the trabecular anatomy in the area at the base of the pedicles where failure occurs.⁴¹ On occasion, with even more severe injury loads, posterior element fractures can occur, most frequently, the vertical fracture of the lamina caused by forces exerted through the facet causing a spreading force on the posterior elements. Such vertical lamina fractures are particularly important because, quite frequently, this fracture will contain an invaginated segment of the dura mater, sometimes with accompanying nerve roots. Surgical intervention posteriorly on such fracture can result in an iatrogenic dural tear and/or root injury.

Neurologically intact patients with burst fractures usually are managed quite successfully by nonoperative means using a rigid orthosis and analgesics. When significant neurologic injury is noted, surgical treatment usually is recommended. Most commonly, this consists of an anterior exposure of the fractured vertebrae and removal of the fractured anterior elements. This procedure is called a *corpectomy*. Concomitant with this (as in cervical spine burst fractures), both adjacent discs are excised to expose the bony end plates. A strut graft is placed; this can be either autograft or allograft or manufactured struts of titanium or ceramic. Generally, a laterally placed rod or plate system also is inserted to afford stability. The anterior approach allows direct decompression of the spinal canal and removal of any retropulsed fragments.

Another alternative is the posterior approach to the spine, which may or may not involve laminectomy and direct exposure of the neural elements. Because the offending compression is directed anteriorly, good visualization of the intraspinal fragments can be difficult from this approach, and usually, decompression is sought by distraction instrumentation. Hooks and screws are placed into vertebrae above and below the fractured segment and

longitudinal stretching forces are applied through an attached rod. This usually results in partial reduction of the neurologic compression. When the posterior longitudinal ligament becomes tight, it will exert a corrective force encouraging the fragments in the canal to migrate back closer to their normal anatomic position. Predictable decompression of the spinal canal using posterior distracting techniques is not absolute. On average, this will result in improvement of the canal diameter, but in some cases, despite a technically well performed procedure, ongoing compression may persist.

Seatbelt Injuries (Flexion Distraction Injuries)

Flexion distraction injuries result from distractive forces on the spine. The mechanism for this is acute forward flexion of the trunk and anterior restraint such as a lap belt type seat belt. As the pelvis and upper torso moves forward, a fulcrum is created that can create a failure of the spine under tension beginning with the posterior elements and extending through the spine. Failure can take place through the soft tissues with tearing of the dorsal fascia, the interspinous ligament, dislocation of the facets, and tearing of the discs. It also may occur through the bone with frank failure in tension of the bone of the spinous process, the lamina, the pedicles, and the body. This "all bone" variant carries the name *Chance fracture*, named not for its unique morphology, but in deference to Dr. Chance who first described this injury in 1958.⁴²

Fortunately, flexion distraction injuries usually do not result in neurologic injury as the spinal neural elements are generally much more tolerant of distractive forces than they are of compression. Unfortunately, when the flexion distraction injury occurs predominantly through soft tissue, reliable healing of the soft tissue is not expected and posterior stabilization using internal fixation and an associated bone graft generally is indicated to restore stability to the spine.

Interestingly, because of the rough irregular surfaces of the bone, fractures of the all bone variant (Chance fracture) are usually quite stable. Bracing is recommended, but the "all bone" Chance injury generally is quite successfully managed nonoperatively.

Fracture Dislocations of the Spine

Fracture dislocations of the spine are severe injuries associated with displaced injury of the bony elements, with either a translational or rotational component. By necessity, the presence of a translational or rotational deformity will result in canal compromise. The majority of patients sustaining these severe injuries do have a neurologic deficit, which is frequently profound (Fig. 43-30).

Fig. 43-30.

Preoperative computed tomography images and postoperative x-ray images of a patient with fractures of T5 and T6 and an "incomplete" spinal cord injury. The spinal canal was decompressed and the fractures stabilized using pedicle screw instrumentation.

Reduction of the displaced bones generally is indicated and is usually the best way to improve the canal dimensions. The prognosis for neurologic recovery in a patient with a neurologically complete injury is dismal. Patients with partial preservation of function often can make remarkable neurologic recoveries. Patients with fracture dislocations of the spine are essentially always managed operatively to stabilize the spine, to safeguard any neurologic function that might remain, or to allow mobilization of the patient and early initiation of rehabilitation.

Disc Herniation

Disc herniation is an extremely common event generally seen between the ages of 20 and 50 years old. It can occur in the cervical, thoracic, or the

lumbar spine. It consists of a tear or an attritional failure of the annulus of the intervertebral disc, allowing the nucleus pulposus material to penetrate through the annulus and enter the canal. The incidence of this phenomenon is impressive. Fortunately, the majority of such events are minimally symptomatic. A majority of the population will have a disc herniation during a normal lifetime. Classically, disc herniations present with axial pain either in the neck or in the lumbar area, which over 1 to 14 days progresses to include a radicular pain in the upper or lower extremity. Nerve root impingements can occur, depending on the location of the herniation, of traversing nerve root or the exiting nerve root at any given level. Large herniations may impinge both of these nerve roots. In the cervical spine, potential for spinal cord compression also is noted, although this is not particularly common. When a disc herniation is causing myelopathic symptoms, it should be treated aggressively.

The expected natural history of disc herniations is that of spontaneous resolution of symptoms. This is presumed to occur through natural accommodation of the nerve root to the compression and to the resolution of the acute inflammatory process that may accompany the acute annular injury. Several studies have demonstrated that the extruded nucleus pulposus material actually undergoes a significant amount of resorption over time as well. Accordingly, at least approximately 90% of radiculopathies due to disc herniation do resolve or substantially improve within 8 weeks. Thus, surgical intervention even for severe radiculopathies is not recommended in this initial 6- to 8-week interval.⁴³ Should significant symptoms persist beyond this point in time, the decision is made between the surgeon and the patient about options for surgery. Should surgery be elected, excision of the involved disc and decompression of the nerve roots can be performed with an excellent prognosis. Thus, the great majority of patients express satisfaction with the results.

Surgical treatment for a cervical disc herniation usually consists of an anterior approach to the spine with dissection through a transverse incision on the anterior neck. Dissection is carried lateral to the trachea and esophagus and medial to the carotid sheath to expose the bones and discs of the anterior cervical spine. The disc is removed in total from anterior to posterior; this allows direct visualization of the dura and the extruded disc. In most cases, the disc space is then bone grafted to effect a fusion between the involved vertebrae. In most cases, a low profile titanium plate is then affixed to the involved vertebrae by locking screws. The advantage of the anterior approach is that it allows visualization of the disc material, including any central component.

An alternative surgical approach is a posterior decompression and laminectomy. Dissection is carried through the midline to expose the posterior elements of the spine. A portion of the lamina at the involved level is removed to allow access into the canal. This is an excellent option for foraminal impingements or for very lateral disc herniations. It is not possible from a posterior approach to visualize an exposed central disc herniation because of the presence of the spinal cord, which cannot be safely touched or manipulated. An advantage to the posterior approach is that this can be done without the need for fusion or instrumentation.

The surgical approach for a disc herniation of the lumbar spine is similar to the posterior approach just described in the cervical spine. A midline incision is created with exposure of the posterior elements of the spine. Portions of the lamina are removed until good visualization of the lateral recess is possible. Unlike the cervical spine, gentle retraction of the dura is possible in the lower lumbar spine, allowing visualization of the traversing nerve roots as well as of the disc fragment. Thus, even a central disc fragment can be removed under excellent direct visualization of the lumbar spine. This can be done from a very small incision, and in nearly every case, without the need for fusion or instrumentation.

Spinal Stenosis

Spinal stenosis is an acquired narrowing of the spinal canal and can occur in the cervical, thoracic, or lumbar spines. This generally is due to a combination of degenerative changes in the spine, loss of disc height, and bulging of both of the annular tissue as well as the ligamentum flavum; both will contribute to narrowing of the canal. The larger culprit is often hypertrophic changes in the facet joints with osteophyte formation, which can contribute to significant nerve impingement. Cervical stenosis can cause progressive myelopathic symptoms of hyperreflexia, ataxia, balance problems, and four quadrant weakness. On occasion, concomitant root compression also can cause upper extremity radicular pains.

In the lumbar spine, a more common picture is that of "neurogenic claudication." Patients are asymptomatic at rest, but with ambulation, they experience progressive discomfort, weakness, and at times, numbness in the lower extremities. The lower extremity symptoms, resulting from lumbar spinal stenosis, generally resolve very promptly with sitting or forward flexion of the body. It can be demonstrated that increasing lumbar lordosis (as with standing or walking) will cause further narrowing of the canal due to bulging of the ligamentum flavum and positioning of the arthritic facets.

Temporary relief for spinal stenosis in both the cervical and lumbar spine can result from epidural administration of corticosteroids. Definitive treatment for disabling symptoms consists of decompressive surgery, specifically removal of the offending laminae and resection of hypertrophic bone from the involved facets.⁴⁴ If extensive bony resection is performed, particularly in the cervical spine, stabilization using bone grafts and internal fixation (rods or plates) may be indicated.

Spinal stenosis is a clinical entity most common in patients >50 years of age and occasionally, substantially older. Unfortunately, the same patient group

often has acquired spinal deformities of degenerative spondylolisthesis or degenerative scoliosis.⁴⁵ The presence of significant symptoms of spinal stenosis in the presence of a deformity such as spondylolisthesis or scoliosis can create a difficult management problem. Simple decompression in the face of a spondylolisthesis or a significant scoliosis may lead to abrupt, precipitous, and problematic progression of the patient's spinal deformity. Accordingly, when decompressive procedures are planned for patients with deformity, in most cases, concomitant fusion procedures with instrumentation are recommended. Unfortunately, these are large and potentially morbid surgical procedures that often are contraindicated for patients with debilitating comorbidities.

Back Pain and Degenerative Disc Disease

Causes for low back pain are myriad, and unfortunately, for many patients, such pains become chronic and disabling. Complaints of low back pain should always alert the physician to the possibility of a dire process such as a malignancy. Metastatic disease is present in the spine with a frightening frequency.

Degenerative disease of the spine is common and clearly can cause disabling low back pain. One enduring mystery, thus far, has been the limited correlation between degenerative disease demonstrated on imaging studies and levels of clinical back pain. Many patients with severe degenerative changes have no pain at all, while others with only mild degenerative disease on imaging studies complain of disabling symptoms. Evaluation and treatment of these patients remains an area of great controversy. One option in the management of disabling low back pain in the presence of degenerative disease is to consider fusion operations of the spine.

Fusion procedures for painful degenerative osteoarthritic joints have historically been very successful in the extremities. Although fusion of the hip and knee for these indications has largely been supplanted by joint replacement procedures, it is recognized that knee fusion and hip fusion, as well as wrist, elbow, and shoulder fusion, can represent very effective pain relieving procedures. Unfortunately, the observed clinical results when fusion operations are applied to the spine are clearly less successful. Complicating issues of secondary gain, psychiatric issues, and the difficult diagnostic questions of which portions of the axial elements are causing the pain fuel the controversy.

Many surgeons advocate the use of *discography*, a provocative test done on an awake patient wherein a needle is inserted percutaneously into a disc space and contrast is injected. Flow of the contrast through the disc and annulus in an abnormal way is interpreted to document degenerative changes within the disc. Simultaneous provocation of "typical" pain by the injection is thought to confirm the anatomic location of the offending pain. Unfortunately, even with the use of discography, the success rate with such fusion procedures is controversial at best. Documentation of small numbers of unmyelinated nerve fibers within the outer annulus of the disc has been widely accepted by many as the true source of such back pain. Recently, the documentation of extensive innervation of the epidural space, and indeed of the vertebral bone itself, has raised other questions about possible pain sources in these patients. Work on this subject is continuing.

A newer option for the management of degenerative disc disease is the use of an intervertebral disc replacement prosthesis. Several designs are now in use throughout the world. Substantial controversy surrounds their use, having to do with their true effectiveness, their potential for loosening, the potential creation of wear debris, and the difficulty associated with a future revision surgery. These prostheses are placed in close proximity to the contents of the spinal canal and to the great vessels. Future management of this challenging clinical problem is presently unclear.

Scoliosis

Scoliosis is a term used to describe a lateral curve of the bones of the spine. This can easily be documented on x-ray images. Because of the anatomy of the spine, lateral bending deformity will always be accompanied by an associated rotational deformity as well, a phenomenon called *coupling*. Thus, the scoliosis curve will always have a rotational component. Scoliosis is a three-dimensional entity.

The description of scoliotic curves is the topic for extensive mechanical and anatomic study, and several good schemes to measure and define the curves are in use. The most common one and most convenient is the Cobb method, after Dr. Cobb's description in 1948.⁴⁶ Lines are drawn along the end plates of the vertebral bodies at either end of the curve and the angle from where these lines intersect is taken as the "magnitude" of the curve. This technique does not take into account the rotational component of the deformities, which are measured by other means.

Scoliosis curves are not only classified by their magnitude, but by their etiology. Scoliotic curves are classified as congenital (developmental abnormal shapes of the involved bones), degenerative (a curve caused by degenerative changes in the joints of the spine), metabolic (caused by generalized genetic metabolic disease such as mucopolysaccharidosis), neurogenic (spinal deformities caused by primary neurologic insult such as cerebral palsy or spinal cord injury), and myogenic curves (those curves associated with primary muscle problems). Such myogenic curves commonly are seen in muscular dystrophy patients. Idiopathic curves are the most common form of scoliosis. It is now emerging that idiopathic scoliosis actually represents a spectrum of genetic disease due to several different genes with variable penetrance. This chapter will limit the majority of discussion to degenerative curves and

Idiopathic curves.

Degenerative curves generally are seen in patients over the age of 50 years old. At times, it is impossible to distinguish a primary degenerative curve from an idiopathic curve with associated degenerative disease. In any event, adults with scoliosis and progressive painful arthritic spines often have disabling symptoms, not only of axial pain, but of imbalance in posture due to these curves. Symptomatic measures using medications, therapy, and activity modification are, at times, rather unsatisfying. In severe cases, where objective deformity is noted and the patient's medical condition warrants, surgical intervention to apply corrective forces by the use of internal fixation with rod and screw constructs can result in substantial improvement and quality of life. These operations are undertaken only after careful forethought, meticulous informed consent, patient education, and careful preoperative and perioperative medical attention. These are challenging surgical procedures with a high rate of complication.

Idiopathic Scoliosis

Idiopathic scoliosis has infantile, juvenile, and adolescent forms. The overwhelming majority of the patients acquire their curves during adolescence. These curves, apparently due to a spectrum of genetic disorders with variable penetrance, generally manifested during early adolescence and may progress rapidly during periods of skeletal growth. Generally speaking, significant progression of these curves is arrested after skeletal maturity. During active skeletal growth, however, rapidly progressive deformity can arise. Initial management may consist of simple observation. Curves that are progressing at a rate likely to lead to significant deformity often are treated by the use of braces. Braces are applied to the trunk to hold the spine in a corrected position. Braces cannot result in permanent correction of a curve, but often are effective in slowing or arresting progression of a curve. Brace treatment for a patient with idiopathic scoliosis is generally most effective for curves between 20° and 40° as measured by the Cobb technique. If bracing is ineffective, or for patients with large curves, surgical intervention may be appropriate. Surgical treatment consists of using rods for instrumentation of the spine in an improved position with grafting and fusion, and can result in dramatic correction of these curves (Fig. 43-31). Such procedures also have the potential for significant complications and always result in markedly diminished truncal motion. The decision for surgery in an adolescent with scoliosis is always carefully considered and generally is undertaken only in the presence of unabated progression. It is a combined decision among the surgeon, parents, and patient.

Neuromuscular Scoliosis

Scoliosis due to neurogenic cause generally is noted early in life. There are hundreds of neurologic conditions that can lead to scoliosis, such as polio and cerebral palsy. Such curves are usually uncompensated, meaning that the patient is unable to lean with his upper body to restore balance. Accordingly, these curves often make standing, and even sitting, unbalanced (Fig. 43-32). Nonambulatory patients often undergo scoliosis correction surgery to facilitate sitting balance and to avoid skin breakdown caused by pelvic obliquity.

ORTHOPEDIC PATHOLOGY AND ONCOLOGY

Orthopedic Pathology and Oncology: Introduction

The orthopedic surgeon quite frequently is asked to deal with both benign and malignant tumors. Given the complexity of these entities, an approach to diagnosing and treating these lesions requires the collaboration of the surgeon, radiologist, and pathologist; ideally with discussion both before and after biopsy and definitive treatment among all three. Failure to allow for adequate communication between all concerned often leads to misdiagnosis or worse.

The most commonly encountered tumor problem facing orthopedic surgeons is that of metastatic disease to the bone. Many carcinomas, most notably lung, prostate, thyroid, breast, and kidney, quite frequently metastasize to the bone. Such skeletal metastases are often painful and may weaken the bone to the point where a pathologic fracture occurs. Unfortunately, the orthopedist is quite frequently the physician who makes the initial diagnosis of metastatic disease, as such painful lesions or associated fractures can be the presenting event for many patients with such cancer.

When first evaluating a patient with a bony lesion, the orthopedist will use imaging studies, always to include plain x-ray images, and often other imaging techniques such as MRI, CT scan, and bone scan. Laboratory studies and patient history also are always considered. Bone lesions are notoriously challenging to identify. The possibility of malignancy or infection must be kept in mind in approaching any abnormal tissue in the bone. The orthopedic oncologist should always consider the possibility that the lesion in question could be a metastatic focus with a distant primary, may represent a focus of

infection, may represent a non-neoplastic or developmental lesion, may represent a benign lesion, or may represent a lymphoma or myeloma. Finally, it could represent a primary malignancy of the mesenchymal tissues (a sarcoma).

In patients with suspected metastatic disease, laboratory studies, x-rays, physical examination, and history will quite frequently reveal a primary source of tumor. Generally, the treatment rendered for the osseous metastases is nonsurgical. Unfortunately, a large metastatic lesion within the bone will frequently weaken the bone to the point of fracture. If a fracture has already occurred at the time of presentation, surgical treatment for stabilization and palliation of pain usually is indicated. Prevention is often recommended, as bone healing in the phase of metastatic disease is reliable. Restoring function to the patient is a high priority in such lesions that are frequently treated by internal fixation and sometimes with bone grafting.

There are a number of non-neoplastic lesions of bone that mimic neoplasms. In the majority of cases, the first concern is that of accurate diagnosis. A malignant bone neoplasm, if misdiagnosed, can lead to disaster.

Benign non-neoplasms of the bone are relatively common. They must be differentiated from malignant lesions. Benign lesions may be indolent, but some benign neoplasms are locally aggressive and destructive. Certain aggressive benign lesions, when occurring in difficult locations such as the spine, may result in paralysis or death.

Bone Neoplasms

Sarcomas are the result of malignant transformation of cells of mesenchymal lineage. Some sarcomas are slow growing, while others are rapidly progressive. They are discussed here individually.

Metastatic Diseases

Unfortunately, pathologic fractures are common. Any surgery on a lesion of this kind will be accompanied by an intraoperative biopsy of the abnormal tissue. Another frequently encountered problem is that of patients with metastatic disease that have large bony lesions that have not yet resulted in fracture.⁴⁷ Recognizing these lesions can be surprisingly difficult. As much as 50% of a long bone substance may be destroyed by tumor before such lesions are visible on routine x-rays (Fig. 43-33). A large lesion occupying a significant portion of the shaft or long bone should be considered for prophylactic internal fixation. Procedures often can be done without opening the fracture site by inserting rods or nails from a distal site to traverse the lesion. Such internal fixation procedures can actually protect the bone from fracture and can spare the patient a much more involved surgery.

Impending fracture of the proximal femur (arrow) from metastatic breast carcinoma. Internal fixation using an intramedullary device (Zickel nail) with

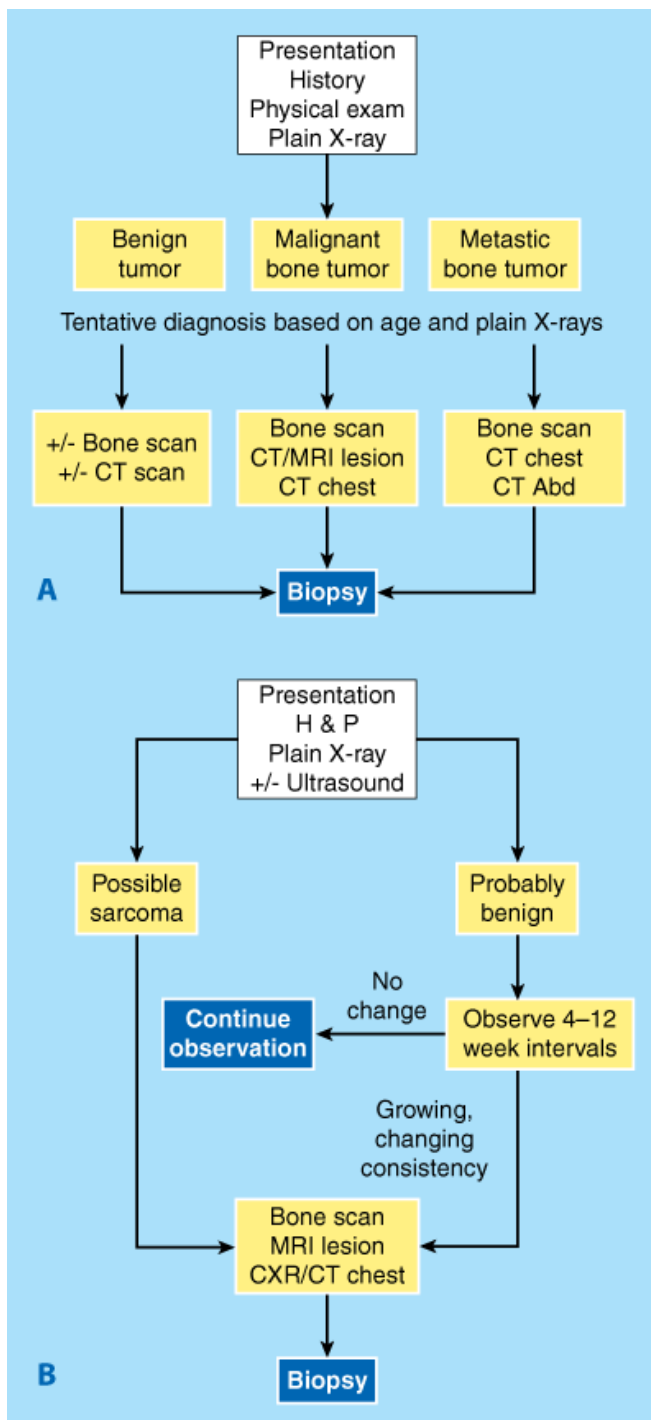

subsequent radiation therapy allows local control of the tumor and healing of the fracture.

Management of Patients with Sarcomas of the Bone

The initial step in managing patients with bone sarcomas is a complete medical evaluation, including laboratory studies, investigation of the chest for possible metastatic lesions, and an assessment for other possible bony lesions (Fig. 43-34). In almost every case, initial biopsy is performed as a separate step before any surgical intervention.⁴⁸ It is imperative that surgical planning and procedures be executed by an experienced tumor surgeon. The biopsy incision is carefully planned to traverse a minimum number of tissue planes so that the entire area of the biopsy dissection including the skin incision may be excised should the patient subsequently undergo a definitive resection of the tumor.^{49,50} Accordingly, incisions are as small as possible and oriented longitudinally.^{51,52} Discussion of the biopsy with the interpreting pathologist is strongly encouraged before performing the biopsy.⁵³ Whenever possible, biopsy tissue is obtained for "permanent" pathology analysis as well as culture and frozen section (Fig. 43-35). The frozen section is performed intraoperatively whenever possible.⁵⁴ The purpose of the frozen section is not to provide a diagnosis; indeed, frozen section examination of sarcoma lesions is rarely definitive. The purpose of the frozen section is to ensure that the obtained tissue represents a reasonable sampling of the abnormal tissue. The critical information sought with the frozen section analysis is to ensure that the biopsy has been taken "within the lesion." Following this, the incision is closed. No further surgical treatment is undertaken until the final diagnosis has been established.

Definitions of surgical margins for bone and soft tissue sarcomas.

(Modified with permission from Enneking WF et al: A system for the surgical staging of musculoskeletal sarcoma. Clin Orthop 153:106, 1980.)

Metastatic Sarcomas

Metastases from sarcomas can arise in many different tissues, but the most common site of initial metastatic disease is the lung. When a sarcoma is suspected, physical examination and imaging of the chest is an early and important consideration.

Chemotherapy in the Treatment of Sarcomas

Use of chemotherapy before definitive surgical resection neoadjuvant treatment is now commonly a part of the management of many, if not most, sarcomas.⁵⁵ Effective therapeutic agents have been developed over the last 30 years that are often effective in causing a reduction in the size of the malignant lesions. Chemotherapy alone is not successful in affecting a cure of any sarcoma; however, combined combinations of chemotherapy and surgery can lead to gratifying long-term survival rates and cures.

Bone-Forming Tumors—Osteoid Osteoma (Benign)

Osteoid osteoma is a benign bone-forming lesion of uncertain etiology that presents with a central radiolucent nidus (<1.5 cm) and dense surrounding sclerosis. This lesion occurs in patients under the age of 20 years old (usually under the age of 12) but can occasionally occur in older patients. They are predominantly intracortical in location except when they occur in the small bones of the hands and feet where they are intramedullary. Radiologically, they are noted to be a dense cortical sclerosis on plain film. The nidus can be difficult to observe, and CT often is helpful in this regard. Histologically, the nidus is a dense fibrovascular proliferation with abundant new bone formation and active osteoblastic and osteoclastic activity. The surrounding sclerosis is very dense and approaches that seen in the normal cortex.

The pain produced by this tumor can be quite intense. Interestingly, this pain is predictably dramatically responsive to aspirin or a NSAID medication. Indeed, regular medication with anti-inflammatories often can present definitive treatment for these lesions which in a significant proportion of cases spontaneously regress, usually after a period of 1 to 7 years. Should more aggressive treatment be contemplated, an accessible lesion can be treated by percutaneous radiofrequency ablation (heat administered through high frequency alternating currents). On other occasions, it can be treated by surgical excision.

Osteoblastoma (Benign)

Osteoblastoma is a relatively rare bone-producing tumor that can grow locally to large size although it does not metastasize. Patients may present with local pain, or on occasion, a mass. The histologic appearance of the lesions consists of cells with regularly shaped nuclei often seen with areas of hemorrhagic tissue and irregularly deposited osteoid.

Osteoblastoma is, by definition, >1.5 cm and has histologic features identical to the nidus of the osteoid osteoma. Although these lesions can occur anywhere, they have a propensity to develop in the posterior elements of the spine where they can mimic a malignancy radiologically. The radiologic appearance is of a purely lytic lesion with occasional internal matrix production. In smaller or thinner bones, the osteoblastoma will often "break out" into the surrounding soft tissue mimicking a malignant lesion. Histologically, an osteoblastoma will show new bone formation in irregular distributions with a rich fibrovascular stroma. Mitotic figures can be noted, especially if the lesion has been fractured or during pregnancy, but malignant transformation is rare. Osteoblastomas generally are managed by excision or local curettage.

Osteogenic Sarcoma

Osteogenic sarcomas are malignant. There are an array of subtypes of osteogenic sarcomas that display varying degrees of potential for metastases. Osteogenic sarcoma tumors are distinguished by the direct synthesis of osteoid by the tumor cells. A low-grade variant of the osteogenic sarcoma is the periosteal osteogenic sarcoma. This is a slow-growing tumor and predictably occurs on the external surface of a long bone cortex. It is very common on the posterior aspect of the distal femur. Periosteal osteogenic sarcoma generally appears to be a large, circumscribed, densely sclerotic mass arising from the cortex. It generally is adherent to or continuous with the bone. Treatment for a periosteal osteogenic sarcoma (after confirmation by a carefully planned biopsy) is surgical excision with a wide margin. Adjunctive radiation therapy or chemotherapy may be indicated for periosteal osteogenic sarcomas with good levels of cure. Long-term survival from a periosteal osteogenic sarcoma after a successful wide local excision can be >90%.

Classic Osteosarcoma (Malignant)

High-grade *osteogenic sarcomas* generally take origin from within the medullary cavity of the bone and are the most common type of osteogenic sarcoma (Fig. 43-36). It is the most common bone malignancy in children and is especially common in the distal femur, proximal tibia, and proximal humerus. Osteogenic sarcomas may contain focal areas of cartilage formation; occasionally other mesenchymal tissues such as fat or muscle may be seen. The presence of any bone formation by the tumor cells, however, establishes the diagnosis of osteogenic sarcoma.

Fig. 43-36.

Low-power photomicrograph reveals cartilage matrix that entraps and destroys bone. The myxoid nature to the matrix suggests a grade II lesion.

Treatment for high-grade osteogenic sarcomas nearly always involves preoperative and postoperative chemotherapy as well as a wide excision of the lesion.⁵⁶ Frequently, this necessitates amputation. In some cases, it is possible to resect large segments of a long bone, such as the tibia or the fibula, and reconstruct the limb. This is a highly specialized area of orthopedic surgery with the use of specific prostheses (generally custom designed). The use of large osteochondral allografts often can be very helpful to preserve function in these patients. Chemotherapy and local radiation is frequently used.

Long-term survival after the successful local resection of a high-grade osteogenic sarcoma can be >60%.

Osteosarcoma, although predominantly seen in young patients, can be seen in older patients as a result of previous radiation or chemotherapy or underlying conditions such as Paget's disease. Unfortunately, the osteosarcomas that arise in these conditions are uniformly high grade.

CARTILAGE-FORMING TUMORS

Cartilage-Forming Neoplasms

Cartilage-forming neoplasms are another clinical challenge. As one might expect, there are both benign and malignant cartilage-forming tumors that present in the bone. When there is any possibility that the orthopedic surgeon is dealing with a malignant lesion, it is obligatory to work the patient up adequately for possible metastases before undertaking any definitive biopsy or treatment. As with bone-forming lesions, special attention is placed on ruling out other sites of bone involvement and possible metastatic foci in the lungs. General principles for biopsy of a cartilage containing lesion are identical with those discussed previously (Fig. 43-44) for bone-forming lesions. Care is taken to plan a small incision, which can be easily incorporated entirely into a large debulking or extralesional excision procedure. As with the treatment of bone-forming lesions, it is strongly recommended that the biopsy procedure be performed by a surgeon who is trained and comfortable with the definitive surgical management as well. Preoperative consultation with the pathologist and intraoperative frozen section to ensure that an adequate specimen is obtained are important steps.

A. Magnetic resonance imaging of the hips demonstrates a large, soft tissue mass anterior to the right hip with heterogeneous signal and a sharp demarcation from the surrounding tissue. **B.** A medium-power photomicrograph demonstrates cartilage and bone maturing in an endochondral mechanism with delicate vessels that merges with the surrounding soft tissue (hematoxylin-eosin, original magnification x 100).

Benign Cartilage Lesions

Chondromas are benign cartilage-forming tumors. When they occur centrally on the bone, they are referred to as *enchondromas*. When these lesions occur in the cortical bone, they are referred to as *periosteal chondromas*. Both forms of chondromas are most commonly seen in the long bones. They are particularly common in the bones of the hand, where they can cause pathologic fracture. Other common sites for chondromas are the proximal femur and humerus. Most enchondromas are identified as incidental findings on x-ray taken for other purposes. The radiographic appearance of an enchondroma is that of a generally round or oval-shaped lesion within the bone without significant bony reaction. All cartilage-forming tumors can contain areas of calcification. Microscopic analysis of an enchondroma reveals normal appearing cartilage. The lesion generally contains a small number of cartilage cells that do not show proliferation or pleiomorphism. The enchondroma frequently has such a familiar and benign appearance on x-ray imaging that management often consists of simple observation. In cases where lesions are large, painful, or display any atypical radiographic features, careful investigation and work-up for biopsy are indicated. On many occasions, biopsy (always accompanied by culture) is accompanied by curettage and bone grafting.

The clinical syndrome of *Ollier's disease* refers to patients with multiple enchondromas. This condition also can be called *multiple enchondromatosis*. The related *Maffucci's syndrome* is used to describe patients with multiple enchondromas and multiple soft tissue angiomas. Patients with Maffucci's syndrome or Ollier's disease are at risk for malignant transformation of their enchondromas and therefore do require ongoing periodic evaluations throughout their lives (see Fig. 43-7).

Enchondromas may involve any bone that originates in cartilage. They are frequently seen in the bones of the hands and feet but can be seen in the long bones and the pelvis. Enchondromas are thought to arise from islands of cartilage that are left behind as the growth plate moves away from them. These islands can grow independently and slowly increase in size. The longer they are present, the more they will mature through endochondral ossification and calcify, which appears as arcs and rings on plain films. In the hands and feet, enchondromas can thin the cortex, increasing the chance for fracture.

Osteochondroma

Osteochondromas are benign cartilage-forming lesions that arise within the cortex of the bone, usually in the metaphyseal region. The lesions arise from abnormalities in the epiphyseal growth plate. Lesions have a cartilage "cap" that proliferates and can form a substantial-sized mass beneath the cartilage in histologically normal bone. Osteochondromas may be broad based (sessile), or on some occasions, have a defined, discrete stalk. Such osteochondromas are called *pedunculated*. For lesions with a characteristic appearance, observation alone can suffice. In some patients, however, the lesions can become painful, usually because of mechanical problems. In such cases, they can be surgically resected. Any painful osteochondroma should be taken seriously, however, as there is a described incidence (approximately 1%) of malignant transformation.

Chondroblastoma

Chondroblastomas are benign cartilage-forming tumors nearly always found in the epiphysis area of a young patient usually before skeletal maturity. It is common for patients with chondroblastomas to present with pain. Generally, plain x-ray images of the joint reveal a focus of bone lysis or resorption surrounded by a rim of sclerotic, reactive bone (Fig. 43-37). Proliferating cells are seen within the lytic portion of the lesion and may represent chondroblasts. A small, but significant percentage of chondroblastomas are capable of metastases. Generally, they are managed by curettage and bone grafting.

Benign chondroblastoma (Codman's tumor) of the humerus.

Chondrosarcomas

Chondrosarcoma is a malignant neoplasm of cartilage (Figs. 43-38 and 43-39). It is most common in adults and is commonly seen in the pelvis, spine, proximal humerus, and the knee. Most frequently, the presenting symptom is that of local pain. X-ray images show an expansive destructive lesion of the bone frequently with focal areas of calcification within the tumor (Figs. 43-40 and 43-41). It is important to differentiate the x-ray finding of calcification within cartilage tumors from that of ossification within a bone-forming tumor such as osteogenic sarcoma. The cartilage present in a chondrosarcoma is visualized on an x-ray as a disorganized density without cortication or trabecularization. Chondrosarcomas too often present challenging problems with management. Many of the tumors are within the spine or pelvis skeleton, making ablative surgery or amputation difficult or impossible. Further, many, if not most, chondrosarcomas are slow growing and are, thus, often less susceptible to chemotherapy and radiation therapy than many other sarcomas.

Plain film of the proximal humerus demonstrates an ivory-like lesion of the proximal diaphysis with sunburst type periosteal reaction.

Treatment of a chondrosarcoma generally consists of a wide surgical resection alone.

FIBROUS LESIONS OF THE BONE

Aneurysmal Bone Cysts

An aneurysmal bone cyst is a reactive condition not thought to represent a neoplasm, which consists of a cyst. It can present after a pathologic fracture or due to complaints of local pain with an associated mass. Histology reveals large, blood-filled spaces with a true endothelial lining, foreign-body-type giant cells, and occasional woven bone formation. Care must be taken to examine the lesion adequately as secondary aneurysmal change is quite common and many lesions diagnosed as aneurysmal bone cyst are actually caused by another lesion with associated extensive cyst formation. Small lesions may be followed with simple observation, however, because risk of pathologic fracture means that the majority is treated by local curettage and bone grafting.

Unicameral Bone Cyst

Unicameral bone cyst is a benign lesion, most commonly found in the metaphyseal regional of long bones (frequently the humerus of growing children). This lesion can present after pathologic fracture, but also is occasionally noted due to local pain or a mass. The cause for this condition is unknown. Radiographic appearance is generally that of a large, single, cystic structure within the bone. The histologic appearance of the lesion is that of a fluid-filled cystic area within the bone. The lining of the unicameral bone cyst is composed of fibrous tissue with occasional giant cells. Small lesions may be managed by simple observation, whereas larger lesions, in which fracture risk is significant, are managed by a local curettage and bone grafting.

Fibrous Dysplasia (Fibro-Osseous Dysplasia)

Fibrous dysplasia is a commonly seen lesion in children. It is usually an isolated, slow-growing hematoma consisting of mixed bone and fibrous tissue. Fibrous dysplasia is a lesion composed of a spindle-shaped, mononuclear stroma with woven bone formation. This lesion may involve one bone (monostotic) or multiple bones (polyostotic). The radiologic features usually demonstrate areas of radiolucency with a hazy and diffuse internal matrix production often termed *ground glass*. The histologic features show a bland spindle cell proliferation with irregularly shaped woven bone formation. The bone arises directly out of the background stroma. Occasional giant cells, hemorrhage, and myxoid degeneration can occur, especially if the lesion is fractured. It most frequently is asymptomatic but, unfortunately in some patients, large metaphyseal lesions can lead to focal growth disturbance and bone deformity. Pathologic fracture also is sometimes seen. In the absence of fracture or deformity, the lesions usually are painless and asymptomatic and they are most commonly diagnosed as incidental findings on radiographs. When present in the proximal femur, successive fracture events may lead to a characteristic "Shepherd's crook" appearance to the proximal femur. Plain radiographs often are diagnostic and small lesions may be managed by simple observation. When lesions cause significant symptoms or when pathologic fracture is considered likely, curettage and internal fixation bone grafting often are offered as treatment.

Non-Ossifying Fibroma

Non-ossifying fibroma is one of the most common bone lesions and can be found commonly as incidental lesions and in autopsy series. It presents as an eccentrically located, radiolucent lesion of the metaphysis with a lobulated or soap-bubble appearance. These proliferations have a dense peripheral sclerosis and may or may not have a fracture associated with it. Histologically, these lesions are composed of bland spindle stromal cells in a storiform pattern with admixed giant cells and xanthoma cells. Hemosiderin can be noted if the lesion is fractured. These lesions usually are treated conservatively. If a fracture is present, it can be curetted and grafted.

VASCULAR LESIONS OF BONE

Hemangiomas of Bone

Hemangiomas of bone are benign conditions that represent foci of dilated vascular venous structures within the bone. Hemangiomas are not neoplasms. Hemangiomas are commonly seen in the vertebral bodies where characteristic appearance of sclerosis is accompanied by coarse vertical striations within the bone. This characteristic appearance generally is adequate to establish the diagnosis. Hemangiomas rarely require treatment.

Tumors of Hematopoietic Tissue

Tumors of the hematopoietic tissues include lymphomas and myelomas. Surgical treatment of lymphomas are discussed in Chap. 10.

Myeloma is a malignancy that results from the transformation of cells of the plasma-cell lineage. Multiple myeloma is usually a systemic disease. Proliferating, malignant, antibody-producing plasma cells infiltrate the marrow in multiple bones. This can result in focal areas of bone resorption, often with a patchy distribution, creating an appearance of "moth-eaten" bones. Frequently, the process is diffuse and systemic, leading to diffuse nonfocal loss of bone in a condition that nearly exactly mimics osteoporosis in its radiographic presentation. Presenting symptoms are often systemic complaints such as weakness, lethargy, or weight loss. Commonly, the condition may manifest as a pathologic fracture.

Myeloma is most common in patients >50 years of age and can present in patients in their eighth and ninth decades of life. On this basis, any patient with clinical signs of diminished mineral density, particularly those who sustain a fracture, may have an underlying multiple myeloma. The diagnosis most commonly is made by laboratory studies.

Plasma cells will produce a monoclonal spike on serum protein electrophoresis in the majority of cases. The presence of a characteristic monoclonal spike may establish the diagnosis. In some patients, the secreted antibody [which may be from any antibody group—immunoglobulin (IG) G, IgA, IgM] may be apparent and rapidly cleared from the blood and can almost always be seen on a urine protein electrophoresis study. Frequently in such patients, the erythrocyte sedimentation rate is elevated as the result of the altered serum protein composition.

Solitary Myeloma (Plasmacytoma)

In some patients, the presence of a myeloma is limited to a single solitary osseous lesion: a plasmacytoma. When a patient evaluation indicates the likelihood that a solitary bone lesion is the sole focus of the myeloma, local radiation may be appropriate. Treatment for all of these myelomas generally centers around chemotherapy, often using multiple agents.

Chordoma

Chordomas are slow-growing malignancies derived from embryonic notochord cells. Chordomas nearly always arise in the axial skeleton and most commonly involve the occiput or the sacrum. They can be found in the vertebrae. Chordomas are not found in the extremities.

About one third of these tumors arise intracranially (skull base), about half are found in the sacrum, with the rest in the spine. Radiographically, cranial chordomas occur in the midline of the base of the skull and produce destruction of the spheno-occipital and hypophyseal areas. Sacrococcygeal chordomas take on an oval or circular appearance as they break out of the sacrum and grow into the pelvis. Microscopically, the hallmark is the large physaliferous cell, whose vacuolated cytoplasm gives it a soap-bubble appearance. These lesions are biphasic with the second population of polyhedral cells with an eosinophilic cytoplasm.

Chordoma patients usually present with local pain and, given their proximity to the spine, often present with radicular or myelopathic symptoms. Sacral tumors may present rectal or urinary sphincter dysfunction, and occasionally, GI obstructive symptoms. Plain radiographs will often, but certainly not always, reveal the lesion. A central area of bony destruction with a soft tissue mass is characteristic. Chordomas are frequently fatal, however, because without local control, these centrally located tumors can threaten vital functions. The mainstay of treatment is wide local resection with a wide surgical margin. On rare occasions, radiation therapy may be indicated. In general, chordomas are not responsive to chemotherapy.

Chordomas are malignant tumors that are slow growing, locally destructive and invasive, and late to metastasize.

Giant Cell Tumor of Bone

Giant cell tumor of bone is a benign neoplasm of bone that can be very aggressive and destructive locally. The cellular origin for this tumor is unknown. Giant cell tumor of bone is most frequently seen in the long bones and is rare in children. Diagnosis is generally made following patient complaints of local pain. X-ray images reveal a lytic expansile lesion of the bone that is most frequently localized in the metaphysis of a long bone. Histologic analysis shows a mixture of round, oval, and spindle-shaped cells and numerous multinucleic giant cells. Treatment of giant cell tumor of bone involves aggressive and complete local resection. An incomplete resection frequently results in recurrence and may result in significant functional impairment and even amputation.

Giant cell tumors of bone are locally aggressive and destructive lesions that arise in the metaphysis of long bones in skeletally mature individuals. Giant cell tumors of bone are commonly found around the knee but can be seen in many locations. Plain films will show an eccentrically located metaphyseal lesion that is radiolucent. Most of the lesions will show cortical breakout with an associated soft tissue mass. Morphologically, these lesions consist of rounded mononuclear cells with admixed giant cells, hemosiderin, and new bone formation. These lesions have a high tendency to recur.

Ewing's Sarcoma of Bone

Ewing's sarcoma of bone, or Ewing's tumor, is a small, round cell sarcoma most common in children and younger adults. Ewing's sarcoma is most common in the long bones, especially the metaphyseal regions of the femur, tibia, and humerus. Patients present with complaints of local pain, interestingly, often accompanied by fever.

Ewing's sarcoma is an undifferentiated tumor occurring in children and primarily involves the diaphysis of long bones. Radiographically the early Ewing's tumor may be relatively inconspicuous. The tumor appears as an ill-defined area of "moth-eaten" osteolytic destruction. It becomes more pronounced as the tumor progresses and often will show an aggressive periosteal reaction. The usual microscopic picture is that of sheets and geographic areas of small round blue cells with pale nuclei. There is no matrix production within these tumors unless there is an associated fracture. These cells are loaded with glycogen and a periodic acid–Schiff histochemical stain will be positive. These tumors have a characteristic 11:22 translocation that can be very helpful in making the correct diagnosis (Fig. 43-42).

A. Plain film of the elbow shows a permeative lesion of the ulna with a periosteal response in an "onion skin" pattern. **B.** A medium power photomicrograph reveals bland, small, round, blue cells and vessels characteristic of Ewing's sarcoma (hematoxylin-eosin, original magnification x 40).

Treatment of Ewing's sarcoma begins with a carefully planned biopsy. Definitive treatment may or may not involve surgical resection, but multiagent chemotherapy and radiation are the mainstays of treatment.

Subungual Exostosis

Subungual exostosis is a subperiosteal, osteochondral proliferation usually in the distal toes, but it can be located in the fingers. The x-ray will show a mineralized formation, usually the distal phalanx with a soft tissue swelling and occasionally ulcer formation. Additionally, there is no communication with the underlying medullary canal that separates this from a true osteochondroma. Histologically, these lesions are composed of chondro-osseous matrix that emerges into the surrounding soft tissue. The cellular proliferation can be quite reactive and misinterpreted as a more aggressive process. Definitive treatment is surgical resection. These lesions often can recur if the overlying fibrous cap is not entirely removed (Figs. 43-43 and 43-44).

Fig. 43-43.

Medium-power photomicrograph shows maturing bone intimately associated with soft tissue (hematoxylin-eosin, original magnification x 100).

Myositis Ossificans

Myositis ossificans is the result of posttraumatic ossification of a hematoma in the soft tissue. It most often occurs in muscle but can occur in fascia, tendon, joint capsule, and occasionally, fat. In cases of myositis ossificans, the endochondral bone formation follows essentially the same process as that of fracture callus formation. The damaged soft tissue is removed and the hematoma begins to organize with mesenchymal cells that differentiate into chondroblastic, osteoblastic, and vascular-type cells. Radiologically, these lesions are noted in the soft tissue and show an arrangement of bone and cartilage at the periphery of the lesion and interior soft tissue. This results in an "egg shell" calcification/ossification. Histologically, the features are bone and cartilage at the periphery of the lesion and a fibrovascular core. Over time, the outer endochondral ring will remodel to lamellar bone with an interior fibro-fatty center.

Paget's Disease

Paget's disease is a relatively common condition of bone, most frequently seen in patients >40 years of age. Paget's disease may be mono-ostotic, or it may be seen in multiple bones. It is most commonly seen in the pelvis and spine but may also frequently occur in the humerus, femur, and tibia. The lesion results from abnormalities in the bone in the remodeling process, felt to be due to abnormalities in the osteoclasts. X-ray images of pagetic bone show characteristic sclerosis with coarsened trabeculae, cortical thickening, and often, cortical expansion of the bone. The appearance of the bone may also contain lytic as well as sclerotic areas.

Microscopic appearance of pagetic bone shows broad irregular trabeculae, often with visible lines (indicating incomplete mineralization). On occasion, the striking appearance of "mosaic bone" is seen, which refers to large areas of incompletely mineralized bone that creates an appearance reminiscent of mosaic tile. The critical histologic feature of Paget's disease is not the partial mineralized bone, however; it is the presence of large osteoclasts with abnormally large numbers of nuclei. Normal osteoclasts will have from two to four nuclei, in pagetic bone it is common to see osteoclasts with from five to 50 or more nuclei.

It is speculated that the large abnormal osteoclasts result from late effects of a pre-existing paramyxovirus infection. It is believed that increased bony resorption by these abnormal osteoclasts causes local lysis of bone. The rapid healing process that follows leads to the disorganized and coarse bony texture.

Bones involved with advanced Paget's disease can be subject to pathologic fracture. Bony abnormalities surround joints and often lead to accelerated arthritic change. Paget's disease is common in the spine, particularly in the lumbar spine. The characteristic bony expansion and arthritic change in the spine frequently results in the clinical syndrome of spinal stenosis.

Treatment of Paget's disease generally is nonsurgical with the use of antiresorptive medicine such as bisphosphonates and/or calcitonin. Such medical treatment is usually sufficient for most patients with Paget's disease. Neglected Paget's or resistant cases will occasionally go to surgery for lumbar decompressive laminectomy (for spinal stenosis) or for joint replacement. Surgical treatment for patients with Paget's disease must be preceded by antiresorptive therapy as arteriovenous shunting in pagetic bone is frequently encountered. Bone bleeding can be a major problem in Paget's patients who are not medically treated.

Stress Fracture

Stress fractures are a result of an active remodeling as a result of stress that most often is noticed in an episode of sudden increase in physical activity. This is very common in military recruits during basic training, but this can be seen in anyone with a sudden increase in athletic activity. Localized pain and tenderness is typical, and the skin can be locally red. X-ray examination may be unrevealing early on; however, subsequent films may show a periosteal reaction to increase suspicion for this condition. The most common location for stress fractures is the proximal tibia, but they can occur anywhere. As the fracture develops, films will show a lucent line perpendicular to the long axis of the involved bone. Histologically, this process is composed of aggregates of the osteoclasts removing bone with paucity of osteoblastic response and a variable amount of periosteal response.

JOINT RECONSTRUCTION

The Surgical Treatment of Arthritis

One of the most challenging problems facing the orthopedic surgeon is the treatment of degenerative and inflammatory diseases of joints. In all cases, the primary objectives are to relieve pain and to preserve motion and function. In the treatment of any joint complaint, a thorough evaluation of the patient's symptoms, history, and a thorough physical examination are essential. The orthopedic surgeon must distinguish between inflammatory disease and degenerative disease. The laboratory and imaging studies are also tremendously useful. It is always hoped that a nonsurgical means can be used to help the patient. Medications, physical therapy, rest, braces, and time are often all that is needed to assist the patient with an arthritic joint. On frequent occasion, however, more invasive treatments are necessary.

Injection of Joints

For several decades, the treatment options for painful joints have included the injection of various substances. Local anesthetic agents can be injected into a joint for diagnostic purposes. Corticosteroids are frequently injected into joints for symptomatic relief (this can be done for both inflammatory disease and osteoarthritis). The use of intra-articular corticosteroid injections is controversial. This often provides short-term relief of pain and swelling symptoms; however, the long-term consequences of this technique are debated.

More recently, injections of high-molecular-weight, polysaccharide molecules such as hyaluronic acid have become popular in the treatment of degenerative disease of large joints. The utility of this technique is not yet quite clear in the evidence-based literature, but it does appear that at least some patients get substantial and somewhat lasting relief from these techniques.

Synovectomy

Synovectomy is the surgical removal of substantial portions of the synovial lining of a joint. This is another procedure that can, on occasion, help a patient. The technique frequently has been applied to joints damaged by hemophilia. In severely symptomatic disease, intra-articular synovectomy also can be of benefit to patients with inflammatory disease such as rheumatoid arthritis.

Periarticular Osteotomy

Arthritic joints often develop angular deformities. This can be from selective loss of cartilage from areas of high wear. It also can be from malalignments, either congenital or acquired after injury. It is quite common, for example, for osteoarthritis of the knee to be severe in the medial tibial-femoral portion of the joint and relatively mild in the lateral compartment. An osteotomy of the proximal tibia to selectively transfer weight to the healthier cartilage can often provide a prolonged period of relief to such patients. In a similar way, young adults with malaligned hips can often benefit from osteotomies of the proximal femur to create better femoral acetabular articulation.

Fusion

Many arthritic joints can be surgically treated by bony arthrodesis fusion instead of joint replacement. This is most frequently performed in joints where motion is not critical. Fusion of certain joints of the foot (including painful degenerative arthritis of the first metacarpal and numerous bones of the midfoot) can be satisfactorily managed by applying bone grafts across the involved joint, transfixing the joint with internal fixation, screws, or periarticular plates.

The arthritic wrist frequently is managed by fusion procedures, as the mobility of the shoulder, elbow, and fingers will usually allow preservation of excellent useful function.

Arthrodesis of the shoulders is less frequently performed than arthroplasty of the shoulder, but it is an established and reasonably successful procedure. Nonetheless, fusion of the glenohumeral joints often allows satisfactory function, particularly in heavy laborers because of the compensatory motion of the trunk, scapulothoracic joints, elbow, and wrist.

Joint Arthroplasty—(Joint Replacement)

Patients with severe intractable joint pain can be treated with prosthetic replacement of the diseased joint with an artificial joint composed of metal and plastic. This technique was successfully introduced by Sir John Charnley in the 1960s who successfully developed and first performed total joint replacement procedures on the hip. The genius of Dr. Charnley has been amply demonstrated as this procedure continues to remain one of the most successful operative interventions.⁵⁷

A joint prosthesis, in nearly all cases, involves a mobile surface, most commonly composed of high-molecular-weight polyethylene (the original material chosen by Dr. Charnley), which is affixed to metal components that are anchored to the involved native bone. The metal components of a joint prosthesis can be affixed to native bone by precise carpentry and impaction (impaction fit). Such metal implants often are surfaced with porous metals that allow bony ingrowth (porous coated implants). In Dr. Charnley's original procedure, a polymer of methylmethacrylate was used to cement the metal components in place. Polymethylmethacrylate cement material continues in common use today, although the majority of hip and knee replacements are now performed with noncemented technique.

Total Hip Arthroplasty

Images of a total hip replacement procedure are displayed in Figs. 43-6, 43-13, 43-33, 43-45, 43-46, 43-47, 43-48, 43-49, and 43-50. The patient has a severely arthritic joint surface with sclerosis and cystic changes in both the femoral and acetabular articular surfaces. The patient was experiencing severe pain with essentially all activities of daily living and had lost the ability to move about normally. After the failure of conservative care to improve function, the patient can be taken to surgery for replacement of the hip.

Anteroposterior radiograph of a patient with chronic osteomyelitis. The patient had a compound (open) fracture of his tibia treated with an open reduction and internal fixation. He has developed a chronic infection. The plate that was on his tibia has been removed. The bone is denser than normal, and the medullary canal cannot be seen well. This suggests that there is sequestered (necrotic) bone that needs to be débrided if the infection

is to be controlled.

The hip joints can be exposed through a variety of surgical approaches. The most commonly performed is the posterior approach to the hip. The incision is made through the skin and fascia of the lateral proximal thigh, and dissection is continued deeper to expose the posterolateral portion of the proximal femur, the greater trochanter, and associated muscles. The short rotators are dissected away from the proximal trochanter, and the femoral neck is exposed by entering the hip capsule. Removal of the femoral head is accomplished by transecting the femoral neck with a power saw and dislocating the femoral head. The proximal femur is prepared by successive removal of bone from the medullary cavity. Specially shaped reamers and rasps are inserted to create an appropriate space for the stem of the femoral prosthesis. Similarly, any remaining articular cartilage is removed from the acetabulum using sequentially sized reamers to the level of good cancellous bone. The acetabular portion of the prosthesis, which contains the high-molecular-weight polyethylene articular surface, is attached to a metal cup. The prosthesis (usually metal or ceramic) is then impacted into place. The joint is then relocated, and the wound is closed.

Great care is taken during the performance of this surgery to attain a functional anatomic position for both the femoral and acetabular components. Malposition of either component can lead to rotational deformity, premature wear, or dislocation. As is readily apparent, during the surgical exposure, many of the intrinsic stabilizers of the hip joint are divided during the dissection needed to perform the surgery. Accordingly, following a total hip replacement procedure, restrictions are placed on the patient's range of motion until an adequate amount of scar is formed to help preserve long-term stability of the joint.

Total Knee Arthroplasty

Total knee replacement involves resecting the native articular surface and subchondral bone from the femur, tibia, and the patella. Analogous to hip replacements, the distal femur generally is reconstructed with a large metal weightbearing surface shaped to mimic the femoral condyles. The tibial plateau is replaced by a high-molecular-weight polyethylene surface usually attached to a flat metal surface, which is then affixed to the distal tibia by a stem, or screws, or both. The patella surface generally is reconstructed with a high-molecular-weight polyethylene articular surface.

As with the hip, these components may be affixed to the bone using polymethylmethacrylate cement, although press fit components using various surface treatments to promote adhesion and bone ingrowth also are commonly used.

A total knee replacement generally is accomplished through an anterior peripatellar approach, with the knee widely exposed; the articular surfaces are resected using precise saw cuts, guided by templates and jigs. Appropriate alignment of the components is essential for a successful result. Also critical is ligamentous balancing of the knee, such that medial and lateral stabilizing ligaments and the patellar tendon can function normally. Knee replacements can be performed with implants designed to make use of the normal cruciate ligaments. Other total knee designs accommodate these stabilizing functions as well and involve resection of these ligaments.

Complications of Total Joint Arthroplasty

Artificial joints are used to replace worn out and damaged natural joints. Sadly, the artificial joints themselves are also subject to wear and damage and can fail by a variety of mechanisms. Total joint replacement components can loosen, fracture, or disassemble.

Artificial joints can be damaged by virtue of corrosion or simply "wear out." Other complications include infection (acute, delayed, or chronic), contracture, and periprosthetic fracture.

As arthritis and osteoporosis are both disease processes most common in older patients, they often occur together. Insertion of a prosthetic joint in a patient with osteoporosis requires special care to prevent intraoperative fractures. The purpose of an artificial joint creates a stress riser at the interface between prosthesis and bone. Unfortunately, fractures adjacent to total joint implants are not uncommon. Treatment for this problem is individualized and may involve internal fixation, replacement of the prosthesis, or both.

Corrosion, Wear, and Osteolysis

Osteolysis is a major concern to the total knee replacement surgeon. The term *osteolysis* can be used to describe virtually any form of bony resorption, including that associated with metastatic disease or infection. In joint replacement, it generally refers to one of two unwanted phenomena. Osteolysis is a term that is used to describe focal bony resorption at the immediate interface between the prosthesis and the bone or the cement mantle and the bone. The motion of a loose implant on the bone prosthesis interface is such that bony resorption can occur, and unfortunately, without surgical revision, there is frequent progression of bone resorption to the point where mechanical symptoms of hip pain or knee pain result. The presence of an increasing zone of osteolysis in the periprosthetic region becomes a strong relative indication for revision of the implant.

A more serious and problematic form of osteolysis is that caused by a noninfectious inflammatory reaction to wear debris. Wear of the high-molecular-

weight polyethylene articular surface can generate and disperse microscopic particles of high-molecular-weight polyethylene, which often cause a focal tissue inflammatory reaction. Reticuloendothelial cell proliferation and the action of other inflammatory cells may result at times in very aggressive rates of bony resorption. The process often is painful. When extensive osteolysis of this type is allowed to proceed for substantial lengths of time, serious and problematic loss of periarticular bone can result, adding additional difficulty to revision surgery. Particulate methylmethacrylate cement debris also can play a role in this form of osteolysis.

Due to this problem of osteolysis, joint prosthesis designers have focused a great deal of attention on precisely engineering the articular surfaces and exploring options for other bearing surfaces materials. Metal on metal bearing surfaces and the use of other plastics or ceramics are areas of intense ongoing study.

All total joint replacement prostheses have the potential to wear out or loosen. Accordingly, they are rarely indicated for young active patients, who will place a high mechanical demand on the prosthetic joint, although joint replacement may be very appropriate for "low demand" patients with systemic inflammatory disease.

Revision or replacement of a loose infected or "worn out" joint prosthesis is an involved and technically challenging procedure. Such surgeries often involve extensive and difficult cement removal, and may involve the need for extensive bone grafting. For some difficult clinical challenges, custom-made revision prosthesis is used.

PEDIATRIC ORTHOPEDIC SURGERY

The treatment of musculoskeletal pathology in pediatric patients is different in many ways from the treatment of adult patients. The orthopedic surgeon treating pediatric patients must be aware of numerous congenital and developmental conditions. Further, the skeletal system is growing. Preservation of normal growth is a significant priority in the management of this patient group.

The pediatric orthopedic surgeon must be able to recognize and treat a large number of inherited congenital conditions, which include inherited metabolic disorders, inherited neurologic conditions, and inherited musculoskeletal anatomic abnormalities. The diagnosis and treatment of these inherited syndromes and disorders are beyond the scope of this chapter.

Birth Injuries Causing Neurologic Impairment

BRACHIAL PLEXUS PALSY

Injury of the brachial plexus during delivery was once a commonly encountered management problem. Patient with associated plexus injuries can present with mild, moderate, or severe impairment of the involved upper extremity, which can, on occasion, involve upper or lower roots and trunks of the plexus. Modern obstetrical practice has markedly decreased the incidence of this problem, which unfortunately still occurs in approximately 0.2% of all births. Such injuries are associated with large birth weight, forceps delivery, breech presentation, and prolonged labor. A plexus injury may represent a stretch injury or, on some occasions, a frank avulsion of nerve roots. In most patients, nonsurgical management is pursued with aggressive therapy and passive exercise to preserve motor motion in the shoulder while awaiting return of neurologic function. In unusual cases, surgical repair of injured roots and trunks of the plexus is performed.

CEREBRAL PALSY

Cerebral palsy is a nonprogressive neuromuscular disorder, which usually is recognized before age 2 years old. It is considered to take origin from an injury to the developing brain. Usually, the specific cause is not identifiable. There is a wide variation in the consequences for cerebral palsy that may or may not be associated with mental impairment. Cerebral palsy is classified in physiologic and anatomic categories as spastic (the most common), athetotic, ataxic, and mixed. The majority of cerebral palsy patients are hyperreflexic with increased muscle tone and spasm. Such patients also are classified as having hemiplegia (upper and lower extremities) or diplegia where low extremity problems are greater than those in the upper extremity. Patients with cerebral palsy frequently develop spinal deformities, which is discussed separately in the Scoliosis section. Orthopedic treatments center on maintaining function and preserving range of motion. Tendon lengthening procedures, release of contractures, and tendon transfers can be helpful both in upper and lower extremities. Gait disorders are the focus of a great deal of attention, and often, major improvements in walking ability can be accomplished by well-planned tendon lengthening procedures and contracture releases.

Because of unbalanced muscle forces due to associated spasticity, hip dysfunction, unfortunately, which frequently leads to hip dislocation or subluxation, is a significant problem for many cerebral palsy patients. Initial treatment often consists of abductor tendon releases that can be very rewarding. In some cases where a diagnosis is made late, or where soft tissue releases are unsuccessful, tendon balancing procedures may be combined with open reduction of a hip joint, sometimes augmented by acetabular reconstruction or osteotomy of the proximal femur.

Knee contracture due to hamstring tightness is another commonly seen problem. Hamstring lengthening and other muscular tendon releases can be helpful.

Foot and ankle deformities can also result from a cerebral palsy and usually are treated, even in nonambulatory patients, to facilitate shoe wear. Maintaining normal foot anatomy is essential in an ambulatory patient. The most common foot deformity caused by cerebral palsy is an equinovalgus foot, which is caused by heel cord contracture and peroneal spasm. Tendon balancing can be helpful. In severe cases, bony reconstruction also can be indicated.

Skeletal Growth

Acquired musculoskeletal disorders in the pediatric patient cover a wide spectrum of disease, which includes injury, inflammatory disease, and developmental disorders. In all of these conditions, the treating surgeon must remember that immature bones are actively growing; preserving bone growth is a high priority of treatment (Fig. 43-51). In addition, the immature skeleton is incompletely ossified. Accurate diagnosis of an injury or musculoskeletal condition can be much more difficult because large portions of the skeleton are still cartilaginous and may be invisible radiographically with plain film. As can be seen, the epiphysis, generally containing an articular surface, is positioned at the ends of the long bone with an intervening physis or growth plate. The normal epiphysis is the site of longitudinal growth of a long bone. It is wide enough to be readily visible on clinical x-rays. The physis has specific layers or zones defined histologically adjacent to the epiphyseal bone known as the *reserve zone* of pluripotent cells. Proceeding from the reserve zone is the *zone of differentiation*, where differentiation of cartilage is first demonstrated. Below the zone of differentiation is the *zone of proliferation*, characterized by extensive cell division. Beneath the zone of proliferation is the *zone of maturation*, where more mature chondrocyte morphology is manifest. Beneath the zone of maturation is the *hypertrophic zone* where cells increase in size. Cell death and calcification of the cartilage matrix then occurs in the *zone of calcification*.

Structure and function relationships of the growth plate. Calcified cartilage bars form scaffold for osteoblasts to deposit new bone; osteoclast-like cells reabsorb calcified cartilage through remodeling. FGF = fibroblast growth factor; Gr. = growth; IGF-I = insulin-like growth factor I; PTHrP = parathyroid hormone-related peptide; TGFβ = transforming growth factor beta.

Preservation of normal growth in this area is important. Injury or insult to the growth plate can lead to premature growth arrest or angular deformity of the limb and a significant cosmetic and functional problem. Surrounding the metaphyseal and diaphyseal bone is the periosteal layer. The periosteum in immature individuals is far more thick and cellular than in adults. This metabolically active periosteum is responsible for the synthesis of new bone onto the diaphyseal and metaphyseal bone and is responsible for the circumferential growth of the bones. In very young patients, the metaphysis and epiphysis may be completely unossified.

Ossification centers in the epiphysis and will appear in a very predictable order. An understanding of the expected sequence of ossification and its expected chronology are critical for the appropriate treatment of young patients. It must also be noted that some bones, particularly those of the spine, normally manifest multiple distinct ossification centers.

General Considerations in Pediatric Fractures

The treatment of a fractured bone in a pediatric patient involves all of the issues present in adult injuries. In a child, however, treating physicians and surgeons are also much concerned with the status of the growth plate. Unfortunately, the epiphyseal growth plate is a very common site of fracture, as this unossified area of the bone is naturally weak and prone to fracture. Careful treatment of the injured growth plate is a high priority of treatment, and it must be kept in mind that reduction of fracture fragments through and across the growth plate must be done with great care.

Classification of Growth Plate Injuries

Classification of growth plate injuries has important implications as doctors communicate about the treatment of a patient. The exact type of physeal injury is important for the prognosis and treatment of the fracture. Salter and Harris described a very useful classification of growth plate injuries.⁵⁸ A type I injury is a simple transverse failure of the physis without involvement of the ossified epiphysis or metaphysis. A Salter-Harris type II fracture contains a component of fracture through the growth plate in continuity with a fracture of the metaphysis. Salter-Harris type III fracture occurs partially through the epiphysis and partially through the growth plate. These fractures are essentially always intra-articular. A Salter-Harris type IV injury is one which has a fracture line extending through the physis extending from the metaphysis through into the epiphysis. Finally, a Salter-Harris type V injury is a subtle injury where the physis itself is injured but not displaced.

Treatment of pediatric injuries that involve the growth plate are centered around precise and accurate reduction of the fragments and growth plate. Internal fixation of growth plate injuries is performed with great care to assist in the accurate positioning of the fragments for optimal healing. When possible, effort is made to avoid placing hardware that extends through the growth plate for fear of increasing the chance of premature growth plate closure.

Diaphyseal Injuries in a Pediatric Patient

Fractures of the diaphysis of the long bones of pediatric patients are often treated closed. Interestingly, precise and accurate reduction of such fractures is, at times, less critical in pediatric patients than it is in adult patients because of the extensive remodeling that pediatric patients are capable of. An angular deformity within the plane of an adjacent joint is often completely remodeled by the accommodating growth of the child. When internal fixation of a diaphyseal fracture is performed on a child, the physis is avoided whenever possible.

Fractures of the Pediatric Hip

Pediatric hip fractures carry a high potential for growth arrest and deformity. Very young patients with hip fractures are frequently treated by casting. A large cast encompassing the abdomen, lower back, pelvis, and lower limb is often a good choice. Such "spica" casts are well tolerated by very young patients, to some degree, because the period of immobilization can be relatively short in a very young patient because of their rapid healing potential. Displaced fractures of the hip in somewhat older patients are frequently managed operatively. If the displacement is mild, it may be managed with a spica cast. In some cases, a screw is inserted through a very small skin incision through the trochanteric region of the femur and traverse to fracture physis and engage the femoral head. It is necessary to do this with direct fluoroscopic image guidance. Careful attention to the screw position in these two planes is essential to make sure there is no penetration of the femoral head.

Fractures of the Intratrochanteric Region in the Pediatric Hip

In very young patients, this injury may be managed with a spica cast. In older patients, internal fixation may also be used.

Fractures of the Femoral Shaft

In children, femur fractures are usually low-energy injuries in contrast to adult femur fractures. Fractures of the femoral shaft in pediatric patients <6 years old may be managed with a spica cast. Minor degrees of angular deformity are acceptable and will remodel. More major degrees of angular deformities (up to 30° in the sagittal plane) may be acceptable because of the growth potential in these very young patients. Fractures in patients >6 years of age can be managed by limited internal fixation (Fig. 43-52). Flexible intramedullary nails are popular in the treatment of this injury.⁵⁹ A patient who is approaching skeletal maturity (14 years or older) may be managed by a rigid intramedullary reamed nail, much as would be used in an adult. Extra-articular fractures of the distal femur or of the proximal tibia are generally managed in a long leg cast, unless there is excessive displacement or angulation.

Fractures of the Pediatric Ankle

Fractures of the ankle in pediatric patients virtually always involve the growth plate. Salter-Harris I and II injuries (without physeal fractures) are generally managed by simple casting (Fig. 43-53). Intra-articular fractures (Salter-Harris III or IV) are usually managed by closed reduction and internal fixation using percutaneous pins or screw fixation. In general, smooth nonthreaded pins are used, and care is taken not to traverse the physis unless

absolutely necessary for stability.

Anteroposterior and lateral x-ray images of a Salter-Harris type II fracture of the distal tibia in a child. The displaced fracture involving the physis was reduced and immobilized in a cast.

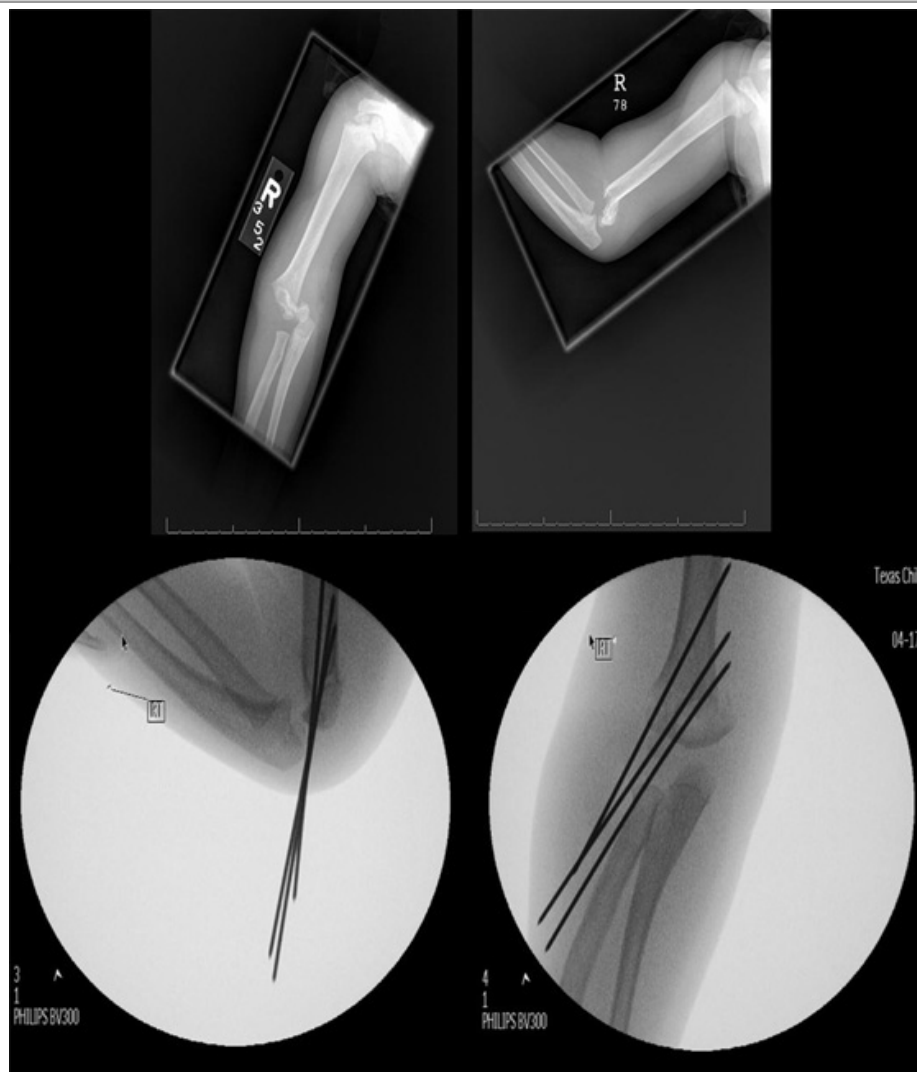

Usually, the medial portion of the distal tibial physis fuses before the lateral. In such patients, an interesting fracture called a *juvenile Tillaux* fracture can occur. This Salter-Harris type II fracture involves a fracture through the lateral epiphysis and lateral physis. For these patients with the growth plate in the process of closing, open reduction and precise internal fixation generally is recommended. Another challenging physeal injury in pediatric patients is the so-called *triplane fracture*. This is a complex Salter-Harris type IV fracture involving fractures to the physis, metaphysis, and epiphysis. Usually the three fractures occur in three orthogonal planes. This injury is usually managed by closed reduction with or without percutaneous pinning. This fracture often requires CT imaging to assess degree of joint line displacement.

Fractures of the Pediatric Elbow

Fractures of the pediatric elbow create a special anxiety in the treating orthopedic surgeon. The elbow is a complex joint with articulation between the distal humerus and both the radius and ulna. In addition, there are separate ossification centers for the radial head: the olecranon as well as the medial and lateral epiphysis of the humerus. In very young patients, a fracture through the distal humeral epiphysis is often mistaken for a dislocation of the elbow (an injury that is extremely rare) (Fig. 43-54). A complete understanding of the ossification centers of the elbow as well as the timing of their appearance is essential to the confident diagnosis of the exact injury. Such fractures that also involve injury to the shafts of the radius or ulna are the pediatric equivalent of the Monteggia and Galeazzi fractures described previously in Fractures of the Ulnar Radius. Reduction and accurate alignment of the articular surfaces and accurate positioning of the radial head (often dislocated in these injuries) are high priorities in treatment. In general, closed

reduction and percutaneous pin placement (often by necessity traversing the growth plate) is usually the most appropriate treatment option.⁶⁰

A displaced supracondylar fracture in a child is shown before and after reduction and percutaneous pin fixation.

In assessment and treatment to these injuries, great attention must be placed to the neurovascular anatomy about the elbow. Associated injury to the brachial artery, to the traversing radial ulna and medial nerves are common. Assessment of the neurovascular function is essential before, during, and after treatment. Even after successful closed reduction, pinning, and immobilization, close meticulous follow-up for maintenance of reduction and of neurovascular status of the limb is important.

DEVELOPMENTAL DISEASE IN CHILDREN

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) was previously called *congenital dysplasia of the hip*. The disorder is characterized by instability of the developing hip and may progress to frank, chronic dislocation of the hip. DDH is seen most frequently in newborns with a positive family history, who have breech positioning in utero, who are female, or who are firstborn.⁶¹⁻⁶³ The disorder does not appear to have a strong genetic component.

The most unfortunate situation in patients with DDH is in those who are diagnosed late. A chronically dislocated hip is a challenging problem for clinical management. Such untreated dislocations lead eventually to contracted hip musculature, a dysplastic acetabulum, and the formation of a fibrous "pulvinar," which can occupy the acetabulum and prevent reduction. As these are potential serious consequences, effort is put into early diagnosis of DDH. Newborns, generally within the first 3 days of life, are examined for hip instability. Two maneuvers are performed, one of which is Ortolani's test,

which consists of gentle elevation and abduction of the femur. With the abduction maneuver, a palpable click or pop will signify the relocation of a dislocated hip. Another maneuver, Barlow's test, is performed by gentle adduction and depression of the femur (posterior pressure), which can cause a similar palpable click or pop as a hip in its normal position slips into a dislocated position. It is important that these maneuvers be performed gently and only after proper training. Infants with a dislocated or dislocatable hip will sometimes seem to have leg discrepancies of the femur when the hip is positioned in 90°. It also is possible to make a tentative diagnosis based on the appearance of the skinfolds of the buttock. X-ray images can be helpful, but in the case of newborn children, the relevant portions of the acetabulum and femoral head are not yet ossified and x-ray diagnosis is a bit unreliable. More helpful is the use of ultrasound to image the hips. A skilled ultrasonographer can often demonstrate an impressive amount of detail in a dislocated or dislocatable hip. When the diagnosis is made promptly, treatment can, in most cases, result in an essentially normal hip joint. If the diagnosis is made later, prognosis may not be as favorable. Treatment of undiagnosed patients after they attain walking age (9 to 14 months) can be very challenging.

Treatment of Developmental Dysplasia of the Hip

Treatment of a newborn who has a dislocated or dislocatable hip generally is based on achieving proper positioning of the femoral head in the acetabulum and maintaining a concentric reduction. In most cases with a dislocatable hip, the child is placed in a Pavlik harness, which maintains the hips in flexion and mild abduction. Extremes of abduction must be avoided, as maintaining hip in significant abduction can lead to avascular necrosis of the head (Fig. 43-55). With 1 to 3 months of treatment, the Pavlik harness is generally successful. In some patients, with more severe disease, selective tenotomies of some of the adductor muscles may be indicated.

Fig. 43-55.

In neglected or undiagnosed DDH, when the patient reaches walking age without achieving a stable hip, open reduction is often necessary (Fig. 43-56). In such cases, an anterior approach to the hip generally is performed. Any pulvinar within the acetabulum is removed, and the femoral head is located. Often, these procedures are combined with capsular releases and adductor tenotomies. In cases with significant muscular contraction, femoral shortening (osteotomy to shortening of the femur) may be indicated. Following open reduction of osteonecrosis of the femoral head can occur. Restoration of the full pain-free motion of the hip is not always possible. In rare cases where open reduction does not produce a stable hip, some patients with severe DDH may be managed by pelvic osteotomy, where acetabular reconstruction or the creation of an acetabular shelf is performed.⁶³ In some cases, a varus osteotomy of the proximal femur also may be considered.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease, also known as *coxa plana*, is a condition of the pediatric hip characterized by a flattened, misshapen femoral head.⁶⁴ The etiology of the problem is related to osteonecrosis of the proximal femoral epiphysis and is thought to result from vascular compromise.⁶⁵ Legg-Calvé-Perthes disease generally presents in children, usually males, between the ages of 4 and 8 years old. Presenting symptoms generally include groin or knee pain, decreased hip range of motion, and a limp. The Trendelenburg gait (tilting of the pelvis) is also commonly seen. Symptomatic treatment with traction, physical therapy, abduction exercise, crutches, and occasionally, femoral and pelvic osteotomies, are all offered as treatments. Unfortunately, a good solution for Legg-Calvé-Perthes disease has been elusive thus far.

Slipped Capital Femoral Epiphysis

A *slipped capital femoral epiphysis* (SCFE) is an acquired disorder of the epiphysis thought to be associated with weakness in the perichondrial ring of the growth plate.⁶⁶ Children within the ages of 10 to 16 years old are noted to have the displacement of the epiphysis on the femoral neck. In most cases, there is no identifiable trauma history. It is not known whether this is acquired insidiously or acutely (Fig. 43-57). It is associated with African American heritage, obesity, and is somewhat more common in boys than in girls. Twenty-five percent of cases are bilateral. SCFE usually is diagnosed in patients who complain of pain. It is important to know that the pain caused by this pathology is usually located in the groin and proximal anterior thigh. It is also quite common for patients to complain of pain about the knee. In pediatric patients with complaints of knee pain, an effort should always be made to assess the ipsilateral hip as well.

Fig. 43-57.

Radiographic images of a young patient with a slipped capital femoral epiphysis, before (**A**) and after (**B**) screw fixation.

Treatment for virtually all SCFE patients is percutaneous screw fixation. The procedure is done through a small skin incision; a screw is inserted through the femoral neck to engage the epiphysis. Reduction of the slipped epiphysis is contraindicated because of an increased risk of avascular necrosis. Most practitioners find one screw to be adequate to prevent further slip.

Lower Extremity Rotational Abnormalities

The pediatric patients with lower extremity rotational abnormalities present with abnormal rotation of the lower extremities often resulting in "intoeing" stance and gait. The diagnosis of femoral anteversion, tibial torsion, and metatarsus adductus are used to describe rotational abnormalities at these respective anatomic locations. It should be noted that most children do have a mild degree of intoeing as a normal developmental stage.

Excessive rotation in internal rotation in the femur, most commonly seen in children age 3 to 7 years old, will usually correct by age 8. Severe degrees of rotation with functional impairment that do not correct after age 10 or 11 years old may be managed by rotational femoral osteotomy.

Tibial torsion is the most common cause of an intoeing gait. This is most frequently noted in 1- and 2-year-old children. This is often bilateral. Although occasionally intoeing can be marked, pediatric tibial torsion will completely resolve without treatment in almost every case.

Metatarsus adductus is a condition of forefoot adduction, generally seen in infants. Of note, this may be associated with DDH of the hip. As with most rotational abnormalities, the overwhelming majority of these cases also resolve spontaneously.

Congenital Talipes Equinovarus

Congenital talipes equinovarus, unfortunately frequently called *club foot*, is a common problem in pediatric orthopedic surgery (Fig. 43-58).⁶⁷ In involved patients, this disorder, which is slightly more common in males than females, is associated with contractures of the medial tendons of the foot, often associated with a tight Achilles tendon.⁶⁸ Contractures of the joint capsules of the ankle, hindfoot, and midfoot are also noted. Such feet are evaluated by radiographs before, during, and after treatment.⁶⁹ In most cases, the problem can be corrected by meticulous sequential corrective casting of the foot. A successful program of casting may be complete in from 1 to 5 months and can often yield an essentially normal foot before walking age. In patients with more severe disease or in those who initiate treatment later, surgical release of contracted soft tissues may be necessary.⁷⁰ In most cases, such surgical releases are not contemplated before 6 to 8 months of age.⁷¹

Characteristic deformities of talipes equinovarus, or club foot.

Osgood-Schlatter Disease

Osgood-Schlatter disease is a very common problem most often seen in athletically active adolescents. This disorder is characterized by ossification in the distal patellar tendon at the point of its insertion onto the tibial apophysis. This disorder is thought to result from mechanical stress on the tendinous insertional area. X-ray views of the involved knee show a characteristic irregularity in the insertional area and often show separately discrete ossicles within the tendon itself. The disease will present with severe local pain and exquisite tenderness in the area of the tibial tubercle.

Effective treatment for the disease can be obtained by activity restriction, which is generally quite unwelcomed by the patient. If the symptoms are improved, athletic participation can be reasonable. In almost every case, symptoms do regress after skeletal maturity or the discontinuance of active athletic participation. In rare cases, persistent symptoms into adulthood can occur. Moderate success can be obtained by surgical excision of ossicles within the tendon of adults.

The Future of Orthopedic Surgery

The treatment of musculoskeletal disease is progressing at a rapid pace. There is a very strong trend toward the use of less invasive surgical techniques, and the technology necessary for minimally invasive surgery is advancing rapidly.

During the next decade, application of molecular medicine techniques to numerous musculoskeletal problems are likely. The use of molecular genetic techniques to enhance or even replace many of our present surgical treatments.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 44. Surgery of the Hand and Wrist >

KEY POINTS

1. Surgery of the hand is a regional specialty, integrating components of neurologic, orthopedic, plastic, and vascular surgery.
2. Understanding hand anatomy is the key to proper diagnosis of injury, infection, and degenerative disease of the hand.
3. After evaluation and/or treatment, patients should be splinted to protect the injured digits and keep the collateral ligaments of the injured joints on tension (metacarpophalangeal joints flexed, interphalangeal joints extended).
4. Clinical examination, particularly noting the area of greatest tenderness and/or inflammation, is the most useful diagnostic tool for hand infections.
5. If a patient managed conservatively for "cellulitis" does not improve within 24 to 48 hours of appropriate IV antibiotics, abscess must be suspected.
6. Vascular injuries producing warm ischemia (incomplete amputations or direct vessel trauma with compromised distal perfusion) must be addressed urgently to prevent irreversible tissue loss.
7. Healing of an injured or diseased structure in the hand is not the endpoint of treatment; the goal of any intervention must be to obtain structural healing, relief of pain, and maximization of function.

TREATMENT PRINCIPLES

The highly mobile, functional, and strong hand is a major distinguishing point between human beings and the nonhuman primates. The hand is an essential participant for activities of daily living, vocation, and recreational activities. The hand is even adaptable enough to read for the blind and speak for the mute. The underlying goal of all aspects of hand surgery is to maximize mobility, sensibility, stability, and strength while minimizing pain. These goals are then maximized to the extent possible given the patient's particular pathology.

Bones

The hand is highly mobile in space to allow maximum flexibility in function. As such, a number of directions particular to the hand are necessary to properly describe position, motion, etc.¹ *Palmar* (or *volar*) refers to the anterior surface of the hand in the anatomic position; *dorsal* refers to the posterior surface in the anatomic position. The hand can rotate at the wrist level; rotation to bring the palm down is called *pronation*, to bring the palm up is called *supination*. Because the hand can rotate in space, the terms medial and lateral are avoided. Radial and ulnar are used instead as these terms do not vary with respect to the rotational position of the hand. Abduction and adduction, when used on the hand, refer to movement of the digits away from and toward the middle finger, respectively (Fig. 44-1).

Terminology of common hand motions.

[Reproduced with permission from American Society for Surgery of the Hand (ed): *The Hand: Examination and Diagnosis*, 3rd ed. Copyright © Elsevier, 1990.]

The hand is comprised of 19 bones arranged in five rays.² A ray is defined as a digit (finger or thumb) from the metacarpal (MC) base to the tip of the digit (Fig. 44-2A). The rays are numbered 1 through 5, beginning with the thumb. By convention, however, they are referred to by name: thumb, index, middle, ring, and small. There are five metacarpals, comprising the visible palm of the hand. Each digit has a proximal and a distal phalanx, but only the fingers have a middle phalanx as well. The metacarpophalangeal (MP) joint typically allows 90° of flexion with a small amount of hyperextension. In addition, the fingers can actively abduct (move away from the middle finger) and adduct (move toward the middle finger). The thumb, in contrast, moves principally in the flexion-extension arc at the MP joint. Although there can be laxity in the radial and ulnar direction, the thumb cannot actively move in these directions at the MP level. The proximal interphalangeal (PIP) joint is the critical joint for finger mobility. Normal motion is 0 to 95° (full extension to flexion). The distal interphalangeal (DIP) joint also moves only in a flexion-extension plane from 0 to 90° on average. The thumb interphalangeal (IP) joint also moves only in a flexion-extension plane. Its normal motion is highly variable between individuals, but averages 0 to 80°.

Bony architecture of the hand and wrist. **A.** Bones of the hand and digits. All rays have metacarpophalangeal (MP) joints.

The fingers have proximal and distal interphalangeal (PIP and DIP) joints, but the thumb has a single IP joint. **B.** Bones of the wrist: the proximal row consists of the scaphoid, lunate, and capitate. The distal row bones articulate with the metacarpals: the trapezium with the thumb, the trapezoid with the index, the capitate with the middle, and the hamate with the ring and small. The pisiform bone is a sesamoid within the flexor carpi ulnaris tendon. It overlaps the triquetrum and hamate but does not contribute to a carpal row. CMC = carpometacarpal; TFCC = triangular fibrocartilage complex.

Each of the MP and IP joints has a radial and ulnar collateral ligament to support it. The IP joint collateral ligaments are on tension with the joint fully extended. For the fingers, the MP joint collateral ligaments are on tension with the joint bent 90°. Collateral ligaments have a tendency to contract when not placed on tension; this becomes relevant when splinting the hand (see Trauma section on splinting below).

The wrist consists of eight carpal bones divided into two rows (see Fig. 44-2B).² The proximal row consists of the scaphoid, lunate, and triquetrum. The lunate is the principal axis of motion of the hand onto the forearm. It bears approximately 35% of the load of the wrist onto the forearm. The scaphoid is an oddly shaped bone, which bears 55% of the load of the hand onto the forearm, but also serves as the principal link between the proximal and distal rows, allowing for motion while maintaining stability. Both the scaphoid and the lunate articulate with the radius. The triquetrum resides ulnar to the lunate. It does not interact with the ulna proximally; rather it interacts with a cartilage suspended between the ulnar styloid and the distal radius called the *triangular fibrocartilage complex* (see Fig. 44-2B). The remaining 10% of load of the hand onto the forearm is transmitted through the triangular fibrocartilage complex.³

The distal row consists of four bones. The trapezium resides between the scaphoid and the thumb MC. Distally, it has a saddle-shaped surface, which interacts with a reciprocally saddle-shaped base of the thumb MC to allow for high mobility of the thumb carpometacarpal (CMC) joint in radial-ulnar and palmar-dorsal directions and opposition (see Fig. 44-1B). The trapezoid rests between the scaphoid and the index finger MC. The capitate, the largest carpal bone and first to ossify in a child, lies between the lunate and the middle finger MC but also interacts with the scaphoid on its proximal radial surface. The index and middle finger CMC joints are highly stable and have minimal mobility. The hamate is the ulnar-most bone in the distal row, sitting between the triquetrum proximally and the ring and small finger metacarpals distally. The ring and small finger CMC joints are mobile, but principally in the flexion-extension direction.

The pisiform is a carpal bone only by geography. It is a sesamoid bone within the flexor carpi ulnaris (FCU) tendon (see below under Muscles Affecting the Hand and Wrist). It does not bear load, and can be excised, when necessary, without consequence.

Muscles Affecting the Hand and Wrist

The wrist is moved by multiple tendons that originate from the forearm and elbow. The digits of the hand are moved by both intrinsic (originating within the hand) and extrinsic (originating proximal to the hand) muscles. All of these muscles are innervated by the median, radial, or ulnar nerves (or their branches) (Fig. 44-3).

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Cross-section of the wrist at the midcarpal level. The relative geography of the neurologic and tendinous structures can be seen. The transverse carpal ligament (TCL) is the roof of the carpal tunnel, passing volar to the median nerve and long flexor tendons. The TCL is also the floor of the ulnar tunnel, or Guyon's canal, passing dorsal to the ulnar artery and nerve. The wrist and digital extensor tendons are also seen, distal to their compartments on the distal radius and ulna. Bones: C = capitate; H = hamate; P = pisiform; S = scaphoid. Tendons (flexor digitorum superficialis is volar to flexor digitorum profundus within the carpal tunnel): 2 = index finger; 3 = middle finger; 4 = ring finger; 5 = small finger. A = artery; APL = abductor pollicis longus; ECRB = extensor carpi radialis brevis; ECRL = extensor carpi radialis longus; ECU = extensor carpi ulnaris; EDC = extensor digitorum communis; EDQ = extensor digiti quinti; EIP = extensor indicis proprius; EPB = extensor pollicis brevis; EPL = extensor pollicis longus; FCR = flexor carpi radialis; FPL = flexor pollicis longus; N = nerve.

Three muscles flex the wrist, all of which originate from the medial epicondyle of the humerus. The flexor carpi radialis (FCR, median nerve) inserts on the base of the volar index finger MC. The FCU (ulnar nerve) also originates from the proximal ulna and inserts on the volar base of the small finger MC. The palmaris longus tendon does not insert on a bone; it inserts on the palmar fascia, located deep to the skin in the central proximal palm, and is absent in up to 15% of patients. The FCR tends also to deviate the wrist radially, the FCU ulnarly.

All three wrist extensors are innervated by the radial nerve or its branches. The extensor carpi radialis longus (ECRL) originates from the distal shaft of the humerus and inserts on the dorsal base of the index finger MC. The extensor carpi radialis brevis (ECRB) originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the middle finger MC. The extensor carpi ulnaris (ECU) originates from the lateral epicondyle of the humerus and inserts on the dorsal base of the small finger MC. The ECRL tends to deviate the wrist radially; the ECU ulnarly.

The long flexors of the fingers all originate from the medial epicondyle of the humerus. The flexor digitorum superficialis (FDS) inserts on the base of the middle phalanx of each finger and primarily flexes the PIP joint. The flexor digitorum profundus (FDP) inserts on the base of the distal phalanx and primarily flexes the DIP joint. The flexor pollicis longus (FPL) originates more distally, from the ulna, radius, and interosseous membrane between them in the forearm. It inserts on the base of the distal phalanx of the thumb and primarily flexes the IP joint. All of these tendons can also flex the more proximal

joint(s) in their respective rays. All of these muscles are innervated by the median nerve (or its branches) except the FDP to the ring and small finger, which are innervated by the ulnar nerve.

The extrinsic extensors of the fingers and thumb are all innervated by the PIN (branch of the radial nerve). The extensor digitorum communis (EDC) originates from the lateral epicondyle of the humerus and extends the MP joints of the fingers. It is somewhat unusual in its insertion in that it does not insert on the dorsal base of the proximal phalanx, but rather into a soft tissue sling called the *sagittal hood* that surrounds the proximal phalanx base and pulls up on the volar surface in a hammock-like manner. More distally in the dorsal forearm, the extensor indices proprius (EIP) and extensor digiti quinti (EDQ) originate from the ulna, radius, and posterior interosseous membrane and insert on the sagittal hood of the index and small fingers, respectively.

The thumb has three separate extrinsic extensors. All of these originate from the dorsal ulna in the mid-forearm and are innervated by the PIN. The abductor pollicis longus (APL) inserts on the radial base of the thumb MC to produce some extension, but mostly abduction. The extensor pollicis brevis (EPB) inserts on the base of the thumb proximal phalanx. The extensor pollicis longus (EPL) inserts on the base of the thumb distal phalanx.

The intrinsic muscles of the hand are what allow human beings fine, subtle movements of the hand. Microsurgery, typing, and even video gaming would be difficult, if not impossible, without them.

The thenar muscles originate from the volar radial surface of the scaphoid and trapezium and the flexor retinaculum. The abductor pollicis brevis inserts on the radial base of the thumb proximal phalanx and abducts the thumb in a radial and volar direction. The opponens pollicis (OP) inserts on the radial distal aspect of the thumb MC and draws the thumb across the palm toward the small finger. The flexor pollicis brevis (FPB) inserts on the base of the thumb proximal phalanx and flexes the thumb MP joint. The abductor pollicis brevis, OP, and superficial head of the FPB are all innervated by the thenar motor branch of the median nerve.

The lumbrical muscles are unique in the body in that they originate from a tendon. Each finger's lumbrical originates from the FDP tendon in the palm. The lumbrical tendon passes along the radial aspect of the digit to flex the MP and extend the IP joints. The index and middle lumbricals are median nerve innervated, and the ring and small finger lumbricals are ulnar nerve innervated.

The hypothenar muscles originate from the pisiform, hamate, and flexor retinaculum and insert on the ulnar base of the small finger proximal phalanx. The abductor digiti quinti abducts the small finger. The opponens digiti quinti brings the small finger across the palm in reciprocal motion to the OP. The flexor digiti quinti flexes the small finger MC. All these muscles are innervated by the ulnar nerve.

The interosseous muscles occupy the space between the MC bones. Their tendons insert on the bases of the proximal phalanges. All act to flex the MP joints and extend the IP joints. The three palmar interosseous muscles adduct the fingers. The four dorsal interosseous muscles abduct the fingers. The adductor pollicis originates from the middle finger MC and inserts on the ulnar base of the thumb proximal phalanx. It acts to adduct the thumb. All of these muscles, as well as the deep head of the FPB, are innervated by the ulnar nerve.

Tendons and Pulleys

Multiple pulleys pass over or surround the extrinsic tendons en route to or within the hand. Their purpose is to prevent bow stringing of the tendon, which would decrease the efficiency of its force transmission.

The most well known of the wrist level pulleys is the flexor retinaculum, also known as the *transverse carpal ligament*. It attaches to the scaphoid tubercle and trapezium radially, and the hook of the hamate bone and pisiform ulnarly. Deep to this ligament, between the scaphoid (radially) and the hamate (ulnarly), pass the FDS, FDP, and FPL tendons as well as the median nerve. This area is also known as the *carpal tunnel* (see Fig. 44-3).

On the dorsum of the wrist, the extensor retinaculum is divided into six compartments. Beginning on the radial aspect of the radius, the first compartment contains the APL and EPB tendons. The second holds the ECRL and ECRB tendons. The EPL passes through the third compartment. The fourth compartment contains the EIP and EDC tendons; the fifth, the EDQ, and the sixth, the ECU. The sixth compartment is located on the ulnar aspect of the distal ulna. Although the compartments end at the radiocarpal/ulnocarpal joints, the relative geography of the tendons is preserved over the carpal bones (see Fig. 44-3).

In the hand, the pulleys maintain the long flexor tendons in close apposition to the fingers and thumb. There are no extensor pulleys within the hand. Each finger has five annular and three cruciate pulleys (Fig. 44-4). The second and fourth (A2 and A4) pulleys are the critical structures that prevent bowstringing of the finger.⁴ The remaining pulleys can be divided as needed for surgical exposure or to relieve a stricture area.

Drawing of anteroposterior and lateral view of the pulley system.

Vascular

Two major arteries serve the hand. The radial artery travels under the brachioradialis muscle in the forearm. At the junction of the middle and distal thirds of the forearm, the artery becomes superficial and palpable, passing just radial to the FCR tendon. At the wrist level, the artery splits into two branches. The smaller, superficial branch passes volarly into the palm to contribute to the superficial palmar arch. The larger branch passes dorsally over the scaphoid bone, under the EPL and EPB tendons (known as the *anatomic snuffbox*), and back volarly between the proximal thumb and index finger metacarpals to form the superficial palmar arch.

The ulnar artery travels deep to the FCU muscle in the forearm. When the FCU becomes tendinous, the ulnar artery resides deep and slightly radial to it. At the wrist, the artery travels between the hamate and pisiform bones superficial to the transverse carpal ligament (known as *Guyon's canal*) into the palm. The larger, superficial branch forms the superficial palmar arch. The deeper branch contributes to the deep palmar arch (Fig. 44-5A). In 97% of patients, at least one of the deep or superficial palmar arches is intact, allowing for the entire hand to survive on the radial or ulnar artery.⁵

Arteries of the hand and finger. **A.** Relative position of the superficial and deep palmar arches to the bony structures and each other; note the radial artery passes dorsal to the thumb metacarpal base, through the first web space, and anterior to the index metacarpal base as it forms the deep arch. **B.** The neurovascular bundles lay volar to the midaxis of the digit with the artery dorsal to the nerve; Grayson's ligament (volar) and Cleland's ligament (dorsal) connect the bone to the skin surrounding the bundle.

Each digit receives a radial and ulnar digital artery. For the thumb, the radial digital artery may come from the deep palmar

arch or the main body of the radial artery. The larger ulnar digital artery comes off the deep arch as either a single unit, the princeps pollicis artery, or less frequently, as the first common digital artery, which then splits into the radial digital artery to the index finger and the ulnar digital artery to the thumb. The second, third, and fourth digital arteries typically branch off the superficial palmar arch and pass between the index/middle, middle/ring, and ring/small fingers respectively, ultimately dividing into two proper digital arteries each. The ulnar digital artery of the small finger comes off as a separate branch from the superficial arch. Within the finger, the proper digital arteries travel lateral to the bones and tendons, just palmar to the midaxis of the digit, but dorsal to the proper digital nerves (see Fig. 44-5B).

Nerve

Three principal nerves serve the forearm, wrist, and hand: the median, radial, and ulnar nerves. The most critical of these from a sensory standpoint is the median nerve. The median nerve begins as a terminal branch of the medial and lateral cords of the brachial plexus. It receives fibers from C5–T1. The palmar cutaneous branch of the median nerve serves the proximal, radial-sided palm. The main body of the median nerve splits into several branches after the carpal tunnel: a radial digital branch to the thumb, an ulnar digital nerve to the thumb, and a radial digital nerve to the index finger (sometimes beginning as a single first common digital nerve); the second common digital nerve that branches into the ulnar digital nerve to the index finger and the radial digital nerve to the middle finger; and a third common digital nerve that branches into the ulnar digital nerve to the middle finger and a radial digital nerve to the ring finger. The digital nerves provide volar-sided sensation from the MC head level to the tip of the digit. They also, through their dorsal branches, provide dorsal-sided sensation to the digits from the midportion of the middle phalanx distally via dorsal branches. The thenar motor branch of the median nerve most commonly passes through the carpal tunnel and then travels in a recurrent fashion back to the thenar muscles. Less commonly, the nerve passes through or proximal to the transverse carpal ligament en route to its muscles.

In the forearm, the median nerve gives motor branches to all of the flexor muscles except the FCU, and the ring and small finger portions of the FDP. Distal median motor fibers (with the exception of those to the thenar muscles) are carried through a large branch called the *anterior interosseous nerve*.

The ulnar nerve is a terminal branch of the medial cord of the brachial plexus. It receives innervation from C8 and T1 roots. The FCU and FDP (ring/small) receive motor fibers from the ulnar nerve. In the distal forearm, 5 cm above the head of the ulna, the nerve gives off a dorsal sensory branch. Once in the hand, the nerve splits into the motor branch and sensory branches. The motor branch curves radially at the hook of the hamate bone to innervate the intrinsic muscles as described above in Muscles Affecting the Hand and Wrist. The sensory branches become the ulnar digital nerve to the small finger and the fourth common digital nerve which splits into the ulnar digital nerve to the ring finger and the radial digital nerve to the small finger. The sensory nerves provide distal dorsal sensation similar to the median nerve branches.

The radial nerve is the larger of two terminal branches of the posterior cord of the brachial plexus. It receives fibers from C5–T1 nerve roots. It innervates all of the extensor muscles of the forearm and wrist, principally through its PIN branch. The major exception to this is the ECRL, which is innervated by the main body of the radial nerve in the distal upper arm. Unlike on the flexor surface, there is no ulnar nerve contribution to extension of the wrist, thumb, or finger MP joints. As noted above in Muscles Affecting the Hand and Wrist, the ulnar innervated intrinsic hand muscles are the principal extensors of the finger interphalangeal joints, although the long finger extensors (EDC, EIP, EDQ) make a secondary contribution to this function.

In the proximal dorsal forearm, the superficial radial nerve (SRN) is the other terminal branch of the radial nerve. It travels deep to the brachioradialis muscle until 6 cm proximal to the radial styloid, where it becomes superficial. The SRN provides sensation to the dorsal hand and the radial three and one half digits up to the level of the mid-middle phalanx (where the dorsal branches of the proper digital nerves take over, as described earlier in this section). The dorsal branch of the ulnar nerve provides sensation to the ulnar one and one half digits and dorsal hand in complement to the SRN.

HAND EXAMINATION

Emergency Room/Inpatient Consultation

A common scenario in which the hand surgeon will be introduced to the patient is in trauma or other acute situations. The patient is evaluated by inspection, palpation, and provocative testing. Upon inspection, one should first note the position of the hand. The resting hand has a normal cascade of the fingers, with the small finger flexed most and the index finger least (Fig. 44-6). Disturbance of this suggests a tendon or skeletal problem. Also note any gross deformities or wounds, and what deeper structures, if any, are visible in such wounds. Observe for abnormal coloration of a portion or all of the hand (this can be skewed by ambient temperature or other injuries), gross edema, and/or clubbing of the fingertips.

Fig. 44-6.

In the normal resting hand, the fingers assume a slightly flexed posture from the index finger (least) to the small finger (most).

Palpation typically begins with the radial and ulnar artery pulses at the wrist level. Pencil Doppler examination can supplement this and evaluate distal vessels. A pulsatile signal is normally detectable by pencil Doppler in the pad of the finger at the center of the whorl of creases. Discrepancies between digits should be noted. If all other tests are inconclusive, pricking the involved digit with a 25-gauge needle should produce bright red capillary bleeding. If an attached digit demonstrates inadequate or absent blood flow (warm ischemia), the urgency of completing the evaluation and initiating treatment markedly increases.

Sensation must be evaluated before any administration of local anesthetic. At a minimum, light and sharp touch sensation should be documented for the radial and ulnar aspects of the tip of each digit. Beware of writing "sensation intact" at the conclusion of this evaluation. Medicolegally, intact means perfect and can be a liability if the sensation is measured more thoroughly after an intervention and noted not to be perfect. Rather, one should document what was tested (e.g., "light and sharp touch sensation present and symmetric to the tips of all digits of the injured hand"). In the setting of a sharp injury, sensory deficit implies a lacerated structure until proven otherwise. Once sensation has been evaluated and documented, the injured hand can be anesthetized for patient comfort during the remainder of the examination (see below under Local Anesthesia).

Ability to flex and extend the wrist and digital joints is typically examined next. At the wrist level, the FCR and FCU tendons should be palpable during flexion. The wrist extensors are not as readily palpated due to the extensor retinaculum. Ability to flex the DIP joint (FDP) is tested by blocking the finger at the middle phalanx level. To test the FDS to each finger, hold the remaining three fingers in slight hyperextension and ask the patient to flex the involved digit (Fig. 44-7). This maneuver makes use of the fact that the FDP tendons share a common muscle belly. Placing the remaining fingers in extension prevents the FDP from firing, and allows on the FDS, which has a separate muscle belly for each tendon, to fire. Strength in grip, finger abduction, and thumb opposition is tested and compared to the uninjured side. Range of motion (ROM) for the

wrist, MP, and IP joints should be noted and compared to the opposite side.

Fig. 44-7.

The examiner holds the untested fingers in full extension, preventing contracture of the flexor digitorum profundus. In this position, the patient is asked to flex the finger, and only the flexor digitorum superficialis will be able to fire.

If there is suspicion for closed space infection, the hand should be evaluated for erythema, swelling, fluctuance, and localized tenderness. The dorsum of the hand does not have fascial septae, thus dorsal infections can spread more widely than palmar ones. The epitrochlear and axillary nodes should be palpated for enlargement and tenderness. Findings for specific infectious processes will be discussed in the Infections section.

Additional examination maneuvers and findings, such as those for office consultations, will be discussed with each individual disease process covered later in this chapter.

HAND IMAGING

Plain X-Rays

Almost every hand evaluation should include plain x-rays of the injured/affected part. A standard, anteroposterior, lateral, and oblique view of the hand or wrist (as appropriate) is rapid, inexpensive, and usually provides sufficient information about the bony structures to achieve a diagnosis in conjunction with the symptoms and findings.⁶

Lucencies within the bone should be noted. Most commonly, these represent fractures, but they can, on occasion, represent neoplastic or degenerative processes. Great care should be taken to evaluate the entire x-ray, typically beginning away from

the area of the patient's complaint. Additional injuries can be missed that might affect the treatment plan selected and eventual outcome.

Congruency of adjacent joints also should be noted. The MP and IP joints of the fingers should all be in the same plain on any given view. Incongruency of the joint(s) of one finger implies fracture with rotation. At the wrist level, the proximal and distal edge of the proximal row and proximal edge of the distal row should be smooth arcs,⁷ known as *Gilula's arcs* (Fig. 44-8A). Disruption of these implies ligamentous injury or possibly dislocation (see Fig. 44-8B).

Fig. 44-8.

A

Gilula's arcs are seen shown in this normal patient (**A**) and in a patient with a scaphoid fracture and perilunate dislocation (**B**).

Computed Tomography

CT scanning of the hand and wrist can provide additional bony information when plain x-rays are insufficient. Comminuted fractures of the distal radius can be better visualized for number and orientation of fragments. Scaphoid fractures can be evaluated for displacement and comminution preoperatively as well as for the presence of bony bridging postoperatively (Fig. 44-9). CT scans are also useful for CMC fractures of the hand where overlap on a plain x-ray lateral view may make diagnosis difficult.

Fig. 44-9.

A. Preoperative images demonstrate a nonunion of a scaphoid fracture sustained 4 years earlier. **B.** Postoperatively, cross-sectional imaging with a computed tomography scan in the coronal plan demonstrates bone crossing the previous fracture line. This can be difficult to discern on plain x-rays due to overlap of bone fragments.

Unlike the trunk and more proximal extremities, CT scans with contrast are less useful to demonstrate abscess cavities.

Ultrasonography

Ultrasonography has the advantages of being able to demonstrate soft tissue structures and being available on nights and weekends. Unfortunately, it is also highly operator dependent. In the middle of the night, when magnetic resonance imaging (MRI) is not available, ultrasound may be able to demonstrate a large deep infection in the hand but is rarely more useful than a thorough clinical examination.

Magnetic Resonance Imaging

MRI provides the best noninvasive visualization of the soft tissue structures. With contrast, MRI can demonstrate an occult abscess. Unfortunately, it usually is not available on nights and weekends when this information is often needed. MRI also can demonstrate soft tissue injuries such as cartilage or ligament tears or tendonitis (usually by demonstrating edema in the area in question). It can demonstrate occult fractures that are not sufficiently displaced to be seen on x-ray or CT (again, by demonstrating edema). MRI also can demonstrate vascular disturbance of a bone, as with the patient with avascular necrosis of the scaphoid shown in Fig. 44-10.

Fig. 44-10.

T1-weighted magnetic resonance imaging (seen here) shows perfused bone as *white*. In this patient, there is the absence of whiteness where the scaphoid should be (*dashed circle*), consistent with avascular necrosis.

Angiography

Angiography of the upper extremity is rarely used. Magnetic resonance angiography and computed tomography angiography in many centers provide sufficient resolution of the vascular structures to make it necessary. Also, primary vascular disease of the upper extremity is relatively uncommon. In the trauma setting, vascular disturbance usually mandates exploration and direct visualization of the structures in question, and angiography is thus obviated.

For a patient with vascular disease of the upper extremity, angiography of the upper extremity is usually performed through a femoral access much like with the leg. An arterial catheter can be used to deliver thrombolytic drugs to treat an occlusive process.

TRAUMA

The upper extremity-injured patient may have additional injuries to other parts of the body. All injured patients should receive an appropriate trauma survey to look for additional injuries. Although the hand provides critical function to the patient, treatment of life or more proximal limb-threatening injuries takes precedence.

The patient with upper extremity trauma is evaluated as described in the Hand Examination section. Perform an appropriate sensory examination early. Once sensory status has been documented, administration of local anesthesia can provide comfort to the patient during the remainder of the evaluation and subsequent treatment. Patients should receive tetanus toxoid for penetrating injuries if more than 5 years have passed since the last vaccination.

Local Anesthesia

Anesthetic blockade can be administered at the wrist level, digital level, or with local infiltration, as needed. Keep in mind that all local anesthetics are less effective in areas of inflammation. The agents most commonly used are lidocaine and

bupivacaine. Lidocaine has the advantage of rapid onset while bupivacaine has the advantage of long duration (average 6 to 8 hours).⁸ Although bupivacaine can produce irreversible heart block in high doses, this is rarely an issue given the amounts typically used in the hand. For pediatric patients, the tolerated dose is 2.5 mg/kg. This can be easily remembered by noting that when using 0.25% bupivacaine, 1mL/kg is acceptable dosing.

A commonly held axiom is that epinephrine is unacceptable to be used in the hand. Several recent large series have dispelled this myth.⁹ Epinephrine should not be used in the fingertip, and not in concentrations higher than 1:100,000 (i.e., what is present in commercially available local anesthetic with epinephrine). Beyond that, its use is acceptable and may be useful in an emergency room (ER) where tourniquet control may not be available. Also, as most ER procedures are done under pure local anesthesia, many patients will not tolerate the discomfort of the tourniquet beyond 30 minutes.¹⁰ Not only will epinephrine provide hemostasis, it also prolongs the effect of the local anesthetic.

Simple lacerations, particularly on the dorsum of the hand, can be anesthetized with local infiltration. This is performed in the standard fashion.

Blocking of the digital nerves at the MC head level is useful for volar injuries distal to this point and for dorsal injuries beyond the midpoint of the middle phalanx (via dorsal branches of the proper digital nerves). Fingertip injuries are particularly well anesthetized by this technique. There are two principal ways to anesthetize a digit (Fig. 44-11A and 44-11B). The flexor sheath technique introduces the needle in the slightly more sensitive volar skin at the MC head level; the intermetacarpal technique introduces the needle in the slightly less sensitive web space skin, but requires two injections for a single digit.

Local anesthesia can be administered at the digital or the wrist level. **A.** A single injection into the flexor tendon sheath at the metacarpal head level provides complete anesthesia for the digit. **B.** Alternatively, one can inject from a dorsal approach into the web space on either side. **C.** The superficial radial nerve is blocked by infiltrating subcutaneously over the distal radius from the radial artery pulse to the distal radioulnar joint. The dorsal sensory branch of the ulnar nerve is blocked in similar fashion over the distal ulna. **D.** To block the ulnar nerve, insert the needle parallel to the plane of the palm and deep to the flexor carpi ulnaris tendon; aspirate to confirm the needle is not in the adjacent ulnar artery. **E.** To block the median nerve, insert the needle just ulnar to the palmaris longus tendon into the carpal tunnel. One should feel two points of resistance: one when piercing the skin, the second when piercing the antebrachial fascia.

Blocking one or more nerves as they cross the wrist can provide several advantages: anesthesia for multiple injured digits,

avoiding areas of inflammation where the local anesthetic agent may be less effective, and avoiding injection where the volume of fluid injected may make treatment harder (such as fracture reduction). Four major nerves cross the wrist: the median nerve, SRN, ulnar nerve, and dorsal sensory branch of the ulnar nerve (see Fig. 44-11C, 44-11D, and 44-11E). When blocking the median and ulnar nerves, beware of intraneural injection, which can cause irreversible neural scarring. If the patient complains of severe paresthesias with injection, or high resistance is encountered, the needle should be repositioned.

Fractures and Dislocations

For dislocations and displaced fractures, a visible deformity is often present. Nondisplaced fractures may not show a gross deformity, but will have edema and tenderness to palpation at the fracture site. The fracture should be described for its displacement, rotation, and angulation. The fracture should also be described in terms of comminution, the number and complexity of fracture fragments. Displacement is described as a percentage of the diameter of the bone; rotation is described in degrees of supination or pronation with respect to the rest of the hand; angulation is described in degrees. To avoid confusion, it is useful to describe in which direction the angle of the fracture points. All injuries should be evaluated for nearby wounds (open) that may introduce bacteria into the fracture site or joint space (Fig. 44-12).

Fig. 44-12.

Schematic representation of types of fractures by presence/absence of nearby wound, location within the bone, complexity, and orientation.

[Reproduced with permission from American Society for Surgery of the Hand (ed): *The Hand: Examination and Diagnosis*, 3rd ed. Copyright © Elsevier 1990.]

Once the initial force on the fracture ceases, the tendons passing beyond the fracture site provide the principal deforming force. Their force is directed proximally and, to a lesser extent, volarly. Based on this, the stability of a fracture can be determined by the orientation of the fracture with respect to the shaft of the bone. Transverse fractures are typically stable. Oblique fractures typically shorten. Spiral fractures typically rotate as they shorten and thus require surgical treatment.

Fractures of the tuft of the distal phalanx are commonly seen. Slamming of a finger in a door is a common causative mechanism. These fractures are often nondisplaced and do not require treatment beyond protection of the distal phalanx from additional trauma while the fracture heals.

Displaced transverse fractures of the phalanges can usually be reduced with distraction. The distal part is pulled away from the main body of the hand, then pushed in the direction of the proximal shaft of the finger, then distraction is released. Postreduction x-rays should always be performed to document satisfactory reduction. Oblique and spiral fractures usually are unstable after reduction. The involved digit(s) should be splinted until appropriate surgical intervention can be performed.

Articular fractures of the interphalangeal and MPs are worrisome because they may compromise motion. Chip fractures must be evaluated for instability of the collateral ligaments. If the joint is stable, the patient should initially be splinted for comfort. Motion therapy should be instituted early (ideally within the first week) to prevent stiffness. For larger fractures, the patient should be splinted until surgical treatment can be performed. In surgery, the fracture is typically internally fixated to allow for early motion, again with the goal of preventing stiffness.¹¹

Dislocations of the PIPs produce traction on the neurovascular structures but usually do not lacerate them. In general, the patient should not be sent home with a joint that remains dislocated. Most commonly, the distal part is dorsal to the proximal shaft and sits in a hyperextended position. For this patient, the examiner gently applies pressure to the base of the distal part until it passes beyond the head of the proximal phalanx. Once there, the relocated PIP joint is gently flexed, confirming the joint is, in fact, reduced. The joint is splinted in slight flexion to prevent redislocation. On occasion, the head of the proximal phalanx may pass between the two slips of the FDS tendon. For these patients, the joint cannot be reduced in a closed fashion.

Angulated fractures of the small finger MC ("boxer's fracture") are another common injury seen in the ER. Typical history is that the patient struck another individual or rigid object with a hook punch. These often are stable after reduction using the Jahss maneuver (Fig. 44-13).

Fig. 44-13.

Source: Brunicaardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

The Jahss maneuver. The surgeon fully flexes the patient's small finger into the palm and secures it in his distal hand. The proximal hand controls the wrist and places the thumb on the patients fracture apex (the most prominent dorsal point). The examiner distracts the fracture, pushes dorsally with the distal hand (*up arrow*) and resists dorsal motion with the proximal hand (*down arrow*).

Fractures of the base of the thumb MC base often are unstable. The Bennett fracture displaces the volar-ulnar base of the bone. The remainder of the articular surface and the shaft typically dislocate dorsoradially and shorten. The thumb often appears grossly shortened, and the proximal shaft of the MC may reside at the level of the trapezium or even the scaphoid on x-ray. In a Rolando fracture, a second fracture line occurs between the remaining articular surface and the shaft. These fractures nearly always require open reduction and internal fixation.

In general terms, most nondisplaced fractures do not require surgical treatment. The scaphoid bone of the wrist is a notable exception to this rule. Due to peculiarities in its vascular supply, particularly vulnerable at its proximal end, nondisplaced scaphoid fractures can fail to unite in up to 20% of patients, even with appropriate immobilization. Recent developments in hardware and surgical technique have allowed stabilization of the fracture with minimal surgical exposure. One prospective randomized series of scaphoid waist fractures demonstrated shortening of time to union by up to 6 weeks in the surgically treated group, but no difference in rate of union.¹² Surgical treatment for nondisplaced scaphoid fractures is not indicated for all patients, but may be useful in the younger, more active patient who would benefit from an earlier return to full activity.

Ligament injuries of the wrist can be difficult to recognize. Patients often present late and may not be able to localize their pain. In severe cases, the ligaments of the wrist can rupture to the point of dislocation of the capitate off the lunate, or even the lunate off the radius. Mayfield and colleagues classified the progression of this injury into four groups.¹³ In the most severe group, the lunate dislocates off the radius into the carpal tunnel. In some circumstances, the scaphoid bone may break rather than the scapholunate ligament rupturing. Attention to the congruency or disruption of Gilula's arcs will help the examiner to recognize this injury. For patients with the type 4 (most severe) and some with the type 3 injury, the examiner

should also evaluate for sensory disturbance in the median nerve distribution, as this may indicate acute carpal tunnel syndrome (CTS) and necessitate more urgent intervention.

After reduction of fractures and dislocations (as well as after surgical repair of these and many other injuries), the hand must be splinted in a protected position. For the fingers, MP joints should be splinted 90°, the IPs at 0° (called the *intrinsic plus position*). The wrist is generally splinted at 20° extension, as this puts the hand in a more functional position. This keeps the collateral ligaments on tension and helps prevent secondary contracture. In general, one of three splints should be used for the ER patient (Fig. 44-14). The ulnar gutter splint uses plaster around the ulnar border of the hand. It is generally appropriate for small finger injuries only. Dorsal plaster splints can be used for injuries of any of the fingers. Plaster is more readily contoured to the dorsal surface of the hand than the volar surface, particularly in the setting of trauma-associated edema. For thumb injuries, the thumb spica splint is used to keep the thumb radially and palmarly abducted from the hand. For injuries involving the thumb MP joint or distal, the IP joint should be included in the splint. For more proximal injuries, it need not be included.

Fig. 44-14.

Common splints used for hand injuries/surgeries. **A.** Ulnar gutter splint. The ring and small fingers are included. The surgeon pushes on the dorsum of the fingers with the distal hand to produce interphalangeal (IP) joint extension and metacarpophalangeal joint flexion to 90° while the proximal hand controls wrist position. **B.** Dorsal four-finger splint. As with the ulnar gutter splint, finger metacarpophalangeal joints are flexed to 90° with IP joints kept fully extended. **C.** Thumb spica splint. One easy method to fabricate is to place one slab of plaster radially over the wrist and thumb with a second square of plaster over the thenar eminence that joins the first. In this patient the IP joint was not included. For injuries at, or distal to, the metacarpophalangeal joint, the IP should be included in the splint.

Tendons

Injuries to the flexor and extensor tendons compromise the mobility and strength of the digits. On inspection, injury normally is suspected by loss of the normal cascade of the fingers. The patient should be examined as described above in

Emergency Room/Inpatient Consultation to evaluate for which tendon motion is deficient. If the patient is unable to cooperate, extension of the wrist will produce passive flexion of the fingers and also demonstrate a deficit. This is referred to as the *tenodesis maneuver*.

Flexor tendon injuries are described based on zones (Fig. 44-15). Up until 40 years ago, zone 2 injuries were always reconstructed and never repaired primarily due to concern that the bulk of repair within the flexor sheath would prevent tendon glide. The work of Dr. Kleinert and colleagues at the University of Louisville changed this "axiom" and established the principle of primary repair and early controlled mobilization postoperatively.¹⁴ Flexor tendon injuries should always be repaired in the OR. Although they do not need to be repaired on the day of injury, the closer to the day of injury they are repaired, the easier it will be to retrieve the retracted proximal end. The laceration should be washed out and closed at the skin level only using permanent sutures. The hand should be splinted as described above in Fractures and Dislocations; one notable difference is that the wrist should be splinted at slight flexion (about 20°) to help decrease the retracting force on the proximal cut tendon end.

Fig. 44-15.

The zones of flexor tendon injury: *I*. Flexor digitorum superficialis insertion to the flexor digitorum profundus insertion. *II*. Start of the A1 pulley to the flexor digitorum superficialis insertion. *III*. End of the carpal tunnel to the start of the A1 pulley. *IV*. Within the carpal tunnel. *V*. Proximal to the carpal tunnel.

Extensor tendons do not pass through a sheath in the fingers. As such, bulkiness of repair is less of a concern. With proper supervision/experience and equipment, primary extensor tendon repair can be performed in the ER.

Very distal extensor injuries near the insertion on the dorsal base of the distal phalanx may not have sufficient distal tendon to hold a suture. Closed injuries, called *mallet fingers*, can be treated with extension splinting of the DIP joint for 6 continuous weeks. For patients with open injuries, a dermatotendodesis suture is performed. A 2-0 or 3-0 suture is passed through the distal skin, tendon remnant, and proximal tendon as a mattress suture. Be sure to use a suture of a different color than the skin closing sutures to help prevent removing the dermatotendodesis suture(s) too soon. The DIP joint is splinted in extension.

More proximal injuries are typically repaired with a 3-0 braided polyester suture. Horizontal mattress or figure-of-eight sutures should be used, two per tendon if possible. Great care should be used to ensure matching the appropriate proximal and distal tendon ends. The patient is splinted with IP joints in extension and the wrist in extension per usual. MP joints should be splinted in 45° flexion, sometimes less. Although this position is not ideal for MP collateral ligaments, it is important for taking tension off the tendon repairs. The patient should be seen within 1 week of repair to initiate hand therapy.

Nerve Injuries

In the setting of a sharp injury, a sensory deficit implies a nerve laceration until proven otherwise. For blunt injuries, even displaced fractures and dislocations, nerves often are contused but not lacerated and are managed expectantly. Nerve repairs require appropriate microsurgical equipment and suture; they should not be performed in the ER. As with tendons, nerve injuries do not require immediate exploration. However, earlier exploration will allow for easier identification of structures. Earlier exploration also will allow for less scar tissue to be present; the nerve must be resected back to healthy nerve fascicle before repair. Delay between injury and repair can thus make a difference between the ability to repair a nerve primarily or the need to use a graft. The injured hand should be splinted with MPs at 90° and IPs at 0°, as described above in Fractures and Dislocations.

Vascular Injuries

Vascular injuries have the potential to be limb or digit threatening. A partial laceration of an artery at the wrist level can potentially even cause exsanguinating hemorrhage. Consultations for these injuries must be evaluated urgently.

Initial treatment for an actively bleeding wound should be direct local pressure for no less than 10 continuous minutes. If this is unsuccessful, an upper extremity tourniquet inflated to 100 mmHg above the systolic pressure should be used. It should be noted that one should keep this tourniquet time to <2 hours to avoid tissue necrosis. Once bleeding is controlled well enough to evaluate the wound, it may be cautiously explored to evaluate for bleeding points. One must be very cautious if attempting to ligate these to ensure that adjacent structures such as nerves are not included in the ligature.

The hand must be evaluated for adequacy of perfusion to the hand as a whole as well as the individual digits. Capillary refill, turgor, Doppler signal, and bleeding to pinprick all provide useful information regarding vascular status. The finger or hand with vascular compromise requires urgent operative exploration. Unlike the complete amputation, in which the amputated part can be cold preserved (see below in Amputations and Replantation), devascularization without amputation produces warm ischemia, which is tolerated only for a matter of hours.

For the noncritical vascular injury, two treatment options exist. Simple ligation will control hemorrhage. At least one of the palmar arterial arches are intact in 97% of patients,⁵ so this will usually not compromise hand perfusion. Each digit also has two arterial inflows and can survive on one (see Amputations and Replantation section below). In the academic hospital

setting, however, consideration should be given to repairing all vascular injuries. Instructing a resident in vascular repair in the noncritical setting will produce a more skilled and prepared resident for when a critical vascular injury does arise.

SPECIAL CONSIDERATIONS

Amputations and Replantation

After replantation was first reported,¹⁵ replantation was attempted for nearly all amputations. Over the ensuing decades, more stringent guidelines have been established regarding what should be replanted. Indications for replantation include amputations of the thumb, multiple digit amputations, and amputations in children. Relative contraindications to replantation include crush injuries, injuries to a single digit distal to the PIP joint, and patients who are unable to tolerate a long surgical procedure. As with all guidelines, one should evaluate the particular needs of the injured patient. In East Asian cultures, a greater emphasis has been placed on salvaging all digits if at all possible due to the societal association of hand integrity with character integrity. In these settings, distal single digit amputations often will be replanted.

In preparation for replantation, the amputated part and proximal stump should be appropriately treated. The amputated part should be wrapped in moistened gauze and placed in a sealed plastic bag. This bag should then be placed in an ice water bath. Do not use dry ice and do not allow the part to contact ice directly; frostbite can occur in the amputated part, which will decrease its chance of survival after replantation. Bleeding should be controlled in the proximal stump by as minimal a means as necessary, and the stump dressed with a nonadherent gauze and bulky dressing.

For digital amputations deemed unsalvageable, revision amputation can be performed in the ER if appropriate equipment is available. Bony prominences should be smoothed off with a rongeur and/or rasp. Great care must be taken to identify the digital nerves and resect them back as far proximally in the wound as possible; this helps decrease the chance of painful neuroma in the skin closure. Skin may be closed with permanent or absorbable sutures; absorbable sutures will spare the patient the discomfort of suture removal several weeks later. For more proximal unsalvageable amputations, revision should be preformed in the OR to maximize vascular and neural element control.

Prostheses can be made for amputated parts. The more proximal the amputation, the more important to function the prosthesis is likely to be. Although finger level prostheses generally are considered cosmetic, those patients with multiple finger amputations proximal to the DIP have demonstrable functional benefit from their prostheses as well.¹⁶

Fingertip Injuries

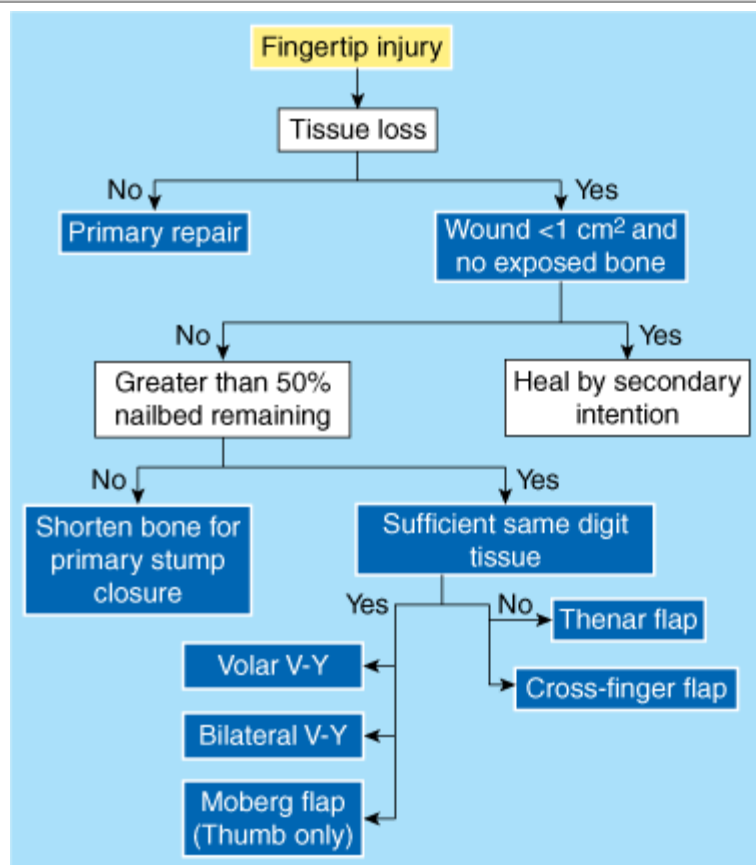

Fingertip injuries are among the most common pathologies seen in an ER. The usual history is that a door closed on the finger (commonly the middle, due to its increased length) or something heavy fell on the finger.

Initial evaluation should include: wound(s) including the nail bed, perfusion, sensation, and presence and severity of fractures. For the common scenario, complex lacerations with minimally displaced fracture(s) and no loss of perfusion, the wound is cleansed, closed, and splinted in the ER. To properly assess the nail bed, the nail plate (hard part of the nail) should be removed. A Freer periosteal elevator is well suited for this purpose. Lacerations are repaired with 6-0 fast gut suture. Great care must be taken when suturing as excessive traction with the needle can further lacerate the tissue. After repair, the nail folds are splinted with the patient's own nail plate (if available) or with aluminum foil from the suture pack. This is done to prevent scarring from the nail folds down to the nail bed that would further compromise healing of the nail.

In some situations, tissue may have been avulsed in the injury and be unavailable for repair. Choice of treatment options

depends on the amount and location of tissue loss (Fig. 44-16). For wounds <1 cm with no exposed bone, secondary intention will produce excellent functional and aesthetic results. For larger wounds or wounds with bone exposed, one must decide if the finger is worth preserving at the current length or if shortening to allow for primary closure is a better solution. A useful guideline is the amount of fingernail still present; if greater than 50% is present, local or regional flap coverage may be a good solution.

Treatment algorithm for management of fingertip injuries. See text for description of flaps.

If sufficient local tissue is present, homodigital V-Y flaps can be considered. If volar skin is in excess, a volar V-Y flap can be raised and advanced distally. If not, bilateral V-Y flaps can be raised and advanced distally to meet in the midline. Both of these flaps allow for full-thickness tissue to be brought distally. The proximal apex of the donor site should not cross the DIP flexion crease. Common postoperative complaints include hypersensitivity at the tip and cold intolerance.¹⁷ For the thumb only, the entire volar skin including both neurovascular bundles can be raised and advanced distally up to 1.5 cm.¹⁸ The thumb receives separate vascularity to its dorsal skin from the radial artery. This flap is not advisable for the fingers. Patients retain full sensibility in the advanced skin and can be mobilized within days of surgery (Fig. 44-17A, 44-17B, and 44-17C).

Local flaps for digital tip coverage. **A** through **C**. For thumb injuries, Moberg described elevation of the entire volar skin with both neurovascular bundles for distal advancement. Sensation to the advanced skin is maintained. **D** through **F**. An 8-year-old girl underwent fingertip replantation that did not survive. A thenar flap was transferred to cover the defect. Some authors advise against its use in patients >30 years old. **G** through **I**. In this 45-year-old man, the entire skin of P3 of the long finger was avulsed and unrecoverable. A cross-finger flap was transferred and provides excellent, durable coverage. The border of the flap and surrounding skin is still apparent 4.5 months after surgery

For wounds too large to cover with homodigital tissue, regional flaps can be considered. The skin from the distal radial thenar eminence can be raised as a random pattern flap (see Fig. 44-17D, 44-17E, and 44-17F). The finger is maintained in flexion for 14 to 21 days until division of the flap pedicle and inset of the flap. Some authors have reported prolonged stiffness in patients over 30 years old, but careful flap design helps minimize this complication.¹⁹ Alternatively, the skin from the dorsum of the middle phalanx of an adjacent digit can be raised as a flap to cover the volar P3 (see Fig. 44-17G, 44-17H, and 44-17I). The flap is inset at 14 to 21 days. Long-term studies have shown this flap develops sensation over time.²⁰

Patients with fingertip injuries must be assessed for the possibility of salvage of the injured digit(s) taken within the context of the patient's recovery needs and goals. The surgeon then matches the available options to the particular patient's needs (see Fig. 44-16).

High-Pressure Injection Injuries

High-pressure devices are commonly used for cleaning and applications of liquids such as lubricants and paint. Most commonly, the inexperienced worker accidentally discharges the device into his nondominant hand at the base of the digit.

Severity of injury depends on the amount and type of liquid injected; hydrophobic compounds cause greater damage.

These injuries are typically quite innocuous to inspection. They are, however, digit threatening emergencies. The patient should be informed of the severity of the injury, and exploration is ideally performed within 6 hours of injury. Up to 50% of such injuries result in loss of the digit, although recent studies with early recognition and treatment have decreased this number.²¹ Early, frank discussion with the patient and initiation of appropriate treatment produce the best results and medicolegal protection.

Compartment Syndromes

Compartment syndromes can occur in the forearm and/or the hand. As in other locations, these are potentially limb-threatening issues. Principal symptoms are pain in the affected compartments, tense swelling, tenderness to palpation over the compartment, and pain with passive stretch of the muscles of the compartment.²² Pulse changes are a late finding; normal pulses do not rule out compartment syndrome.

There are three compartments in the forearm and four groups of compartments in the hand. The volar forearm is one compartment. On the dorsum of the forearm, there is the dorsal compartment as well as the mobile wad compartment, beginning proximally over the lateral epicondyle. In the hand, the thenar and hypothenar muscle wads each behave as a separate compartment. The seven interosseous muscles each behave as a separate compartment.

Compartment syndrome can be caused by intrinsic and extrinsic causes. Intrinsic causes include edema and hematoma due to fracture. Extrinsic causes include splints and dressings that are circumferentially too tight and IV infiltrations. Infiltrations with hyperosmolar fluids such as x-ray contrast and dextrose-50 are particularly dangerous because additional water will be drawn in to neutralize the hyperosmolarity.

Measurement of compartment pressures can be a useful adjunct to assessment of the patient. The Stryker pressure measurement device or a similar device is kept in many operating rooms for this purpose. The needle is inserted into the compartment in question, a gentle flush with 0.1 to 0.2 mL of saline clears the measurement chamber, and a reading is obtained. Studies have disagreed whether the criteria is a pressure (30 to 45 mmHg, depending on the series), or within a certain amount of the diastolic blood pressure.²³

Compartment releases are performed in the OR under tourniquet control. Release of the volar forearm compartment includes release of the carpal tunnel. As the incision travels distally, it should pass ulnarly and then curve back radially just before the carpal tunnel. This avoids a linear incision across a flexion crease and also decreases the chance of injury to the palmar cutaneous branch of the median nerve. One dorsal forearm incision can release the dorsal compartment and the mobile wad. In the hand, the thenar and hypothenar compartments are released each with a single incision. The interosseous compartments are released with incisions over the index and ring MC shafts. Dissection then continues radial and ulnar to the index and ring finger metacarpal shafts to release all of the interosseous muscle compartments. Any dead muscle is débrided. Incisions are left open and covered with a nonadherent dressing. The wrist and hand are splinted in the protected position as described above in Fractures and Dislocations. The wounds are re-explored in 2 to 3 days to assess for muscle viability. Often, the incisions can be closed primarily, but a skin graft may be needed for the forearm.

If the examiner feels the patient does not have a compartment syndrome, elevation and serial examination are mandatory. When in doubt, it is better to release an early compartment syndrome than wait to release and risk muscle necrosis. Progression of compartment syndrome can lead to Volkmann's ischemic contracture with muscle loss, and scarring that may compress nerves and other critical structures. Medicolegally, it is far easier to defend releasing an early compartment

syndrome than delaying treatment until the process has progressed to necrosis and/or deeper scarring.

COMPLICATIONS

Nonunion

Any fractured bone has the risk of failing to heal. Fortunately, in the fingers and hand, this is a rare problem. Tuft injuries, where soft tissue interposes between the fracture fragments, have a relatively higher risk of this problem. The nonunited tuft can be treated with débridement and bone grafting, or revision amputation, depending on the needs and goals of the patient. Phalangeal and MC nonunions are also quite rare. They can similarly be treated with débridement of the nonunion, grafting, and rigid fixation.²⁴ More proximally, the scaphoid bone of the wrist has a significant risk of nonunion even if nondisplaced (see Fig. 44-9A). Any patient suspected of a scaphoid injury, namely those with tenderness at the anatomic snuffbox, should be placed in a thumb spica splint and re-evaluated within 2 weeks, even if initial x-rays show no fracture. Scaphoid nonunions can be quite challenging to repair,²⁵ and immobilization at the time of injury in a thumb spica splint is essentially always warranted.

Stiffness

The desired outcome of any hand injury is a painless, mobile, functional hand. Multiple factors can contribute to decreased mobility: complex injuries of soft tissue and bone, noncompliance of the patient with postoperative therapy, and inappropriate splinting. The surgeon performing the initial evaluation can greatly impact this last factor. Again, the goal of splinting is to keep the collateral ligaments on tension (MPs at 90°, IP joints straight). For severe cases of stiffness, mobilization surgeries such as tenolyses and capsulotomies²⁶ can be performed, but these rarely produce normal ROM. Prevention of joint contractures with appropriate splinting and early, protected mobilization are the best options to maximize mobility at the end of healing.

Neuroma

Any lacerated nerve will form a neuroma. A neuroma consists of a ball of scar and axon sprouts at the end of the injured nerve.²⁷ In unfavorable circumstances, this neuroma can become quite painful. The SRN is particularly notorious for this problem. By providing proximal axon sprouts a target, nerve repair is an excellent preventive technique. In some circumstances, such as injuries requiring amputation, this is not possible. As mentioned above in Amputations and Replantation, the surgeon should resect the nerve stump as far proximally in the wound as possible to avoid the nerve stump healing in the cutaneous scar to minimize this risk.

For the patient who develops a painful neuroma, nonsurgical treatments are initiated first. The neuroma can be identified by the presence of a Tinel's sign. Therapy techniques of desensitization, ultrasound, and electrical stimulation have all proven useful. Corticosteroid injection to the neuroma also has proven useful in some hands.

When these techniques fail, surgery is contemplated. The neuroma can be resected, but a new one will form to replace it. The nerve ending can be buried in muscle or even bone to prevent the neuroma from residing in a superficial location where it may be impacted frequently.

Regional Pain Syndromes

Injuries to the upper extremity can occasionally result in the patient experiencing pain beyond the area of initial injury.

Reflex sympathetic dystrophy and *sympathetic mediated pain* are two terms that have been used in the past to describe this phenomenon. Both are inaccurate, as the sympathetic nervous system is not always involved. Current terminology for this condition is *complex regional pain syndrome* (CRPS). Type I occurs in the absence of a documented nerve injury; type II occurs in the presence of one.²⁸

CRPSs manifest as pain beyond the area of initial injuries. There is often associated edema and changes in hair and/or sweat distribution. Comparison to the unaffected side is useful to better appreciate these findings. Multiple imaging modalities have been evaluated as potential diagnostic tests for CRPS. At this time, there are no imaging studies that can be considered diagnostic for CRPS.²⁹

For the patient in whom the diagnosis of CRPS is not clear, no definitive diagnostic study exists. Patients suspected of CRPS should be referred for aggressive hand therapy. Brief trials of oral corticosteroids have been successful in some series. Referral to a pain management specialist for a trial of stellate ganglion blocks also is frequently used.

NERVE COMPRESSION

Nerves conduct signals along their axonal membranes toward their end organs. Sensory axons carry signals from distal to proximal; motor axons from proximal to distal. Myelin from Schwann cells allows faster conduction of signals. Signals jump from the start of one Schwann cell to the end of the cell (a location called a *gap junction*) and only require the slower membrane depolarization in these locations.

Nerve compression creates a mechanical disturbance of the nerve.³⁰ In early disease, the conduction signal is slowed across the area of compression. When compression occurs to a sufficient degree for a sufficient time, individual axons may die off. On a nerve conduction study, this manifests as a decrease in amplitude. Muscles receiving motor axons may show electrical disturbance on electromyogram when sufficiently deprived of their axonal input.

Compression of sensory nerves typically produces a combination of numbness, paresthesias (pins and needles), and pain. Knowledge of the anatomic distribution of the peripheral nerves can aid in diagnosis. Sensory disturbance outside an area of distribution of a particular nerve (e.g., volar and dorsal radial-sided hand numbness for median nerve) makes compression of that nerve less likely. Diseases that cause systemic neuropathy (e.g., diabetes) can make diagnosis more difficult.

Nerve compression can theoretically occur anywhere along a peripheral nerve's course. The most common sites of nerve compression in the upper extremity are median nerve at the carpal tunnel, ulnar nerve at the cubital tunnel, and ulnar nerve at Guyon's canal. Other, less common locations of nerve compression are described as well. In addition, a nerve can become compressed in scar due to a previous trauma.

Carpal Tunnel Syndrome

The most common location of upper extremity nerve compression is the median nerve at the carpal tunnel, CTS. The carpal tunnel is bordered by the scaphoid bone radially, the lunate and capitate bones dorsally, and the hook of the hamate bone ulnarly (see Fig. 44-3). The transverse carpal ligament, also called the *flexor retinaculum*, is its superficial border. The FPL, four FDS, and four FDP tendons pass through the carpal tunnel along with the median nerve. Of these 10 structures, the median nerve is relatively superficial and radial to the other nine.

An estimated 53 per 10,000 working adults have evidence of CTS. The National Institute for Occupational Safety and Health website asserts "There is strong evidence of a positive association between exposure to a combination of risk factors (e.g., force and repetition, force and posture) and CTS".³¹ There is disagreement among hand surgeons regarding whether

occurrence of CTS in a patient who does repetitive activities at work represents a work-related injury.

Initial evaluation of the patient consists of symptom inventory: location and character of the symptoms, sleep disturbance due to symptoms, history of dropping objects, and difficulty manipulating small objects such as buttons, coins, or jewelry clasps.

Physical examination should begin with inspection. Look for evidence of wasting of the thenar muscles. Tinel's sign should be tested over the median nerve from the volar wrist flexion crease to the proximal palm. Phalen's test (maximal flexion of the wrist for 1 minute) and reverse Phalen's (maximal extension) are tested. Applying pressure over the carpal tunnel while flexing the wrist has been shown in one series to have the highest sensitivity as compared to Phalen's and Tinel's signs.³² Strength of the thumb in opposition also should be tested.

Early treatment of CTS consists of conservative management. The patient is given a splint to keep the wrist at 20° extension worn at nighttime. Many patients can have years of symptom relief with this management. As a treatment and diagnostic modality, corticosteroid injection of the carpal tunnel is often used. Mixing local anesthetic into the solution provides the benefit of early symptom relief (corticosteroids often take 3 to 7 days to provide noticeable benefit), and report of postinjection anesthesia in the median nerve distribution confirms the injection went into the correct location. Multiple authors have shown a strong correlation to relief of symptoms with corticosteroid injection and good response to carpal tunnel release.³³

When lesser measures fail or are no longer effective, carpal tunnel release is indicated. Open carpal tunnel release is a time-tested procedure with documented long-term relief of symptoms. A direct incision is made over the carpal tunnel, typically in line with where the ring finger pad touches the proximal palm in flexion. Skin is divided followed by palmar fascia. The carpal tunnel contents are visualized as they exit the carpal tunnel. The transverse carpal ligament is divided with the median nerve visualized and protected at all times. Skin typically is closed in a single layer, and a volar wrist splint is applied. Improvement in symptoms is typically noted by the first postoperative visit, although symptom relief may be incomplete for patients with long-standing disease or systemic nerve-affecting diseases such as diabetes.

In recent years, endoscopic techniques have been devised to address CTS. All involve avoidance of incising the skin directly over the carpal tunnel. Patients are typically allowed to cautiously move their wrist immediately after surgery. In experienced hands, endoscopic carpal tunnel release provides the same relief of CTS with less intense and shorter lasting postoperative pain. After 3 months, however, the results are equivalent to open release.³⁴ In inexperienced hands, there may be a higher risk of injury to the median nerve with the endoscopic techniques; this procedure is not for the occasional carpal tunnel surgeon.

Cubital Tunnel Syndrome

The second most common location of upper extremity nerve compression is the ulnar nerve where it passes behind the elbow at the cubital tunnel. The cubital tunnel retinaculum passes between the medial epicondyle of the humerus and the olecranon process of the ulna. It stabilizes the ulnar nerve in this location during elbow motion. Over time, or sometimes after trauma, the ulnar nerve can become less stabilized in this area. Motion of the elbow then produces trauma to the nerve as it impacts the retinaculum and medial epicondyle.

Cubital tunnel syndrome may produce sensory and motor symptoms.³⁵ The small finger and ulnar half of the ring fingers may have numbness, paresthesias, and/or pain. Unlike the median nerve, volar and dorsal symptoms in these digits are

explained by ulnar neuropathy at the elbow. The patient also may report weakness in grip due to effects on the FDP tendons to the ring and small fingers and the intrinsic hand muscles. Patients with advanced disease may complain of inability to fully extend the ring and small finger IPs.

Physical examination for cubital tunnel syndrome begins with inspection. Look for wasting in the hypothenar eminence and the interdigital web spaces. When the hand rests flat on the table, the small finger may rest in abduction with respect to the other fingers; this is called *Wartenberg's sign*. Tinel's sign often is present at the cubital tunnel. Elbow flexion test (holding the elbow maximally flexed for 1 minute) often will be positive. Grip strength and finger abduction strength should be compared to the unaffected side. Froment's paper sign can be tested by placing a sheet of paper between the thumb and index finger and instructing the patient to hold on to the paper while the examiner pulls it away without flexing the finger or thumb (this tests the strength of the adductor pollicis and first dorsal interosseous muscles). If the patient must flex the index finger and/or thumb (FDP-index and FPL, both median nerve supplied) to maintain traction on the paper, this is a positive response.

Early treatment of cubital tunnel syndrome begins with avoiding maximal flexion of the elbow. Splints often are used for this purpose. Corticosteroid injection rarely is done for this condition; unlike in the carpal tunnel, there is very little space within the tunnel outside of the nerve. Injection in this area runs a risk of intraneural injection that can cause permanent scarring of the nerve and dysfunction.

When conservative management fails, surgery has been contemplated. Simple release of the cubital tunnel retinaculum, with or without removal of the medial epicondyle, is reported, but is less commonly done. Most commonly, surgery for ulnar nerve compression at the elbow involves transposition of the nerve anterior to the elbow. For heavier patients with lower demand arms, the nerve often is kept in the subcutaneous plane. Great care must be taken to avoid creating a new constriction point with any fascial sling used to keep the nerve anterior. For thinner patients and/or those with higher demand arms, the nerve usually is placed in a pocket within the flexor-pronator muscle mass. The superficial fascia is incised in a stair step fashion. Dissection then proceeds into the muscle mass. All septae within the muscle are incised or excised as appropriate. The nerve is then transposed into the muscle pocket. The fascia is then closed in a z-lengthened fashion to prevent compression on the nerve. The wound is closed in layers, and the arm is splinted with the elbow flexed at 90°. Some surgeons splint the wrist and fingers as well. Therapy, with an initial emphasis on recovering ROM, usually is begun within the first week after surgery.

Other Sites of Nerve Compression

All nerves crossing the forearm have areas described where compression can occur.³⁵ The median nerve can be compressed as it passes under the pronator teres. The anterior interosseous branch of the median nerve can be compressed more distally with isolated motor (no sensory) deficits. The ulnar nerve can be compressed as it passes through Guyon's canal. The radial nerve, or its posterior interosseous branch, can be compressed as it passes through the radial tunnel (distal to the elbow where the nerve divides and passes under the arch of the supinator muscle). The SRN can be compressed distally in the forearm as it emerges from under the brachioradialis tendon, called *Wartenberg's syndrome*. As mentioned at the beginning of the Nerve Compression section, any nerve can become compressed in scar at the site of a previous trauma.

DEGENERATIVE JOINT DISEASE

As with other joints on the body, the joints of the hand and wrist can develop degenerative changes. Symptoms typically begin in the fifth decade of life. Symptoms consist of joint pain and stiffness, and often are exacerbated with changes in the weather. Any of the joints can become involved. As the articular cartilage wears out, pain typically increases and ROM

decreases. The patient should always be asked to what degree symptoms are impeding activities.

Physical findings are documented in serial fashion from the initial visit and subsequent visits. Pain with axial loading of the joint may be present. Decreased ROM may be a late finding. Instability of the collateral ligaments of the joint typically is not found in the absence of inflammatory arthritis.

Plain x-rays are typically sufficient to demonstrate arthritis. Initially, the affected joint has a narrower radiolucent space between the bones. As joint degeneration progresses, the joint space further collapses. Bone spurs, loose bodies, and cystic changes in the bone adjacent to the joint all may become apparent. X-ray findings do not always correlate with patient symptoms. Patients with advanced x-ray findings may have minimal symptoms, and vice versa. Treatment is initiated and progressed based on the patient's symptoms, regardless of imaging findings.

Initial management begins with rest of the painful joint. Splints often are useful but may significantly impair the patient in activities and thus are frequently used at nighttime only. Oral NSAID medications such as ibuprofen and naproxen also are useful. Patients on blood thinners may not be able to take these, and some patients simply do not tolerate the gastric irritation side effect even if they take the medication with food.

For patients with localized disease affecting only one or a few joints, corticosteroid injection may be contemplated. Needle insertion can be difficult because these joint spaces are quite narrow even before degenerative disease sets in. Also, corticosteroid injections are suspensions, not solutions; injected corticosteroid will remain in the joint space and can be seen as a white paste if surgery is performed on a joint that has been previously injected. For this reason, it is unwise to ever inject any joint more than two to three times.

Small Joints (Metacarpophalangeal and Interphalangeal)

When conservative measures fail, two principal surgical options exist: arthrodesis and arthroplasty. The surgeon and patient must decide together as to whether conservative measures have failed. Surgery for arthritis, whether arthrodesis or arthroplasty, is performed for the purpose of relieving pain. Arthrodesis, fusion of a joint, provides excellent relief of pain and is durable over time. However, it comes at the price of total loss of motion.

Silicone implant arthroplasty has been available for over 40 years.³⁶ Rather than a true replacement of the joint, the silicone implant acts as a spacer between the two bones adjacent to the joint. This allows for motion without bony contact that would produce pain. Long-term studies have shown that all implants fracture over time, but usually continue to preserve motion and pain relief.³⁷

In the past 10 years, resurfacing implant arthroplasties have become available for the small joints of the hand. Metals, ceramics, and pyrolytic carbon compounds have all been used to fabricate such implants. These are designed to behave as true joint resurfacers (as knee and hip arthroplasty implants are), and have shown good outcomes in short- and intermediate-term studies.³⁷ Neither the silicone nor the resurfacing arthroplasties preserve (or restore) full motion of the MP or PIP joints. This must be considered before any implant arthroplasty.

Wrist

The CMC joint of the thumb, also called the *basilar joint*, is another common location of arthritis pain. Pain in this joint is particularly disturbing of function as the CMC joint is essential for opposition and cylindrical grasp. Patients will typically complain of pain with opening a tight jar or doorknob, and strong pinch activities such as knitting. Conservative management is used first, as described at the beginning of the Degenerative Joint Disease section. Prefabricated, removable thumb spica

splinting can provide excellent relief of symptoms for many patients.

Multiple surgical options exist for thumb CMC arthritis. Many resurfacing implants have been used in the past; often, they have shown good short- and intermediate-term results and poor long-term results. Resection of the arthritic trapezium provides excellent relief of pain; however, most authors feel that stabilization of the thumb MC base is necessary to prevent shortening and instability.³⁸ Recently, one author has demonstrated excellent long-term results from resection of the trapezium without permanent stabilization of the MC base.³⁹ For both of these operations, the thumb base may not be sufficiently stable to withstand heavy labor. For these patients, fusion of the thumb CMC in opposition provides excellent pain relief and durability. The patient must be warned preoperatively that he will not be able to lay his hand flat after the surgery. This loss of motion can be problematic when the patient attempts to tuck in clothing or reach into a narrow space.

Degenerative change of the radiocarpal and midcarpal joints is often a consequence of scapholunate ligament injury. Often, the initial injury goes untreated, with the patient believing it is merely a "sprain;" the patient is first diagnosed with the initial injury when he presents years later with degenerative changes.

Degenerative wrist changes associated with the scapholunate ligament follow a predictable pattern over many years, called *scapholunate advanced collapse* or *SLAC wrist*.⁴⁰ Because of this slow progression, patients usually can be treated with a motion-sparing procedure (Fig. 44-18A). If there is truly no arthritic change present, the scapholunate ligament can be reconstructed.

Arthritis of the hand and wrist. **A.** This patient injured her scapholunate ligament years before presentation. The scapholunate interval is widened (*double arrow*), and the radioscaphoid joint is degenerated (*solid oval*), but the radiolunate and lunocapitate joint spaces are well preserved (*dashed ovals*). **B.** This patient has had rheumatoid arthritis for decades. The classic volar subluxation of the metacarpophalangeal joints of the fingers (*dashed oval*) and radial deviation of the fingers are apparent.

If arthritis is limited to the radiocarpal joint, two motion-sparing options are available. The proximal carpal row (scaphoid, lunate, and triquetrum) can be removed (proximal row carpectomy). The lunate facet of the radius then articulates with the base of the capitate, whose articular surface is similar in shape to that of the base of the lunate. Most series show maintenance of about 66% of wrist motion and 66% of hand strength or more, as compared to the opposite side.⁴¹ Alternatively, the scaphoid can be excised and four-bone fusion (lunate, capitate, hamate, triquetrum) can be performed. This maintains the full length of the hand and the lunate in the lunate facet of the radius. Some series have shown better strength but less mobility with this technique; others have shown equivalent results to the proximal row carpectomy.⁴² The four-bone fusion does appear to be more durable for younger patients and/or those who perform heavy labor.

If the patient presents with pancarpal arthritis, or motion-sparing measures have failed to alleviate pain, total wrist fusion is the final surgical option. The distal radius is fused through the proximal and distal carpal rows to the third MC, typically with a dorsal plate and screws. Multiple, long-term studies have shown excellent pain relief and durability; this comes at the exchange of total loss of wrist motion. This is surprisingly well tolerated in most patients, especially if the other hand/wrist is unaffected. The only activity of daily life that cannot be done with a fused wrist is personal toileting.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an inflammatory arthritis that can affect any joint in the body. Inflamed synovium causes articular cartilage breakdown with pain and decreased ROM. The goals of hand surgery for the RA patient are relief of pain, improvement of function, slowing progression of disease, and improvement in appearance.⁴³ In addition, swelling of the joint due to the inflammation can cause laxity and even failure of the collateral ligaments supporting the joints. Recent advances in the medical care of RA have made the need for surgical care of these patients far less common than in previous decades.

MP joints of the fingers are commonly affected. The base of the proximal phalanx progressively subluxates and eventually dislocates volarly with respect to the MC head. The collateral ligaments, particularly on the radial side, stretch out and cause the ulnar deviation of the fingers characteristic of the rheumatoid hand. Early in the disease, synovectomy with extensor centralization can be attempted. In more advanced cases, the joint may not be salvageable (see Fig. 44-18B). For these patients, implant arthroplasty is the mainstay of surgical treatment. Silicone implants have been used for >40 years with good results.⁴⁴ The silicone implant acts as a spacer between proximal and distal bone, rather than as a true resurfacing arthroplasty. The radial collateral ligament must be repaired to appropriate length to correct the preoperative ulnar deviation of the MP joint. Extensor tendon centralization is then performed, as needed, at the end of the procedure.

For MP joint and PIP joint disease, fusion is an option. However, because RA usually affects multiple joints, fusion is typically avoided due to impaired function of adjacent joints, which would leave a severe motion deficit to the finger.

Failure of the support ligaments of the distal radio-ulnar joint (DRUJ) leads to the *caput ulnae* posture of the wrist with the ulnar head prominent dorsally. As this dorsal prominence becomes more advanced, the ulna head, denuded of its cartilage to act as a buffer, erodes into the overlying extensor tendons. Extensor tenosynovitis, followed ultimately by tendon rupture, begins ulnarly and proceeds radially. Rupture of the ECU tendon may go unnoticed due to the intact ECRL and ECRB tendons to extend the wrist. EDQ rupture may go unnoticed if a sufficiently robust EDC tendon to the small finger exists. Once the fourth compartment (EDC) tendons begin to fail, the motion deficit is unable to be ignored by the patient.

Surgical solutions must address the tendon ruptures as well as the DRUJ synovitis and instability and ulna head breakdown that led to them.⁴³ Excision of the ulna head removes the bony prominence. The DRUJ synovitis also must be resected. Finally, the remaining distal ulna must be stabilized. Multiple techniques have been described using portions of FCU, ECU, wrist capsule, and combinations thereof.

The ruptured extensor tendons typically are degenerated over a significant length. Primary repair is almost never possible, and the frequent occurrence of multiple tendon ruptures makes repair with graft less desirable due to the need for multiple graft donors. Feldon and colleagues⁴³ recommend the following for increasing numbers of extensor tendon ruptures: for a single finger tendon rupture (most commonly to the small finger), EIP transfer; for two fingers (ring and small fingers), EIP transfer to the small finger and end-to-side repair of the ring finger to the intact middle finger extensor; for three fingers, EIP transfer to ring and small with middle finger end-to-side to the index or FDS (middle or ring finger) transfer to ring and small (if EIP unavailable) and middle finger end-to-side to the index; for rupture of all four finger extensors, FDS (ring) is transferred to the ring and small extensors and FDS (middle) is transferred to the index and middle extensors.

Strict compliance with postoperative therapy is essential to maximizing the surgical result. Due to the chronic inflammation associated with RA, tendon and ligament repairs will be slower to achieve maximal tensile strength. Prolonged nighttime splinting, usually for months, helps prevent recurrence of extensor lag. Finally, the disease may progress over time. Reconstructions that were initially adequate may stretch out or fail over time.

DUPUYTREN'S CONTRACTURE

In 1614, a Swiss surgeon named Felix Plater first described contracture of multiple fingers due to palpable, cord-like structures on the volar surface of the hand and fingers. The disease state he described would ultimately come to be known as *Dupuytren's contracture*. Dupuytren's name came to be associated with the disease after he performed an open fasciotomy of a contracted cord before a class of medical students in 1831.⁴⁵

The palmar fascia consists of collagen bundles in the palm and fingers. These are primarily longitudinally oriented, and reside as a layer between the overlying skin and the underlying tendons and neurovascular structures. There are also connections from this layer to the deep structures below and the skin above. Much is known about the progression of these structures from their normal state (called bands) to their contracted state, but little is known about how or why this process begins.

The Dupuytren's nodule represents the basic unit of disease.⁴⁶ Increased collagen deposition leads to a palpable nodule in the palm. Over time, there is increased deposition distally into the fingers. This collagen becomes organized and linearly oriented. These collagen bundles, with the aid of myofibroblasts, contract down to form the cords that are the hallmark of the symptomatic patient. Detail of the molecular and cellular biology of Dupuytren's disease is beyond the scope of this chapter, but is available in multiple hand surgery texts.⁴⁷

Most nonoperative management techniques will not delay the progression of disease. Corticosteroid injections may soften nodules and decrease discomfort associated with them, but are ineffective against cords. Splinting similarly has been shown not to retard disease progression. Injectable clostridial collagenase has shown promise in clinical trials⁴⁸ but has not yet been reported in large or long-term series. It also is not yet commercially available.

For patients with advanced disease, including contractures of the digits that limit function, surgery is the mainstay of therapy. Although rate of progression should weigh heavily in the decision of whether or not to perform surgery, general guidelines are MP contracture of 30° or more and/or PIP contracture of 20° or more.⁴⁹

Surgery consists of an open approach through the skin down to the involved cords. Skin is elevated off the underlying cords. Great care must be taken to preserve as much as possible of the subdermal vascular plexus with the elevated skin flaps to minimize postoperative skin necrosis. All nerves, tendons, and blood vessels in the operative field should be identified. Once this is done, the involved cord is resected while keeping the critical deeper structures under direct vision. Skin is then closed, with local flap transpositions as needed, to allow for full extension of the fingers that have been released (Fig. 44-19).

Dupuytren's disease. **A.** This patient has cords affecting the thumb, middle, ring, and small fingers. **B.** The resected specimens are shown. **C.** Postoperatively, the patient went on to heal all his incisions and, with the aid of weeks of hand therapy, recovered full motion.

Dermatofasciectomy is an alternative to simple fasciectomy as described in the preceding paragraph. In dermatofasciectomy, overlying skin is resected along with the Dupuytren's cord. The wound is then typically closed with a skin graft.

Dermatofasciectomy should only be performed if the skin cannot be separated from the underlying cords. Skin grafting should only be performed if the remaining skin after resection cannot be rearranged with local flaps to cover the wounds without the need for skin grafting.

In the past, some authors have advocated total fasciectomy of the hand with the idea that recurrence/extension of disease could be prevented. Unfortunately, recurrences still occurred in these patients, and revision surgery became much more difficult.

Complications of surgical treatment of Dupuytren's disease occur as often as 17%.⁵⁰ Problems include: digital nerve laceration, digital artery laceration, buttonholing of the skin, hematoma, swelling, and pain including some patients with CRPS (see above section on Regional Pain Syndromes). Digital nerve injury can be quite devastating, producing annoying numbness at best or a painful neuroma in worse situations. Although the surgeon goes into the operation knowing that he/she must identify the nerves and other critical structures, a fascial cord can be mistaken for a nerve and vice versa. It is best to identify the nerve proximal to the area involved with Dupuytren's disease and track it distally into the affected area.

The hand is splinted in full extension at the end of surgery. Hand therapy typically is instituted within 1 week of surgery to

begin mobilization of the fingers and edema control. The therapist also can identify any early wound problems as he/she will see the patient more frequently than the surgeon. Extension hand splinting is maintained for 4 to 6 weeks with nighttime splinting continued for an additional 6 to 8 weeks. After this point, the patient is serially followed for evidence of recurrence or extension of disease.

TENDONITIS/TENOSYNOVITIS

Trigger Finger

Stenosing tenosynovitis of the flexor tendon sheath, also known as *trigger finger* (TF), is one of the most common upper limb problems to be encountered in hand surgery practice. The condition starts with discomfort in the palm during movements of the involved digits. Gradually, the flexor tendon causes painful popping or snapping as the patient flexes and extends the digit. The patient often will present with a digit locked in a flexed position, which may require gentle passive manipulation to regain full extension.

The phenomenon is due to a difference in size of the affected flexor tendon and the retinacular pulley. The mismatch is due to formation of a nodule in the FDS tendon, where it passes under the A1 pulley in the region of the MC head (see Fig. 44-4). In rare instances, a nodule distal to it in the tendon of the FDP also can be responsible.

The most common etiology of TF is idiopathic formation of a nodule on the flexor tendon that obstructs gliding underneath the A1 pulley. The differential diagnosis includes localized swelling due to a partially lacerated flexor tendon catching against the A1 pulley, a nodule in the FDS that catches against the A3 pulley, locking caused by abnormal MC head shape preventing normal collateral ligament motion (staghorn lesion), foreign body in the MP joint, ganglion cyst of the tendon sheath, and sagittal band rupture causing the EDC to subluxate off the MC head and snap back in extension.

Several studies demonstrate a correlation between TF and activities that require exertion of pressure in the palm while performing powerful grip or repetitive forceful digital flexion. Proximal phalangeal flexion in power-grip activities causes high loads at the distal edge of the A1 pulley.⁵¹ Some have suggested that bunching of the interwoven flexor tendon fibers causes the reactive intratendinous nodule observed at surgery.⁵²

Stenosing tenosynovitis is much more common in women than men.⁵¹ In several series, peak incidence of trigger digit occurred in the fifth to sixth decades of life. The dominant hand is more affected, and involvement of several fingers is not unusual. The most commonly affected digit is the thumb, followed by the ring, long, small, and index fingers.⁵³

Signs and symptoms include palpable popping, clicking or snapping sensation over the A1 pulley, locking in flexion (in later stages, passive manipulation is needed to extend the digit), stiffness of the digit, tenderness over the A1 pulley, flexion deformity or joint contracture in late presentations, especially the PIP joint.

The goal of treatment for trigger digits is to eliminate the locking and allow full movement of the finger or thumb without discomfort. Swelling around the flexor tendon and tendon sheath must be reduced to allow smooth gliding of the tendon.

Nonoperative treatment includes limiting the activities that aggravate the condition. Splinting and/or oral anti-inflammatory medication may help. If symptoms continue, a corticosteroid injection into the tendon sheath at the pulley is often effective in relieving the trigger digit. The authors prefer triamcinolone acetonide (40 mg/mL) mixed with 0.5% plain bupivacaine. The needle is inserted at the MC head, advanced until bone is encountered, and then withdrawn approximately 0.5 mm until resistance gives way, allowing the medication to be injected. Approximately 1 mL is deposited in the tendon sheath. The needle is withdrawn and pressure is applied. Fingers with irreducible flexion contractures should be treated with surgery, not

steroid injection.

Several studies advocate the use of percutaneous trigger release, in which the bevel of a needle is used to section the A1 pulley in an office procedure. This technique has been reported to be a safe alternative to open techniques.⁵⁴ Gilberts and associates compared the results from open vs. percutaneous technique and found similar efficacy but quicker recovery in the percutaneous group.⁵⁵ No serious complications have been reported with this technique, although there is a risk of incomplete pulley release, especially in severe cases. The use of this technique is not recommended in the thumb.

If nonsurgical forms of treatment do not relieve the symptoms, surgery is indicated. This surgery is performed as an outpatient, usually with simple local anesthesia. The goal of surgery is to divide the A1 pulley at the base of the finger so that the tendon can glide more freely. A 10- to 15-mm incision is made over the affected MC head. Blunt dissection is used to spread the subcutaneous tissue and palmar fascia to expose the flexor tendon and sheath. The A1 pulley is identified and sharply transected longitudinally. Care should be taken to identify the demarcation between the A1 and A2 pulleys so that the A2 pulley is not violated. At completion, the finger is ranged to ensure that there is no residual triggering. Gentle traction on the flexor tendons also confirms that the A1 pulley has been completely released. Occasionally, a reduction tenoplasty may need to be performed if a large nodule is present (e.g., in RA). The skin incision is closed and a soft dressing is applied.

Active motion of the finger generally begins immediately after surgery. Normal use of the hand usually can be resumed once comfort and pain control permits. Occasionally, hand therapy is required after surgery to regain better use.

Nonoperative management is felt to be very safe without the risk of major complications. With the open technique, prolonged tenderness over the incision may occur. Infrequent complications include nerve injury, recurrence, and bowstringing of the flexor tendons due to sectioning of the A2 pulley.

De Quervain's Tenosynovitis

De Quervain's disease, described in 1895 by Swiss surgeon Fritz de Quervain, is a stenosing tenosynovitis that causes tendon entrapment of the first dorsal compartment of the wrist. It is a common cause of wrist and hand pain, particular during thumb motion.

The tendons of APL and EPB muscles pass through the first dorsal compartment. These tendons are secured tightly against the radial styloid by the extensor retinaculum. Frequent abduction of the thumb with ulnar deviation of the wrist is thought to create tension and eventual friction along the tendon sheath surrounding the APL and EPB. This friction leads to irritation and swelling of the sheath as well as thickening of the tendon that resists gliding.

The differential diagnosis includes: ganglion of the extensor retinaculum, osteoarthritis of thumb CMC joint, degenerative arthritis at the radioscaphoid joint, CTS, SRN neuropathy at the wrist, scaphoid fracture, and intersection syndrome (see the Intersection Syndrome section).

The average age of presentation is in the fifth and sixth decades, and the condition has been reported to be up to six times more common in women than men.⁵¹ The disease also seems to affect pregnant or recently postpartum women and is thought to be due to repetitive lifting of infants. The wrist is usually affected bilaterally.⁵⁶ De Quervain's also is seen in association with inflammatory conditions such as rheumatoid disease.

Patients usually present with complaints of pain, several weeks to months in duration, along the radial aspect of the wrist aggravated by thumb motion. The most common symptoms are pain when grasping or pinching and tenderness at the first dorsal compartment, where the abductor policis longus and extensor policis brevis pass over the wrist joint (see Fig. 44-3).

In some patients, a lump or thickened mass can be felt in the area 1 to 2 cm proximal to the radial styloid. Severe, sharp pain can be elicited by having the patient flex the thumb across the palm, make a fist, and then ulnarly deviate the wrist (Finkelstein's test) (Fig. 44-20).⁵⁷ There should be no tenderness in the forearm proximal to the first dorsal compartment. Axial loading of the thumb should not elicit tenderness and pain, unless there is concomitant CMC joint arthritis.

Fig. 44-20.

Source: Brunnicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Finkelstein's test. The patient places the thumb in the palm and makes a loose fist. The examiner then ulnarly deviates the patient's wrist (as indicated by the *arrow*). Pain at the first dorsal compartment with this maneuver is a positive response.

If treated early, some cases improve with short periods of rest in a thumb spica splint, followed by stretching exercises designed to improve tendon gliding. The patient should also modify activity to avoid motions that trigger symptoms. Compliance with splinting can be an issue; symptoms tend to recur after the splint is removed and the causative activities are resumed. Oral NSAID medications are of some benefit.

If splinting and NSAIDs fail, corticosteroid injection is the next line of treatment. The technique is similar to that used in TF. Injection into the tendon sheath of the first dorsal compartment has been shown to reduce tendon thickening and inflammation.⁵⁸ Corticosteroid injection has been reported to be effective in 50 to 80% of patients after one to two injections.⁵¹

With corticosteroid injections, possible complications of note include: transient anesthesia of the SRN at the first web space of the dorsal hand, direct injection injury to the radial nerve causing persistent pain (cheiralgia paresthetica), skin hypopigmentation in dark-skinned individuals, subcutaneous tissue atrophy, tendon weakening, and rupture (rare).

More severe cases or those that do not respond to conservative treatment may require surgery to release the first dorsal compartment. In this procedure, a transverse incision is made over the first dorsal compartment approximately 1 cm proximal to the radial styloid. Longitudinal blunt dissection is used to expose the roof of the first dorsal compartment. Sharp

or transverse dissection in this area increases the likelihood of injury to the SRN, which runs superficial to the ligament. The ligament covering the compartment is then sharply opened longitudinally along its dorsal margin. Attention must be paid to the variant anatomy in this region.⁵⁹ Frequently, there is a septum between the EPB and APL tendons;⁶⁰ if this septum is identified, it must also be released, or symptoms will not be relieved. The skin incision is closed and a soft dressing is applied.

Although the surgical management of de Quervain's tenosynovitis is straightforward, complications can be bothersome. Persistent symptoms from an incompletely released first dorsal compartment can necessitate surgical re-exploration. Volar or dorsal subluxation of the tendons is possible; if symptomatic, reconstruction of the sheath with a slip of brachioradialis or a strip of adjacent dorsal retinaculum can be performed. Injury to the SRN is a rare, but serious complication. Laceration or retraction injury to the nerve can cause neuritis or a painful neuroma. The complication is avoided by careful blunt dissection and gentle retraction. Controversy still exists regarding the optimal management of an iatrogenic lacerated radial sensory nerve.

Intersection Syndrome

Intersection syndrome is tenosynovitis in which the tendons in the second dorsal compartment, radial wrist extensors ECRL and ECRB, cross over the tendons of the first dorsal compartment, EPB and APL. Intersection syndrome is characterized by pain in the distal dorsoradial forearm due to irritation of the affected tendons. The pain is proximal and ulnar to that of de Quervain's tenosynovitis and may be associated with localized swelling.⁶¹

Although this condition occurs at the intersection of the tendons of the first and second extensor compartments (proximal to the extensor retinaculum), many contend that the condition is a tenosynovitis of the ECRL and ECRB tendons. Intersection syndrome also can be caused by direct trauma to the second dorsal compartment. The differential diagnosis includes de Quervain's tenosynovitis, thumb CMC arthritis, radial sensory nerve irritation (Wartenberg's syndrome), and EPL tendonitis.

Intersection syndrome is thought to be associated with activities that require repetitive wrist flexion and extension.

Weightlifters, rowers, and other athletes are particularly prone to this condition.

Patients with intersection syndrome complain of dorsal radial wrist or forearm pain. Symptoms are exacerbated by repetitive wrist flexion and extension associated with thumb motion. On examination, a focal swelling at the area of intersection often is present. Active or passive wrist motion may produce a characteristic crepitus in severe cases.

Conservative treatment includes immobilization, activity modification, and pharmacologic intervention. A thumb spica splint effectively immobilizes the wrist extensors and thumb extensors. Several weeks of immobilization, followed by gradual splint weaning, usually is recommended. Activity modification at home and/or work also is critical. NSAIDs help alleviate pain and inflammation.

In recalcitrant cases, a corticosteroid injection into the second dorsal compartment is effective. Once the symptoms are under control, a program of supervised hand therapy leads to long-term recovery.

Surgery can be effective in cases that do not respond to conservative measures. The second extensor compartment is approached through a dorsal longitudinal incision, beginning over the wrist and continuing proximally 3 to 4 cm to the inflamed area.⁶² The dorsal forearm fascia is divided longitudinally. Branches of the radial sensory nerve are identified and protected. The ECRL and ECRB tendons are released by longitudinally incising the extensor retinaculum over the second dorsal compartment. A thorough tenosynovectomy may be performed while elevating and protecting the tendons. The

extensor retinaculum is not repaired. Skin is closed routinely, and the hand is placed in a volar thumb spica splint, maintaining the wrist at 15 to 20° of extension for 1 week. This is followed by early wrist ROM exercises.

No large series documenting treatment outcomes exist in the literature. There are reports that approximately 60% of patients respond to conservative management while 100% of patients who require surgery obtain long-term symptomatic relief.⁶² Release of the second dorsal compartment could theoretically lead to bowstringing of the ECRL and ECRB tendons in extreme wrist extension; however, this complication has not been reported in the literature.

INFECTIONS

The most common cause of hand infections is trauma. Other predisposing conditions include diabetes and neuropathies. Ninety percent of infections are caused by gram-positive organisms *Staphylococcus aureus*, *Streptococcus viridans*, Group A *Streptococcus*, and *S. epidermis*. Infection in the hand, as in most areas of the body, can be localized by five cardinal signs: rubor (redness), calor (heat), tumor (swelling), dolor (pain), and loss of function. Treatment of any hand infection focuses on drainage, antibiotics, splint immobilization, and elevation.⁶³

Cellulitis

Cellulitis of the hand is a nonsuppurative inflammation of the subcutaneous tissues. It is characterized by erythema, swelling, induration and warmth, and pain and tenderness. The most common pathogenic organisms are *Staphylococcus* and *Streptococcus*. Mainstays of treatment are elevation, splint immobilization, and judicious use of antibiotics. By definition, a diagnosis of cellulitis means that no purulence is present. If the patient does not improve within 24 to 48 hours, an abscess must be suspected.

Paronychia

Paronychia is an infection of the nail bed or the periungual soft tissue. It sometimes begins as a hangnail and often presents as a small collection of purulent material at the side of the nail bed. In acute paronychia, the causative organisms are usually *S. aureus* or streptococci, less commonly *Pseudomonas* or *Proteus* species. Organisms enter through a break in the epidermis frequently due to nail biting or aggressive manicuring. In chronic paronychia, infection (usually *Candida* species) enters via the hand receiving prolonged exposure to a moist environment, such as those used as dishwashers.

Paronychia develops along the nail margin (lateral and proximal nail folds), manifesting over hours to days with pain, warmth, redness, and swelling. Pus usually develops along the nail margin, less commonly beneath the nail. Rarely, infection penetrates deep into the finger and may produce infectious flexor tenosynovitis (FTS).

Early treatment is warm compresses or soaks and an antistaphylococcal antibiotic. First-generation cephalosporins have traditionally been used, but the increasing prevalence of methicillin-resistant *S. aureus*⁶⁴ has led the authors to begin empiric treatment with vancomycin. Fluctuant swelling or visible pus should be drained with a Freer elevator or the bevel of an 18-gauge needle inserted between the nail and nail fold (Fig. 44-21). If the abscess resides under the eponychial fold, then a proximally based flap of eponychium can be reflected up to allow for better drainage. An abscess that extends below the nail necessitates partial removal of the nail plate. A thin gauze wick should be inserted for 24 to 48 hours to maintain patency of the drainage tract.

Paronychia. **A.** Fluctuance in the nail fold is the hallmark of this infection. **B.** Technique of drainage between the nail plate and nail fold.

Felon

A felon is a closed-space, purulent infection of the fingertip pulp. It is usually extremely painful, and if left untreated, can lead to ischemia and necrosis. The thumb and index finger are the most commonly affected digits.

The fingertip pulp is divided into numerous small compartments by vertical septa that connect the distal phalanx bone to the overlying skin. Infection in these compartments can lead to abscess formation, tremendous edema, and rapid development of increased pressure in a closed space. The increased pressure may compromise blood flow and lead to necrosis of the skin and pulp.

Wooden splinters or minor cuts are common predisposing causes; however, in half of patients, the condition is idiopathic.

Initial minor injury causes inflammation, which is first confined by the tough fibrous septa within the pulp. Early infection causes pain and tenderness. At this stage, infection may resolve spontaneously with antibiotics. If resolution does not occur, increasing swelling and throbbing pain herald abscess formation.

Felons are characterized by marked throbbing pain, tension, and edema of the fingertip pulp. *S. aureus* is the most common causative organism. More and more community-acquired methicillin-resistant *S. aureus* infections are being reported. Gram-negative organisms have been reported in immunosuppressed patients and diabetics. Fingertip blood glucose measurements have been implicated as an etiology. *Eikenella corrodens* infections have been reported in persons with diabetes who bite their fingernails.⁶³

Adequate early treatment can prevent abscess formation. Tetanus should be updated. Antibiotics with activity against staphylococcal and streptococcal organisms should be administered. In cases where significant tension is present, the fingertip must be decompressed to preserve venous flow, whether or not a frank abscess has formed. The drained fluid should be sent for culture.

The procedure to drain a felon is straightforward (Fig. 44-22). A digital block is performed. This is followed by a short skin incision. Only the skin is incised. Pus is evacuated using a blunt instrument to decrease the chance of severing a digital nerve or entering the tendon sheath. Gauze is loosely packed into the wound to prevent skin closure. A loose dressing and finger splint is applied. The hand is elevated and splinted.

Fig. 44-22.

A and **B**. The area of purulence in a felon is located in the pad of the distal phalanx as shown. **B**. A longitudinally oriented incision is made over the area of maximal fluctuance; this incision should not cross the distal interphalangeal joint crease. See text for additional details.

There is some debate regarding the choice of incision. A longitudinal incision over the area of maximal fluctuance (see Fig. 44-22) is effective and avoids the serious iatrogenic complications associated with other described incisions such as a transverse incision or an incision on the lateral aspect of the finger. The incision should not cross the DIP flexion crease to prevent formation of a flexion contracture. Probing is not carried out proximally to avoid extension of infection into the flexor tendon sheath. Lateral incisions, volar transverse incisions, and hockey stick and fish-mouth incisions have been suggested; however, these incisions offer no benefit and increase the potential for serious injury. In particular, the traditional lateral incision can cause ischemia and anesthesia by injuring one or both neurovascular bundles. The fish-mouth incision can lead to an unstable painful fingertip.

Untreated or incompletely treated infections can lead to osteomyelitis, tenosynovitis, and septic arthritis.

Bites

Human bites to the hand may lead to serious infections from any of the numerous organisms found in the oral cavity. Inoculation typically occurs during an altercation in which the skin and tendons over the MP and/or PIP joints are abraded and lacerated from an opponent's tooth. The initial clinical appearance of these "fight bites" often is deceptively benign, leading to delays in seeking care and more severe infection on presentation.

Human bites require aggressive evaluation and treatment. It is important to understand the mechanism of injury: the skin and joint capsule are trapped between a tooth and underlying bone. A 3-mm penetration can inoculate a joint in the hand.

Treatment of these penetrating injuries includes irrigation and débridement of any purulence or devitalized structure(s). The hand should be immobilized and elevated. The patient should be placed on broad-spectrum antibiotics to cover *Staphylococcus*, *Streptococcus*, and anaerobic bacteria, such as amoxicillin/clavulanic (again recent trends in sensitivities have made penicillins less effective against *Staphylococcus*). *E. corrodens* is an organism commonly isolated from human fight bites. Skin lacerations should be left open to heal secondarily. Dog, cat, and other animal bites are treated similarly.

HERPETIC WHITLOW

Herpetic whitlow is a self-limited herpes simplex virus (HSV) infection of the distal finger. In the United States, HSV infection of the hand occurs in 2.4 cases per 100,000 population per year.⁶⁵ It is the most common viral infection of the hand and infections by HSV1 or HSV2 are clinically indistinguishable. Direct inoculation of the virus into a wound is usually the mechanism of infection. Herpetic whitlow often is found in adult women with genital herpes, children with coexistent herpetic gingivostomatitis, and health care workers exposed to orotracheal secretions.

The infection usually involves a single finger that is painful, erythematous, and swollen. It is characterized by vesicles early in the disease process. After about 2 weeks, the vesicles coalesce, and the infection may be mistaken for a paronychia or felon.

Diagnosis usually is made by a careful history and physical. On examination, tenderness is present but is less severe than that found in bacterial infections. The distinction is very important to make because performing an incision and drainage on a herpetic whitlow can lead to secondary bacterial infection as well as spread of the herpes virus. If the vesicle is unroofed, fluid obtained can be sent for a Tzanck smear and/or viral culture to confirm the diagnosis. Most commonly, however, diagnosis can be made without intervention on the involved digit.

Herpetic whitlow usually resolves spontaneously in 2 to 3 weeks. The main goals of treatment are to prevent both oral inoculation and spread of the infection, as well as to obtain symptomatic relief. The involved digit should be kept covered with a dry dressing. Some authors recommend treatment with oral acyclovir for 10 days if the diagnosis is made early in symptom onset, although acyclovir has not been demonstrated to shorten the course of this self-limited infection. Stronger evidence exists to recommend oral acyclovir for recurrent infections during the prodromal stage, as well as in immunocompromised patients. Infection can recur in 30 to 50% of patients, but the initial infection is typically the most severe.

FLEXOR TENOSYNOVITIS

FTS is a severe pathophysiologic state causing disruption of normal flexor tendon function in the hand. A variety of etiologies are responsible for this process. Most acute cases of FTS are due to purulent infection. FTS also can occur secondary to chronic inflammation as a result of diabetes, RA, crystalline deposition, overuse syndromes, amyloidosis, psoriatic arthritis, systemic lupus erythematosus, and sarcoidosis.

Suppurative FTS has the ability to rapidly destroy a finger's functional capacity and is considered a surgical emergency.

Much of the original work on infectious FTS was done in the early 1900s.⁶⁶ In the 1940s, postoperative sheath irrigation was suggested.⁶⁷ Besser, Carter, Burman, and Nevaizer have described multiple techniques of closed continuous irrigation and/or débridement as early as the 1960s.⁶⁸

Suppurative FTS results from bacteria multiplying in the closed space of the flexor tendon sheath and culture-rich synovial

fluid medium. Natural immune response mechanisms cause swelling and migration of inflammatory cells and mediators. The septic process and this inflammatory reaction within the tendon sheath quickly erode the paratenon, leading to adhesions and scarring. The ultimate consequences are tendon necrosis, disruption of the tendon sheath, and digital contracture.

The primary mechanism of infectious FTS usually is penetrating trauma. Most infections are caused by skin flora, including both *Staphylococcus* and *Streptococcus* species. Bacteria involved vary by etiology of the infection: bite wounds (*Pasteurella multocida*—cat, *E. corrodens*—human); *Bacteroides*, *Fusobacterium*, *Haemophilus* species, gram-negative organisms—diabetic patients; hematogenous spread (*Mycobacterium tuberculosis*, *Neisseria gonorrhea*); water-related punctures (*Vibrio vulnificus*, *M. marinum*). Infection in any of the fingers may spread proximally into the wrist, carpal tunnel, and forearm, also known as *Parona's space*.⁶⁹

With the accumulation of purulence in the flexor tendon sheath, pressure can increase within the closed space and inhibit the inflammatory response. The increased pressure also inhibits blood flow and adds to the destructive process. Tendon ischemia increases the likelihood of tendon necrosis and rupture.

Patients with infectious FTS present with complaints of pain, redness, and fever. Physical examination reveals Kanavel's "cardinal" signs of flexor tendon sheath infection,⁶⁶ which are finger held in slight flexion, fusiform swelling, tenderness along the flexor tendon sheath, and pain over the flexor sheath with passive extension of the digit (Fig. 44-23A).

Suppurative flexor tenosynovitis of the ring finger. **A.** The finger demonstrates fusiform swelling and flexed posture. **B.** Proximal exposure for drainage. **C.** Distal drainage incision.

Kanavel's signs may be absent in patients who are immunocompromised, have early manifestations of infection, have recently received antibiotics, or have a chronic, indolent infection. The differential diagnosis includes inflammatory (nonsuppurative) FTS, herpetic whitlow, pyogenic arthritis, gout, fracture, degenerative arthritis or RA, sesamoiditis, and angioliopoma (found in case reports masquerading as FTS).

If a patient presents with suspected infectious FTS, empiric IV antibiotics should be initiated. Prompt medical therapy in early cases may prevent the need for surgical drainage. For healthy individuals, empiric antibiotic therapy should cover *Staphylococcus* and *Streptococcus*. For immunocompromised patients (including diabetics) or infections associated with bite wounds, empiric treatment should include coverage of gram-negative organisms as well.

Adjuncts to antibiotics include splint immobilization (intrinsic plus position preferred) and elevation until infection is under control. Hand rehabilitation (i.e., ROM exercises and edema control) should be initiated once pain and inflammation are under control.

If medical treatment alone is attempted, then inpatient observation for a minimum of 48 hours is indicated. Surgical intervention is necessary if no obvious improvement has occurred within 12 to 24 hours. In addition, for patients who are immunocompromised or have diabetes, surgery is warranted.

Several surgical approaches can be used to drain infectious FTS. The method used is based upon the extent of the infection. Michon developed a classification scheme⁷⁰ that can be useful in guiding surgical treatment:

Stage I. Findings: Increased fluid in sheath, mainly a serous exudate

Treatment: Catheter irrigation

Stage II. Findings: Purulent fluid, granulomatous synovium

Treatment: Minimal invasive drainage ± indwelling catheter irrigation

Stage III. Findings: Necrosis of the tendon, pulleys, or tendon sheath

Treatment: Extensive open débridement and possible amputation

Current recommendations for stage and I and II infections advocate proximal and distal incisions for adequate drainage and irrigation. A proximal incision is made over the A1 pulley (see Fig. 44-23B). In the digit, either a volar zigzag (Brunner) incision or a midaxial incision may be used distally. This distal incision is made over the region of the A5 pulley (see Fig. 44-23C). A Brunner incision allows better initial exposure but may yield difficulties with tendon coverage if skin necrosis occurs. If used, the midaxial incision should be dorsal to the neurovascular bundle. A 16-gauge catheter or 5F pediatric feeding tube then is inserted into the tendon sheath through the proximal incision. The sheath is copiously irrigated with normal saline. Excessive fluid extravasation into the soft tissue of the digit should be avoided because the resulting increase in tissue pressure can lead to necrosis of the digit. The catheter is removed after irrigation. A small drain is placed in the distal incision, and the wounds are left open. Some surgeons prefer a continuous irrigation technique for a period of 24 to 48 hours. The catheter is sewn in place, and a small drain is placed at the distal incision site. Continuous or intermittent irrigation every 2 to 4 hours with sterile saline can then be performed through the indwelling catheter.

Indications for open tendon sheath débridement include stage III infections, chronic infections, or infections caused by

atypical mycobacteria. To expose the tendon sheath, a Brunner incision or a longitudinal midaxial incision is made along the length of the digit. The thumb and small fingers are approached from the radial side, and the remaining digits are approached from the ulnar side. The incision begins distally at the level of the A5 pulley, or just beyond the distal flexion crease, and is extended proximally to the web space. For extensive infections, the sheath is opened at all of the cruciate pulleys while preserving the A2 and A4 pulleys. The purulent fluid should be sent for aerobic, anaerobic, fungal, acid-fast bacilli, and atypical acid-fast bacilli cultures. In cases of known mycobacterial infection, extensive tenosynovectomy may be necessary. If the small finger or thumb is involved and there is evidence of palmar bursae involvement, an additional incision proximal to the transverse carpal ligament is made to ensure adequate drainage of the radial and ulnar bursae. The sheath is copiously irrigated, and the wounds are left open with drains in place.

After surgery, an intrinsic plus splint is applied, the hand is elevated, and the appropriate empiric antibiotic coverage is instituted while awaiting culture results. The hand is re-examined the following day. Whirlpool therapy and ROM are begun. Drains are removed before discharge from the hospital. The wounds are left open to heal by secondary intention. In severe cases, repeat irrigation and operative débridement may be required.

The length of IV antibiotic treatment is determined by the culture and sensitivity results and specific patient factors. The transition from IV to oral antibiotics should be based not only on the culture results but also on the clinical progress. Oral antibiotics should be continued for 7 to 14 days. Follow-up should continue until the infection has resolved, all wounds are closed, and pain-free full motion has returned.

Patients with infectious FTS that present early and have no comorbidities have a good prognosis. Patients that present with fulminant infection, have chronic infections, or are immunocompromised have increased risks of long-term complications and impairment. The most common complication is finger stiffness secondary to intrasheath adhesions. If loss of functional motion persists, tenolysis is considered 4 months postoperatively. The second major complication is soft tissue necrosis, which is more commonly seen in patients who have diabetes⁷¹ or who present late in the disease process.

Joint Space Infections

The joints of the fingers are easily violated by penetrating trauma. Dorsally, they are only covered by skin and extensor tendon, and laterally, the collateral ligaments lie directly beneath the skin. As a result, sharp objects can readily inoculate the joint with infectious organisms. The common cause of septic arthritis is human or animal bite injuries to the MP joints. Septic arthritis can occur after trauma to the joint with teeth, needles, or thorns, or concomitant with tenosynovitis or osteitis. The symptoms are localized pain, tenderness, and swelling of the joint. Passive movement and axial loading of the joint are very painful. In the early stage, x-rays may demonstrate a slightly widened joint space. Joint destruction may be detected several weeks later. In these cases, osteomyelitis is most likely present. Early surgical treatment is most important to drain the infection and prevent the sequelae of septic arthritis.

Treatment of septic arthritis depends on which joint is involved. For the IP joints, the surgeon incises dorsally and opens the joint just lateral to the terminal extensor tendon (DIP joints) or between the central slip and a lateral band (PIP joints). The joint is irrigated and the skin is left open. For the MP joints, a dorsal incision is made. The extensor tendon is split longitudinally. The joint capsule is incised and partially resected, and the joint irrigated thoroughly. The capsule and skin are left open, but the extensor tendon is closed with a running, locking, absorbable suture. Even in patients treated early, arthritis and fibrous ankylosis cannot always be avoided.

In patients suspected of pyogenic wrist arthritis vs. crystalline arthropathy, arthrocentesis can be attempted before

considering surgical intervention. Lister's tubercle (the bony prominence on the dorsal distal radius that serves as a pulley for the EPL) is palpated. An 18-gauge needle is inserted approximately 1 cm distal to this, angled 10° proximal (rather than true perpendicular) to the skin. Aspirated fluid should be sent for Gram's stain, crystal analysis, and culture. If a "dry tap" yields no fluid, 3 mL of sterile saline should be instilled and then aspirated, and sent for the same studies.

If Gram's stain or culture comes back positive, or the patient's clinical course is compelling for intervention, surgical drainage of the wrist is performed. A longitudinal incision is made between the tendons of the third (EPL) and fourth (EDC and EIP) compartments. The wrist capsule is opened at the scapholunate interval over the radiocarpal joint. Great care is taken to avoid injuring the ligament connecting the scaphoid and lunate bones. A Penrose drain is placed and the skin is left open. The wrist is splinted and the hand elevated. Whirlpool and ROM therapy are begun on postoperative day 1.

Web Space Infections

The second, third, and fourth web spaces are potential sites for infection. Within the web lies a fascial support structure called the *natatory ligament*. This can become contracted in Dupuytren's disease, but in the case of a web space infection, it serves as a partial separation between the volar and dorsal web space. Infection typically occurs as dorsal and volar pus pockets with a narrow connection through the natatory ligament, thus the term *collar button abscess*. On examination, patients typically have pain, swelling, and fluctuance on the palmar and/or dorsal web space surface. The adjacent fingers rest in abduction (Fig. 44-24A) and forced adduction causes pain. These infections are drained through separate dorsal and volar incisions. Great care is taken to leave a skin bridge >1 cm intact in the web. A Penrose drain is placed across both incisions (see Fig. 44-24B) and is removed before discharge from the hospital.

A. The fingers surrounding the involved (second) web space rest in greater abduction than the other fingers. **B.** Dorsal and volar drainage incision are made, separated by a bridge of intact web skin; a Penrose drain prevents the skin from closing

too early.

Palmar Space Infections

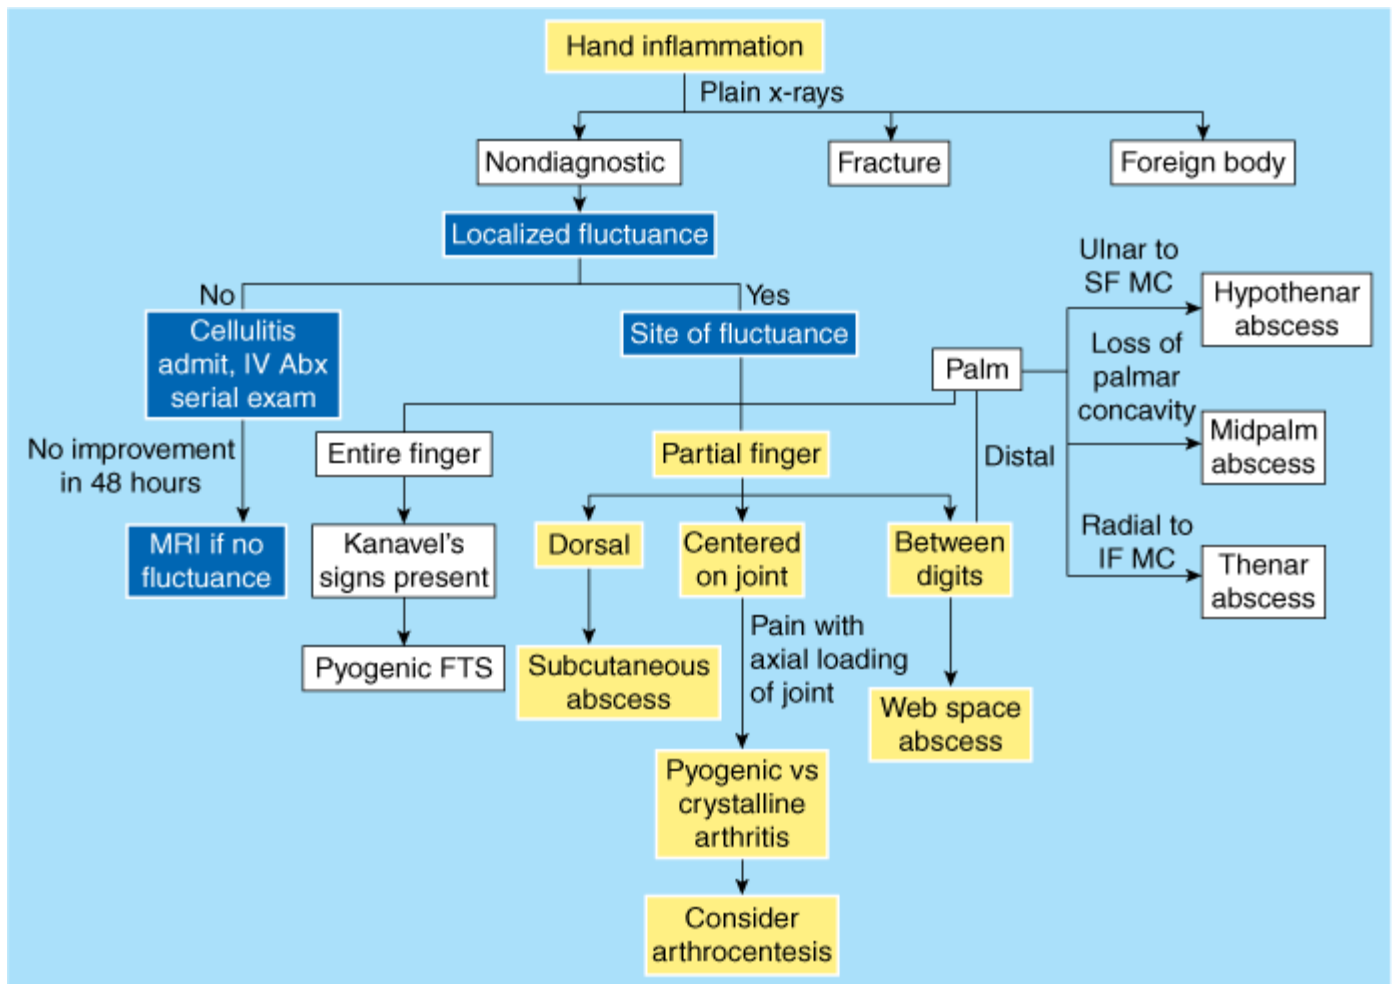

The deep palmar spaces may develop abscesses after puncture wounds. These infections may cause erythema, fluctuance, and pain. The deep fascial spaces of the hand are potential spaces and consist of the hypothenar, midpalmar, and thenar spaces. The hypothenar space begins at the radial border of the hypothenar muscle fascia and passes over the ulnar border of the hand. The midpalmar space is demarcated by the palmar interosseous muscles dorsally and the flexor tendons of the fingers volarly. Lastly, the thenar space consists of the area between the adductor pollicis muscle dorsally and the flexor tendon of the second digit ventrally. In some patients, thenar space infection may spread distally to the first web and then dorsally over the first dorsal interosseous muscle, referred to as a *pantaloön abscess*.

These compartments are susceptible to infection by direct penetrating trauma, spread from a neighboring compartment, or hematogenous seeding. Because of the dorsal location of the hand lymphatics, erythema and swelling commonly appear over the dorsum of the hand, even when the injury is of palmar origin. Treatment involves careful incision and drainage and the usual postoperative modalities. For pantaloön abscesses, a second incision is necessary dorsal to the web space. A bridge of web skin must be left intact to prevent the risk of postoperative web space contracture. A Penrose drain is used similar to treatment for a collar button abscess.

For the patient with inflammation of the hand and suspicion for infection, clinical examination is the most useful diagnostic tool. Plain x-rays are useful to exclude fracture and foreign body. For each abscess location, clinical examination findings can be used to support or exclude a particular diagnosis (Fig. 44-25).

Diagnostic algorithm. Diagnostic work-up for a patient with hand inflammation to evaluate for infection. See text for details about particular infectious diagnoses. Abx = antibiotics; FTS = flexor tenosynovitis; IF MC = index finger metacarpal; MRI = magnetic resonance imaging; SF MC = small finger metacarpal.

TUMORS

Abnormal lumps and bumps, considered to be tumors, are extremely common on the hand. They may vary from benign growths that are simply unsightly to malignant masses that require urgent treatment. Fortunately, most tumors on the hand are benign. Diagnosis usually can be made from the history given by the patient and examination of the lesion. Pathologic examination of tissue provides the final diagnosis.

Tumors may arise from any of the bones or soft tissues. The majority of lesions can be cured by removal but this often can be difficult for anatomic reasons. Tumors can lie close to important structures in the hand, such as nerves and vessels, which must be identified and carefully protected intraoperatively.

Tumors in the hand can be broadly categorized as being benign or malignant; the most common lesions are described below in Benign Lesions and Malignant Tumors.

Benign Lesions

Ganglion cysts are the most common soft tissue tumors in the hand.⁷² These lesions can be painful and usually are found on

the dorsal wrist, followed by the volar wrist, flexor tendon sheath, and the dorsal DIP joint (the mucous cyst). These non-neoplastic, mucinous, fluid-filled pseudocysts arise from synovial linings of irritated and inflamed joints, ligaments, and tendon sheaths. As they have no epithelial lining, the focus of treatment is the site of production or leakage of the synovial fluid, rather than the cyst itself. Cysts may be aspirated; the sudden decrease in cyst pressure may allow the two sides of the stalk to coapt and close. Definitive therapy is surgical excision of the stalk and débridement of the synovial origin. In the common dorsal wrist ganglion, débridement of the dorsal wrist capsule over the scapholunate ligament is felt to be the most important aspect in achieving a low recurrence rate. Volar wrist ganglions arise at the radioscaphocapitate ligament along the radioscaphoid joint. Excision requires complete dissection and protection of the adjacent radial artery and branches of the SRN. For excision of ganglions arising from the flexor tendon sheath, the underlying annular pulleys and adjacent proper digital neurovascular bundles must be protected during dissection.

Lipomas are very common tumors of the body. However, despite their benign nature, the growth of lipomas in the hand can cause neurologic changes by compressing nearby peripheral nerves. They can compress the median nerve and cause symptoms similar to that seen in CTS. Lipomas also can cause sensory deficits from compression of the ulnar nerve and SRN in the hand.⁷³

Enchondromas arise from cartilage and are the most common primary bone tumors of the hand.⁷⁴ These lesions account for >90% of bone tumors seen in the hand.⁷⁵ The proximal phalanges are the most common sites of occurrence, followed by the MC bones. On radiographs, an enchondroma usually is seen as a well-defined radiolucent lesion in the diaphysis or metaphysis and also may have a well-defined sclerotic rim. Although these tumors are benign, local bony destruction can lead to pathologic fracture.

Giant cell tumor of the tendon sheath is the second most common tumor of the hand. This tumor arises from the tendon sheath and includes discrete, nodular, or polypoid masses that affect the digits. The etiology is generally unknown, although a widely accepted explanation describes a reactive hyperplasia associated with an inflammatory process.⁷⁶ The tumor is usually painless and asymptomatic, except for occasional distal numbness if it compresses a nearby digital nerve. Typically, these masses occur along the volar aspect of the hand and fingers and are most commonly adjacent to the DIP joint. The tumors are firm, lobulated, slow-growing masses that are firmly fixed to the underlying structures. The overlying skin often is freely mobile over proximal masses in the fingers. Pressure exerted by the tumors can cause cortical erosion of adjacent bony structures. The treatment of choice is marginal excision of the giant cell tumor.

Giant cell tumor of bone most frequently is found in patients in their second to fourth decades of life. Jaffe provided the current clinical description and grading system used today.⁷⁷ It is characterized by the pathologic presence of multinucleated giant cells. Pain is frequently the primary symptom.⁷⁸ An expanding mass, primarily in the epiphysis, leads to cortical destruction and eventual pathologic fracture. Giant cell tumors are seen in the distal radius, and less commonly, in the phalanges. Nonsurgical treatment includes radiation and embolization. Surgical options include intralesional curettage, although this has been associated with a significant rate of recurrence. Currently, adjuvant therapy such as cryosurgery and bone cement packing has decreased the rate of recurrence following intralesional curettage.⁷⁹

Pyogenic granulomas may occur in the skin as solitary, raised lesions with hyperemic and ulcerated features. Trauma with superimposed infection and/or inflammation is considered to be the most probable cause of these lesions, which are not true neoplasms. Vascular causes have also been described.⁸⁰ Definitive treatment of pyogenic granulomas involves excision with a generous margin of surrounding normal tissue. An alternative effective treatment is to shave off the lesion flush with the skin and coagulate the base.

Malignant Tumors

Squamous cell carcinoma (SCC) is the most common primary malignant tumor of the hand, accounting for 75 to 90% of malignancies.⁸¹ It is two to five times more prevalent in males. Risk factors include sun exposure, x-ray exposure, chronic ulcers, immunosuppression, xeroderma pigmentosa, and actinic keratosis. Solar radiation is the most modifiable risk factor for SCC. Ulcers that develop within old burn or traumatic scars may undergo malignant change (Marjolin's ulcers), representing a more aggressive SCC. Transplant patients on immunosuppressive therapy have a fourfold increased risk of developing skin cancer while patients with xeroderma pigmentosum have a 1000-fold increase in the development of nonmelanotic SCC. These cancers often manifest as small, firm nodules or plaques with indistinct margins. The surface of the lesions may have various irregularities ranging from smooth to verruciform to ulcerated (Fig. 44-26). Scaling, bleeding, and crusting are often seen. Typically, SCC is only locally invasive; however, metastatic rates of up to 20% have been reported in radiation beds and burn scars. Treatment options include curettage and electrodesiccation, cryotherapy, and radiotherapy. Standard treatment is excision with 0.5- to 1-cm margins.⁸¹

Fig. 44-26.

Squamous cell cancer on the dorsal hand. **A.** The patient had a previous excision of squamous cell carcinoma with recurrence along the incision. **B.** Intraoperative defect after resection with 1-cm margins. Paratenon is intact. The wound was temporarily covered with allograft; once final margins were negative, a split-thickness sheet skin was placed.

Basal cell carcinoma (BCC) accounts for 3 to 12% of hand malignancies. Risk factors are similar to those for SCC and include chronic sun exposure, light complexion, and immunosuppression. Other associated conditions include inorganic arsenic exposure and Gorlin's syndrome. BCC classically presents on the hand as a small, well-defined nodule with a translucent, pearly border with overlying telangiectasias. Metastasis are extremely rare. Treatment options for BCC include curettage with electrodesiccation, cryosurgery, and radiation. Standard therapy is surgical excision with 0.5-cm margins. Although performed routinely for facial BCC, Mohs micrographic surgery rarely is indicated for lesions of the hand.

Melanoma accounts for approximately 3% of primary malignant hand tumors, although this incidence is rising.⁸² Risk factors include long-term sun exposure, previous dysplastic nevi, fair complexion, family history of melanoma, and congenital nevi. Lesions with increased growth, change in color or shape, irregular borders, and accelerated growth are suggestive of melanoma. A pigmented lesion under the nail bed must be aggressively pursued with biopsy because of the concern for subungual melanomas. Survival is related to the Breslow thickness of the lesion. The principal treatment is surgical excision or amputation, with 1-cm margins for lesions up to 1 mm in depth, and 2-cm margins for thicker lesions.⁸³ Clinically palpable nodes should be removed to allow staging. Although there is little role for elective lymph node dissections, sentinel lymph node status has been shown to be a valuable prognostic factor. Isolated limb perfusion may offer hope for salvage therapy of metastatic disease. Subungual melanomas are treated with amputation at the level of the DIP joint. Studies have reported a 5-year survival rate of 66% in patients with subungual melanoma.⁸⁴

BURNS

Even though the palm of the hand comprises only 1% of total body surface area, burns of the hand can represent a serious

short- or long-term disability. Hand burns are considered to be severe injuries requiring specialized treatment at a burn center. The management of hand burns is multidisciplinary and requires the expertise of hand surgeons, nurses, and occupational therapists. The multidisciplinary treatment of hand burns begins on the day of injury and may be carried out simultaneously with resuscitation and other treatment. Management objectives include edema control, avoidance of prolonged immobilization, prevention of infection, preservation of viable tissue, and prevention of contractures.

Acute Management

After airway and breathing concerns are addressed in the primary survey, circulation to the hand needs to be assessed. Evaluation of radial, ulnar, and palmar arch pulses should be undertaken by palpation or Doppler ultrasound at initial evaluation and frequently thereafter. Objective evidence of inadequate perfusion (i.e., deteriorating clinical examination with changes in or loss of pulse or Doppler signal) indicates the need for escharotomy, especially in the setting of full-thickness circumferential hand and/or arm burns. Escharotomy may be performed at bedside using a scalpel or electrocautery under local anesthesia and/or IV sedation. In the forearm, axially oriented midradial and midulnar incisions are made for the entire extent of the full-thickness burn. Escharotomy should progress distally (wrist, hand, then digits) as necessary to restore perfusion. Digital escharotomies are achieved via midaxial incisions over the radial aspects of the thumb and small finger, and the ulnar aspect of the index, middle, and ring fingers.⁸⁵ This incision location on the digits is preferred to avoid scars that may be painful on the pinch and contact surfaces of the digits.

Edema formation in burned hands hinders motion and may be a factor in later contracture formation. The hands must be elevated above the level of the heart to minimize edema formation. This is the most important initial step in the management of hand burns and can be done in any sized burn without hindering resuscitation, pulmonary, or other critical care management.

After initial débridement of devitalized tissue, burned hands should be cleansed twice daily. Burns that are clearly partial to full thickness may be managed with silver sulfadiazine cream. Some centers also use mafenide acetate in conjunction with silver sulfadiazine. A number of dressings are available for the treatment of clean partial-thickness burns. Allograft (human cadaver skin), although expensive, provides an excellent temporary dressing. Another option is Biobrane biosynthetic wound dressing (Bertek Pharmaceuticals, Morgantown, WV), a bilayer semisynthetic dressing consisting of an elastic nylon fabric bonded to a semipermeable silastic membrane and coated with collagen polypeptides. Gloves manufactured from this material are available in a variety of sizes and are ideal dressings for clean partial-thickness burns of the hands. Cultured autologous keratinocytes also have been found to be useful in wound coverage.

A burned hand that is not properly positioned, splinted, or ranged will develop debilitating contractures. These contractures represent major disabilities that are difficult to correct with subsequent reconstructive surgery. A typical contracture is an "intrinsic minus" position where the MP joints are fixed in hyperextension and the PIP joints are fixed in a position of flexion.⁸⁶ The collateral ligaments of the MP joint are the most important structures of the burned hand. For this reason, positioning of the burned hand should place the MP joints at maximum flexion to maximally stretch these collateral ligaments. The ideal anatomic position for splinting is the intrinsic plus position with the thumb fully abducted. An orthoplastic splint may be fashioned and secured to the forearm over burn dressings; Velcro straps allow the splint to be loosened to compensate for progressive edema. In special cases, burned hands can be maintained in a safe functional position by temporary Kirshner wire arthrodesis of unstable MP and IP joints.

Occupational therapy has a major impact on hand function following burn injury. Early attention from occupational therapy

can minimize the need for later reconstruction.⁸⁷ Re-establishment of function is the ultimate goal for the patient and is directly dependent upon patient effort expended during occupational therapy sessions. Some clinicians feel that the function present at 1-year postinjury represents that plateau of rehabilitation potential.

In many cases, with good wound care, skin will heal spontaneously without the need for operative intervention. In other cases, surgical excision of the burn with split-thickness skin grafting will be necessary. Grafting should be undertaken as soon as it becomes obvious that wound healing will not be complete by postburn day 14.

Considerable controversy surrounds the need, timing, and method of grafting of burned hands. Several prospective studies show that final surgical management vs. nonoperative care does not impact functional outcome of burned hands. Likewise, function is not affected by the choice of sheet graft over meshed graft, and some claim that cosmetic result is similar with meshed and unmeshed grafts to the hands. The timing of hand graft application is also controversial. For burn patients, the first goal of skin grafting is survival, the second is function, and the third is aesthetics.⁸⁸ This should be taken into account when planning skin grafting to the burned hand. The complete coverage of two burned hands with sheet grafts will likely require harvest of several large autografts. These same autografts, when meshed, could cover a larger area on the trunk, thereby reducing the total burn size. However, it makes little sense to leave a burn survivor with nonfunctional hands because grafting was deferred until the remainder of the skin was healed. A balance between survival and function must be struck.⁸⁹

Tangential excision of burned hands should be performed under tourniquet to minimize potentially significant blood loss. Skin grafts are secured with skin staples, suture, or fibrin glue. Some surgeons will place the hand into a splint before grafting is commenced to minimize shearing. The splint is removed within 1 week, and gentle therapy is initiated. The patient is encouraged to use the hands for activities of daily living, and active ROM exercises are prescribed.

Vacuum-assisted closure devices (V.A.C., KCI, San Antonio, Tex) have advanced wound care, in general, and have particular usefulness in the hand. A sponge specifically designed for the hand is available and is currently used at many centers in the treatment of hand burns (Fig. 44-27). Studies are underway that investigate whether burn progression is limited and edema is reduced by the early application of vacuum therapy. The hand V.A.C. sponge also provides an excellent method of splinting the burned hand in a position of function.

Reconstruction

The most common upper extremity deformities requiring reconstruction after burns are dorsal hand and web space contractures. Ideally, proper positioning prevents dorsal hand contractures. If the initial excision was tangential rather than fascial, such that some remnant dorsal subcutaneous fat remains, a scar release can be performed. The released scar will slide distally, and a skin graft can fill in the defect created behind it. Any release must result in complete ROM of the MP joints. Web space contractures can be minimized by proper early surgery and compression gloves supplemented with web space conformers. In the normal web space, the leading edge of the volar aspect of the web is distal to the dorsal aspect. In the typical dorsal web space contracture, this is reversed, with dorsal syndactyly. When severe, abduction of the digits is limited. Repair can be achieved with local flaps and Z-plasties (Fig. 44-28).

Z-plasty release of web space contracture. **A.** First web space burn contracture. **B.** Immediate postoperative result.

When burns of the hands are deep, initial débridement may result in exposure of viable tendon or joints. Flap coverage is then required. A local flap of choice is the reversed radial forearm flap. Extensive injury may require free-tissue transfer such as a free anterolateral thigh flap (Fig. 44-29) or free lateral arm flap. In cases where local flaps are unavailable due to extent of injury and free tissue transfer is contraindicated because of overall medical condition or vascular insufficiency, other pedicle flaps have been used, such as the groin flap. Recently, dermal substitutes have been used when a flap or full-thickness skin graft would have been necessary but was unavailable or unwise for the patient.⁹⁰

Free anterolateral thigh flap reconstruction of a large dorsal hand wound. Once wound coverage is stable, this flap will need to be surgically revised to achieve proper contour.

Special Situations

Chemical burns of the hands are continuously flushed with water until the pain significantly decreases or stops. Acid burns may require 20 minutes of irrigation while alkali burns may require several hours of irrigation. Hydrofluoric acid burns are a special consideration. This type of burn is marked by slow onset of severe pain as the compound reaches deeper tissues. Hydrofluoric acid avidly binds tissue and circulating calcium, resulting in hypocalcemia that can lead to cardiac arrhythmia and arrest. Following water irrigation, a mixture of calcium gluconate in an aqueous jelly is placed into a surgical glove, which is then used to cover the burned hand. Effectiveness of treatment is assessed by relief of pain. If topical therapy does not relieve pain, then locally injected intra-arterial calcium may be necessary.⁹¹

As electrical current passes through tissue, heat is generated in the intervening muscle and bone, leading to damage and necrosis of these tissues. The skin itself tends to dissipate heat externally and may remain uninjured. The examiner must have a high index of suspicion for deeper pathology, including compartment syndrome and rhabdomyolysis of the forearm muscles. Criteria for performing fasciotomy are similar for other circumstances of compartment syndrome, although some surgeons perform fasciotomy empirically based on mechanism of injury. In the upper extremity, fasciotomy should include the volar, mobile wad, and dorsal compartments of the forearm via two incisions placed 180° to each other. Carpal tunnel

release is performed as part of the forearm release. Fasciotomy of the thenar, hypothenar, and interosseous compartments of the hand also may be performed depending on site of current entry and clinical examination.

VASCULAR DISEASE

Vascular disorders encompass a broad spectrum of pathophysiologic states that results in aberrant microvascular perfusion, potentially threatening the viability of the hand or digits. Vascular disorders of the upper extremity and hand can be classified into acute or chronic categories.

Acute vascular injury to the hand can be due to trauma or iatrogenic causes. Traumatic vascular injury is discussed earlier in this chapter under Vascular Injuries. Iatrogenic causes include radial artery catheterization or drug injection. Acute vessel thrombosis may ensue, which may produce distal ischemia. The hand is assessed for perfusion within the injured adequacy of perfusion distally. Clinical examination and pencil Doppler evaluation may provide sufficient information. When these do not, contrast angiography remains the gold standard evaluation for vessel patency. It also can be used to direct localized thrombolytic therapy or as guidance for balloon embolectomy or vascular bypass, when indicated.

Chronic vascular disorders tend to develop more slowly and are seen in an older population. This category includes atherosclerosis, progressive thrombosis (including hypothenar hammer syndrome), thromboangiitis obliterans (Buerger's disease), embolism, and vasospastic disease.

Atherosclerosis of the brachial, radial, or ulnar artery with acute thrombosis may require surgical exploration, thrombectomy, and possible saphenous vein interposition grafting. Although angioplasty is often used to treat atherosclerotic lesions in other vascular beds, radial and ulnar artery arteriosclerosis is best treated by surgery. Frequently, both radial and ulnar arteries are affected by disease, and hence, the patient presents with symptoms. The presence of a complete palmar arterial arch with good distal runoff may allow good results with repair of only the radial or the ulnar artery. Atherosclerotic changes in the hand and finger arteries are difficult to treat and often associated with severe systemic disease and diabetes. Distal vessels that can receive a bypass graft must be present on angiography to consider a bypass procedure. Amputation may be the best option in cases where pain or gangrene is sufficiently severe. Aneurysms can be resected and repaired primarily with interpositional vein grafts.

Hypothenar Hammer Syndrome

Aneurysmal thrombosis of the ulnar artery at the hook of the hamate is a common type of vascular occlusion in the hand. It is known as *hypothenar hammer syndrome* because it is often the result of repetitive trauma to the ulnar side of the palm associated with pounding as performed by laborers.⁹² Symptoms present may include pain, numbness and tingling, weakness of grip, discoloration of the fingers, and even gangrene or ulcers of the fingertips. Thrombosis of the ulnar artery can dislodge, leading to embolism in the palmar arch or digital vessels.

If acute in onset, proximal occlusions may be embolectomized with a balloon catheter, or sometimes, under direct vision via an arteriotomy. Very distal embolism may require infusion of thrombolytics to dissolve clots and allow reperfusion. Large-vessel acute embolism and reperfusion may result in edema and compartment syndrome, requiring fasciotomy. A high index of suspicion must be maintained.

For the more common scenario of chronic, progressive occlusion, the involved segment of ulnar artery should be resected. There is disagreement in the literature regarding whether simple ligation and excision is sufficient for patients with sufficient distal flow or if all patients should undergo vascular reconstruction.⁹³ The authors' personal preference is to reconstruct all

patients.

Vasospastic Disease

Raynaud's phenomenon results from excessive sympathetic nervous system stimulation. Perfusion is diminished and fingers often become cyanotic. Although the onset of the symptoms is benign, chronic episodes can result in atrophic changes and painful ulceration or gangrene of the digits. Raynaud's disease is present when Raynaud's phenomenon occurs without another associated disease. This disease predominately affects young women and is often bilateral. In contrast, Raynaud's syndrome occurs when Raynaud's phenomenon is associated with an underlying connective tissue disorder, such as scleroderma. Arterial stenosis is present due to disease changes in blood vessels as a result of the specific medical disorder.

Scleroderma is an autoimmune connective tissue disorder resulting in fibrosis and abnormal collagen deposition in tissue. Many organs can be affected, with the skin most commonly and noticeably involved. In this disease, blood vessels are injured by intimal fibrosis leading to microvascular disease. The vessels become subject to Raynaud's phenomenon and patients develop painful, ulcerated, and sometimes necrotic digits.

Sympathectomy can provide pain relief and healing of ulcers for patients with scleroderma and Raynaud's phenomenon. In this procedure, adventitia is stripped from the radial artery, ulnar artery, superficial palmar arch, and digital arteries in various combinations based on which digits are most affected. The decrease in sympathetic tone allows for vasodilation and increased blood flow. Patients being considered for sympathectomy typically undergo a trial of lidocaine infiltration near the vessels one intends to sympathectomize. If the patient notes significant distal pain relief and/or previously ischemic tissue improves in color, sympathectomy may provide the same results in a long-term fashion.⁹⁴

CONGENITAL DIFFERENCES

Congenital differences in a newborn can be particularly disabling as the child learns to interact with the environment through the use of his/her hands. The degree of anomaly can range from minor, such as a digital disproportion, to severe, such as total absence of a bone. In recent years, increasing knowledge of the molecular basis of embryonic limb development has significantly enhanced the understanding of congenital differences. Congenital hand differences have an incidence of 1:1500 births. The two most common differences encountered are syndactyly and polydactyly.⁹⁵

There are numerous classification systems for hand differences. The Swanson classification, adopted by the American Society for Surgery of the Hand, delineates seven groups (headers in bold below), organized based on anatomic parts affected by types of embryonic failures.⁹⁶

Failure of Formation of Parts

The failure of the formation of parts is a group of congenital differences that forms as a result of a transverse or longitudinal arrest of development. Conditions in this group include radial club hand, a deformity that involves some or all of the tissues on the radial side of the forearm and hand, or ulnar club hand, which involves underdevelopment or absence of the ulnar-sided bones.

Failure of Separation of Parts

The failure of the separation of parts comprises conditions where the tissues of the hand fail to separate during embryogenesis. Syndactyly, in which two or more fingers are fused together, is the most common congenital hand deformity. Syndactyly occurs in seven out of every 10,000 live births. There is a familial tendency to develop this deformity. This

deformity often involves both hands, and males are more often affected than females. Surgical release of syndactyly requires the use of local flaps to create a floor for the interdigital web space and to partially surface the adjacent sides of the separated digits (Fig. 44-30). Residual defects along the sides of the separated fingers are covered with full-thickness skin grafts. Surgery is indicated when the webbing occurs distal to the usual point of separation of the fingers and the webbing prohibits full use of the fingers. Surgery usually is performed at 6 to 12 months of age.

Syndactyly. Hand of a 1-year-old patient with complex syndactyly between the long and ring finger. *Complex syndactyly* refers to fingers joined by bone or cartilaginous union, usually in a side-to-side fashion at the distal phalanges. The syndactyly is divided with interdigitating full-thickness flaps, a dorsal trapezoidal-shaped flap to resurface the floor of the web space, and full-thickness skin grafts. Note the skin grafts on the ulnar and radial sides of the new web space.

Duplications of Parts

Duplication of digits is also known as *polydactyly*. Radial polydactyly is usually manifest as thumb duplication. Wassel described a classification system for thumb duplications based on the level of bifurcation.⁹⁷ When two thumbs are present in the same hand, they are rarely both normal in size, alignment, and mobility. In the most common form of thumb duplication, a single broad MC supports two proximal phalanges, each of which support a distal phalanx. Optimal reconstruction requires merging of elements of both component digits. Usually the ulnar thumb is maintained. If the duplication occurs at the MP joint, the radial collateral ligament is preserved with the MC and attached to the proximal phalanx of the ulnar thumb. Surgery is usually performed at 6 to 12 months of age. Ulnar-sided polydactyly, may usually be treated by simple excision.

Overgrowth of Parts

Overgrowth of digits also is known as *macrodactyly*, which causes an abnormally large digit. In this situation, the hand and the forearm also may be involved. In this rare condition, all parts of a digit are affected; however, in most cases, only one digit is involved, and it is usually the index finger. This condition is more commonly seen in males. Surgical treatment of this condition is complex, and the outcomes may be less than desirable. Sometimes, amputation of the enlarged digit is recommended.

Undergrowth of Parts

Underdeveloped fingers or thumbs are associated with many congenital hand deformities. Surgical treatment is not always required to correct these deformities. Underdeveloped fingers may include the following: small digits (brachydactyly), missing

muscles, underdeveloped or missing bones, or absence of a digit.

Constriction Band Syndrome

Constriction band syndrome is a set of congenital differences that occurs when a tissue band forms around the digit(s) arm in utero, causing problems that can affect blood flow and normal growth. This condition may be associated with other problems such as clubfoot, cleft lip, cleft palate, or other craniofacial anomalies. The cause of the ring constrictions is unknown. Some theories suggest that folds or bands in the amniotic membrane may be responsible for this condition.

Generalized Skeletal Problems and Syndromes

This is a rare and complex group of unclassified problems.

Treatment

In addition to the managements described above, treatments for congenital anomalies may include limb manipulation and stretching, splinting of the affected limbs, tendon transfers, external appliances (to help realign misshapen digits or hands), physical therapy (to help increase the strength and function of the hand), correction of contractures, skin grafts, and prosthetics.⁹⁸

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 45. Plastic and Reconstructive Surgery >

KEY POINTS

1. Plastic surgery is the field of surgery that addresses congenital and acquired defects, striving to return form and function.
2. Children diagnosed with cleft and craniofacial anomalies benefit from interdisciplinary care at a specialized center focusing on team care. Long-term follow-up during growth and development is critical for optimal outcomes.
3. Reconstructive surgery attempts to restore form and function through techniques that include skin grafting, use of muscle flaps, bone grafting, tissue expansion, free tissue transfer with microsurgery, and replantation.
4. Aesthetic surgery is surgery performed to reshape the normal structure of the body to improve the patient's appearance and self-esteem. Patients undergoing aesthetic surgery present a unique challenge. The most important outcome parameter is patient satisfaction, and therefore a thorough understanding of the patient's motivations, goals, and expectations is critical.
5. Plastic surgery has been a field of innovation. The future of the specialty likely includes advancements in the areas of regenerative medicine, fetal surgery, and reconstructive transplantation with composite tissue allotransplants.

HISTORICAL BACKGROUND

The field of plastic surgery focuses on the restoration of form and function to those who have congenital and acquired deformities. Plastic surgery routinely addresses new problems and challenges; therefore, the plastic surgeon must have an expert knowledge of anatomy and surgical technique to address new challenges.

The word *plastic* is derived from the Greek *plastikos*, meaning "to mold." Although the term *plastic surgery* can be found in several medical writings from the eighteenth and nineteenth centuries, it was John Staige Davis who established the name of the specialty with the 1919 publication of his book *Plastic Surgery—Its Principles and Practice*.

Certainly, for centuries plastic surgery operations have been performed. One of the earliest accounts of reconstructive surgery can be found in the *Sushruta Samhita*, an early text from the sixth or seventh century B.C. by the practitioner Sushruta. In this writing, the reconstruction of an amputated nose with a pedicled forehead flap and the reconstruction of the ear with cheek flaps was described. In addition, in the first century A.D., the Roman physicians Aulus Cornelius Celsus and Paulus Aegineta described operations for traumatic injuries of the face.

The first textbook of plastic surgery is believed to be Gaspara Tagliacozzi's 1597 publication *De Curtorum Chirurgia per Insitionem*. This text describes the reconstruction of the nose with a pedicled arm flap. The nineteenth century saw advances in reconstructive surgery, including Giuseppe Baronio's successful grafting of sheepskin. The techniques for perfecting human skin grafting followed in the later part of the century.

Great advances in plastic surgery occurred as a result of the first and second world wars. Out of the fields of dental surgery, otolaryngology, ophthalmology, and general surgery, the discipline of plastic surgery was established. The founders of the field include Sir Harold Gillies, an otolaryngologist, who established a center for the treatment of maxillofacial injuries in England; V. H. Kazanjian, a dental surgeon from Boston, who established a center in France for the treatment of facial injuries incurred in World War II; and Vilray P. Blair, from St. Louis, who established centers for the treatment of soft tissue and maxillofacial reconstruction for the U.S. Army. With the onset of World War II, centers of excellence for hand reconstruction appeared as well.

In the last 50 years, advances in the field of plastic surgery have included the transplantation of both autologous and allogeneic tissue, tissue expansion, techniques of moving tissues regionally within the body as muscle and myocutaneous flaps, the distant transfer of free flaps using microsurgery, replantation of traumatically amputated extremities and digits, and the emergence of the field of craniofacial surgery. The future of plastic surgery will likely see further advances in the realms of regenerative medicine, fetal surgery, and reconstructive transplantation with composite tissue allotransplants.

GENERAL PRINCIPLES

Skin Incisions

Human skin exists in a state of tension created by internal and external factors. Externally, skin and underlying subcutaneous tissue are acted on by gravity and clothing. Internally, skin is subjected to forces generated by underlying muscles, joint extension and flexion, and tethering of fibrous tissues from zones of adherence. As a result, when skin is incised linearly it gapes to variable degrees. When a circular skin excision is performed, the skin defect assumes an elliptical configuration paralleling the lines of greatest tension. Carl Langer, an anatomist from Vienna, first fully described these tension lines in the mid-1800s based on his studies of fresh cadavers.¹ A. F. Borges described another set of skin lines that, different from Langer's lines, reflect the vectors of relaxed skin tension.² Although the term *Langer's lines* often is used interchangeably with the term *relaxed skin tension lines*, the former lines describe skin tension vectors observed in the stretched integument of cadavers exhibiting rigor mortis, whereas the latter lines lay perpendicular to and more accurately reflect the action of underlying muscle.² Kraissl's lines, which run along natural wrinkles and skin creases, tend also to follow the relaxed skin tension lines (Fig. 45-1). Relaxed skin tension lines may be exploited to create incisions and reconstructions that minimize anatomic distortion and improve cosmesis. In areas of anatomic mobility, such as the neck or over joints, incisions are oriented less for aesthetic reasons and more with the goal of avoiding scar contractures and subsequent functional compromise. In general, incisions are placed perpendicular to the action of the joint.

Relaxed skin tension lines.

(Reprinted with permission from Wilhelmi et al.¹)

There are situations, however, in which the direction of the incision has been pre-established, as in acute lacerations, burns, or old contracted and distorting scars. In these circumstances the principles of proper incision placement can be combined with simple surgical techniques to reorient the scar and lessen the deformity. The Z-plasty technique uses the transposition of random skin flaps both to

break up a linear scar and to release a scar contracture through lengthening (Fig. 45-2; Table 45-1).

W-plasty is the technique of scar excision and reconstruction in zigzag fashion to camouflage the resulting scar. In areas where pressure or shearing forces are expected, as in weightbearing areas, incision planning should be performed carefully to minimize the effect of antagonistic forces on the healing incision. This point is discussed further in "Pressure Sore Treatment."

Wound Healing

The fundamentals of plastic surgery are based on wound-healing physiology. Wound repair consists of an exquisitely regulated symphony of molecular and cellular instruments that act in concert to restore the local tissue environment to prewound conditions. Metabolic imbalances in the wound milieu drive this orchestration and continue to direct it until healing resolves the mechanical and metabolic problems. Although a detailed review of wound physiology is presented elsewhere in this text, it is useful to emphasize several points.

Tissue injury, be it mechanical or metabolic, profoundly and instantly disrupts the tissue microenvironment and sets into motion a cascade of events that combine to re-establish the environmental status quo. Disrupted blood vessels fill the wound space with red blood cells and plasma. Injured cells release factor III (thromboplastin), which accelerates the clotting cascade. Clotting factors in the plasma are activated, and the coagulation cascade forms thrombin and eventually fibrin. Simultaneously, the complement system activates and produces chemoattractive complement protein fragments. Platelets, activated by thrombin and exposed collagen, release a number of growth factors and cytokines. Traumatized vessels contract in response to both direct physical stimulation (mediated by the autonomic nervous system) and prostaglandins released by platelets. Intact local microvasculature vasodilates and leaks plasma in response to inflammatory mediators such as histamine, kinins, and serotonin. These early events, and others, establish hemostasis and inflammation.³

Platelet activation initiates the first major escalation in the inflammatory response. Within minutes platelets release a number of signaling molecules from their α -granules to attract macrophages, polymorphonuclear cells (PMNs), fibroblasts, and vascular endothelial cells. Within a few hours of injury, PMNs and macrophages invade the wound space and begin to remove tissue debris, coagulation proteins, and bacteria. Although both PMNs and macrophages begin to marginate early, PMNs dominate during the first few days. PMNs also constitute the primary defense against invading organisms that have breached the epithelial barrier. PMNs and macrophages, in concert with the complement system, form the basis of "natural" or "nonspecific" immunity. If there is no infection or foreign material, the neutrophil population quickly diminishes by the second day, whereas macrophages continue to amass.³

Macrophages become the major population by the third day after injury. These cells then dominate the wound region for days to weeks. Macrophages are thought to be the "masterminds" behind the complicated and finely tuned array of repair events that characterizes the proliferative phase of healing. Like neutrophils, activated macrophages continue the task of wound débridement. They are a rich source of degradative enzymes that process the extracellular matrix to make room for remodeling. Tightly coordinated release of the many growth factors, colony-stimulating factors, interleukins, interferons, and cytokines gives the macrophage the ability to regulate migration, proliferation, and specific protein synthesis of multiple cell lines. Macrophages lead the characteristic procession of new tissue into the wound dead space. Immature, replicating fibroblasts follow the macrophages. Mature fibroblasts then advance into the wound space and are, in turn, followed by newly forming capillary buds, the last cells in the procession.³

As previously mentioned, injury perturbs the microenvironment and leads to the autoamplifying inflammatory phase. As a result of these processes, three changes occur in the wound: the environment becomes hypoxic, acidotic, and hyperlactated. There is at least one biochemical pathway by which this low redox potential state can signal cells to take biologic action—the adenosine diphosphoribose (ADPR) system. Specifically, recent evidence has shown that alterations of the polyADPR system affect regulation of collagen and vascular endothelial growth factor (VEGF) transcription.³ Thus, the metabolic state that is so deranged in the wound microenvironment is intimately linked to altered cellular function, which leads to reparative cell phenotypes.

After inflammation has begun, fibroblasts are attracted by many stimuli and then proliferate and migrate into the site of injury. Fibroblasts are the major producers of collagen in the repair response. Substances that increase collagen deposition and maturation include lactate, oxygen, and growth factors. Lack of these agents and steroid treatments decrease collagen in wounds.

Macrophages also usher along angiogenesis, largely through the release of VEGF. VEGF production is upregulated by the same wound metabolic environment that stimulates collagen production. Also like collagen synthesis, VEGF release is increased by hyperoxia. As neovascularization takes place, many of the conditions that signaled the start of the inflammatory and proliferative phases are resolved, and the wound-healing response recedes.

Epidermal cells are attracted to the healing wound by the same cytokines that attract other wound cells. Epithelialization proceeds best in

a moist environment with high oxygen tension.³

Preoperative, intraoperative, and postoperative interventions may be taken by the surgeon to minimize infection and optimize wound healing (Tables 45-2, 45-3, and 45-4). These measures all draw on what we understand of the physiologic wound-healing process.

Table 45-2 Preoperative Management
• Assess and optimize cardiopulmonary function; correct hypertension.
• Treat vasoconstriction: attend to blood volume, thermoregulatory vasoconstriction, pain, and anxiety.
• Assess recent nutrition and provide treatment as appropriate.
• Treat existing infection.
• Assess wound risk using the SENIC index.
• Start administration of vitamin A in patients taking glucocorticoids.
• Maintain tight blood glucose control.

SENIC = Study on the Efficacy of Nosocomial Infection Control.

Table 45-3 Intraoperative Management
• Administer appropriate prophylactic antibiotics at start of procedure. Keep antibiotic levels high during long operations.
• Keep patient warm.
• Maintain gentle surgical technique with minimal use of ties and cautery.
• Keep wounds moist.
• Perform irrigation in cases of contamination.
• Elevate tissue oxygen tension by increasing the level of inspired oxygen.
• Delay closure of heavily contaminated wounds.
• Use appropriate sutures (and skin tapes).
• Use appropriate dressings.

Source: Modified with permission from Hunt TK, Hopf HW: Wound healing and wound infection: What surgeons and anesthesiologists can do. *Surg Clin North Am* 77:587, 1997. Copyright Elsevier.

Table 45-4 Postoperative Management
• Keep patient warm.
• Provide analgesia to keep patient comfortable, if not pain free.
• Keep up with third-space losses. Remember that fever increases fluid losses.
• Assess perfusion and react to abnormalities.
• Avoid diuresis until pain is gone and patient is warm.
• Assess losses (including thermal losses) if wound is open.
• Assess need for parenteral/enteral nutrition and respond.
• Continue to control hypertension and hyperglycemia.

Skin Grafts and Skin Substitutes

Discussion of skin grafting requires a basic review of skin anatomy. Skin is comprised of 5% epidermis and 95% dermis. The dermis

contains sebaceous glands, whereas sweat glands and hair follicles are located in the subcutaneous tissue. The dermal thickness and concentration of skin appendages vary widely from one location to another on the body. The skin vasculature is superficial to the superficial fascial system and parallels the skin surface. The cutaneous vessels branch at right angles to penetrate subcutaneous tissue and arborize in the dermis, finally forming capillary tufts between dermal papillae.⁴

Skin grafting dates back >3000 years to India, where forms of the technique were used to resurface nasal defects in thieves who were punished for their crimes with nose amputation. Modern skin grafting methods include split-thickness grafts, full-thickness grafts, and composite tissue grafts (Table 45-5). Each technique has advantages and disadvantages. Selection of a particular technique depends on the requirements of the defect to be reconstructed, the quality of the recipient bed, and the availability of donor site tissue.

Table 45-5 Classification of Skin Grafts		
Type	Description	Thickness (in)
Split thickness	Thin (Thiersch-Ollier)	0.006–0.012
	Intermediate (Blair-Brown)	0.012–0.018
	Thick (Padgett)	0.018–0.024
Full thickness	Entire dermis (Wolfe-Krause)	Variable
Composite tissue	Full-thickness skin with additional tissue (subcutaneous fat, cartilage, muscle)	Variable

SPLIT-THICKNESS GRAFTS

Split-thickness skin grafting represents the simplest method of superficial reconstruction in plastic surgery. Many of the characteristics of a split-thickness graft are determined by the amount of dermis present. Less dermis translates into less primary contraction (the degree to which a graft shrinks in dimensions after harvesting and before grafting), more secondary contraction (the degree to which a graft contracts during healing), and better chance of graft survival. Thin-split grafts have low primary contraction, high secondary contraction, and high reliability of graft take, often even in imperfect recipient beds. Thin grafts, however, tend to heal with abnormal pigmentation and poor durability compared with thick-split grafts and full-thickness grafts. Thick-split grafts have more primary contraction, show less secondary contraction, and may take less hardily. Split grafts may be meshed to expand the surface area that can be covered. This technique is particularly useful when a large area must be resurfaced, as in major burns. Meshed grafts usually also have enhanced reliability of engraftment, because the fenestrations allow for egress of wound fluid and excellent contour matching of the wound bed by the graft. The fenestrations in meshed grafts re-epithelialize by secondary intention from the surrounding graft skin. The major drawbacks of meshed grafts are poor cosmetic appearance and high secondary contraction. Meshing ratios used usually range from 1:1.5 to 1:6, with higher ratios associated with magnified drawbacks.

FULL-THICKNESS GRAFTS

By definition full-thickness skin grafts include the epidermis and the complete layer of dermis from the donor skin. The subcutaneous tissue is carefully removed from the deep surface of the dermis to maximize the potential for engraftment. Full-thickness grafts are associated with the least secondary contraction upon healing, the best cosmetic appearance, and the highest durability. Because of this, they are frequently used in reconstructing superficial wounds of the face and the hands. These grafts require pristine, well-vascularized recipient beds without bacterial colonization, previous irradiation, or atrophic wound tissue.

GRAFT TAKE

Skin graft take occurs in three phases, imbibition, inosculation, and revascularization. Plasmatic imbibition refers to the first 24 to 48 hours after skin grafting, during which time a thin film of fibrin and plasma separates the graft from the underlying wound bed. It remains controversial whether this film provides nutrients and oxygen to the graft or merely a moist environment to maintain the

ischemic cells temporarily until a vascular supply is re-established. After 48 hours a fine vascular network begins to form within the fibrin layer. These new capillary buds interface with the deep surface of the dermis and allow for transfer of some nutrients and oxygen. This phase, called *inosculation*, transitions into revascularization, the process by which new blood vessels either directly invade the graft or anastomose to open dermal vascular channels and restore the pink hue of skin. These phases are generally complete by 4 to 5 days after graft placement. During these initial few days the graft is most susceptible to deleterious factors such as infection, mechanical shear forces, and hematoma or seroma.⁴

COMPOSITE GRAFTS

Composite tissue grafts are donor tissue containing more than just epidermis and dermis. They commonly include subcutaneous fat, cartilage and perichondrium, and muscle. Although less common than skin grafts, grafts of this type are particularly useful in select cases of nasal reconstruction. Excision of the thick skin of the nasal lobule may create too deep a defect to reconstruct with a full-thickness skin graft. The ear lobe composite graft provides thicker coverage with good color match and a fairly inconspicuous donor site (Fig. 45-3). Similarly, the root of the helix of the ear may be used to reconstruct the alar rim, providing skin coverage, cartilaginous support, and internal lining in a single technique.

Flaps

A flap is a vascularized block of tissue that is mobilized from its donor site and transferred to another location, adjacent or remote, for reconstructive purposes. The difference between a graft and a flap is that a graft brings no vascular pedicle and derives its blood flow from recipient site revascularization, whereas a flap arrives with its blood supply intact.

RANDOM PATTERN FLAPS

Random pattern flaps have a blood supply based on small, unnamed blood vessels in the dermal-subdermal plexus, as opposed to the discrete, well-described, directional vessels of axial pattern flaps (Fig. 45-4). Random flaps are typically used to reconstruct relatively small, full-thickness defects that are not amenable to skin grafting. Unlike axial pattern flaps, random flaps are limited by their geometry. The generally accepted reliable length:width ratio for a random flap is 3:1. Exceptions to this rule abound, however. There are many different types of random cutaneous flaps that differ in geometry and mobility. A *transposition flap* is rotated about a pivot point into an adjacent defect (Fig. 45-5). A *Z-plasty* is a type of transposition flap in which two flaps are rotated, each into the donor site of the other, to achieve central limb lengthening (see Fig. 45-2). Another common transposition flap is the *rhomboid (Limberg) flap* (Fig. 45-6). The *bipedicle flap* is comprised of two mirror-image transposition flaps that share their distal, undivided margin. *Rotational flaps* are similar to transpositional flaps but differ in that they are semicircular (Fig. 45-7). *Advancement flaps* slide forward or backward along the flap's long axis. Two common variants include the rectangular advancement flap and the V-Y advancement flap (Fig. 45-8). Like transposition flaps, *interpolation flaps* rotate about a pivot point. Unlike transposition flaps, they are inset into defects near, but not adjacent, to the donor site. An example of an interpolation flap is the thenar flap for fingertip reconstruction (Fig. 45-9).

Random pattern interpolation flap—the thenar flap. **A.** Middle fingertip injury with exposed bone and tendon. **B.** Elevation of distally based random pattern thenar flap. **C.** Insetting. **D and E.** Function and form at 3 months, after skin grafting of donor site.

(Photographs reproduced with permission from M. Gimbel.)

Fasciocutaneous and Myocutaneous Flaps

The *composition* of a flap is its tissue components. For example, a cutaneous flap contains skin and a variable amount of subcutaneous tissues. A fasciocutaneous flap contains skin, fascia, and intervening subcutaneous tissues. A muscle flap contains muscle only, whereas a myocutaneous flap contains muscle with its overlying skin and intervening tissues. An osseous flap contains vascularized bone only, whereas an osteomyocutaneous flap contains in addition muscle, skin, and subcutaneous tissues.

The *contiguity* of a flap describes its source. Local flaps are transferred from a position adjacent to the defect. Regional flaps are from the same anatomic region of the body as the defect (e.g., the lower extremity region or the head and neck region). Distant flaps are transferred from a different anatomic region to the defect. Local, regional, and distant flaps may be pedicled, in that they remain attached to the blood supply at their source. Distant flaps may also be transferred as *free flaps* by microsurgical techniques; these are completely detached from the body, and their blood supply is reinstated by anastomoses to recipient vessels close to the defect.

Axial pattern flaps are based on an anatomically defined configuration of vessels.⁶ Arising from the aorta are arteries that supply the internal viscera and other deep vessels that divide to form the main arterial supplies to the trunk, head, and extremities. They ultimately feed interconnecting vessels that supply the vascular plexuses of the fascia, subcutaneous tissue, and skin. These interconnecting vessels reach the skin via either fasciocutaneous (also called *septocutaneous*) vessels that traverse fascial septae, musculocutaneous perforators that penetrate muscle bellies, or direct cutaneous vessels that traverse neither muscle bellies nor fascial septae.⁷ Axial pattern flaps, incorporating suprafascial tissues, are supplied by these fasciocutaneous (septocutaneous), musculocutaneous, or direct cutaneous arteries. The internal viscera are also a source of axial pattern flaps, such as the jejunum flap and omentum flap. The circulation of bone- and muscle-containing flaps also is mainly axial in pattern. It also is possible to design local flaps, such as V-Y advancements and

rhomboid flaps, as axial pattern flaps. The volume of tissue reliably supplied by the arterial input (and venous drainage) of an axial pattern flap defines its limits, not length: breadth ratios. This can be clarified conceptually. The arterial tree can be described in terms of angiosomes, territories (anatomic, dynamic, and potential), and choke vessels.⁸ Each artery supplies a block of tissue called an *angiosome*; neighboring angiosomes overlap. The anatomic territory of an artery is defined by the limits of its ramifications, where it forms anastomoses with neighboring anatomic territories. The vessels that pass between anatomic territories are called *choke vessels*. The dynamic territory of an artery is the volume of tissue stained by an intravascular administration of fluorescein into that artery. The *potential territory* of an artery is the volume of tissue that can be included in a flap that has undergone conditioning. Both the dynamic and potential territories extend beyond the anatomic territory of an artery. Although these territories of the artery supplying an axial pattern flap provide some guidance to the limits of such a flap harvest, there remains no quantifiable method to predict these safe limits exactly. By virtue of their defined blood supply, the contiguity of axial pattern flaps, unlike that of random pattern flaps, may be local, regional, or distant, and pedicled or free. Axial pattern flaps may also possess some areas with random pattern circulation, usually located at the flap periphery.

Conditioning refers to any procedure that increases the reliability of a flap. Invoking the delay phenomenon, for example, has improved the survival of flaps whose use is frequently complicated by unpredictable partial necrosis, such as the pedicled transverse rectus abdominis myocutaneous (TRAM) flap. The procedure can be particularly useful in patients at higher risk, such as those who are obese, smoke, or have received radiotherapy. One method of delay for the pedicled TRAM flap is to divide a major portion of its blood supply, the deep inferior epigastric artery on both sides, approximately 2 weeks before transfer. In response, blood from the anatomic angiosome of the superior epigastric artery appears to flow into that of the interrupted deep inferior epigastric artery via intervening choke vessels. As a result, the flap becomes conditioned to rely on the superior epigastric artery. The TRAM flap can then be transferred based on the superior epigastric artery with less risk of its distal portions' becoming ischemic and possibly necrotic. Several theories have been proposed to explain the delay phenomenon, including metabolic compensatory responses to relative ischemia and dilatation of choke vessels; however, its mechanisms remain incompletely understood.⁹

Further subclassifications of flap circulation have been introduced for muscular and fasciocutaneous flaps.¹⁰ Individual muscles have been classified by Mathes and Nahai into five types (I to V) according to their blood supply (Table 45-6). This classification is also applied to the respective myocutaneous flaps. Fasciocutaneous flaps also have been classified by Nahai and Mathes into types A, B, and C (Table 45-7). The inclusion of muscle in a flap may serve to increase flap bulk (so as to obliterate dead space) or to provide a functioning component with the harvest of its motor nerve for coaptation to a recipient motor nerve. The purported advantages of muscle-containing flaps over fasciocutaneous flaps for use in previously infected tissue beds or for fracture healing have been debated.

Table 45-6 Mathes-Nahai Classification of Muscular Flaps		
Classification	Vascular Supply	Example
Type I	One vascular pedicle	Gastrocnemius
Type II	Dominant and minor pedicles (the flap cannot survive based only on the minor pedicles)	Gracilis
Type III	Two dominant pedicles	Rectus abdominis
Type IV	Segmental pedicles	Sartorius
Type V	One dominant pedicle with secondary segmental pedicles (the flap can survive based only on the secondary pedicles)	Pectoralis major

Table 45-7 Nahai-Mathes Classification of Fasciocutaneous Flaps		
Classification	Vascular Supply	Example
Type A	Direct cutaneous vessel that penetrates the fascia	Temporoparietal fascial flap
Type B	Septocutaneous vessel that penetrates the fascia	Radial artery forearm flap

Type C	Musculocutaneous vessel that penetrates the fascia	Transverse rectus abdominis myocutaneous flap
--------	----------------------------------------------------	-----------------------------------------------

With progressive advancements in flap transfer techniques and an understanding of microvascular flap anatomy, plastic surgeons have steadily increased the number and variety of available flaps, thereby improving the results of flap reconstructions. In addition, this knowledge has reduced the morbidity associated with flap harvest. Perhaps the most important advancement in flap surgery within the last two decades has been the introduction of the perforator flap.¹¹ Perforator flaps evolved from the observation that the muscle component of myocutaneous flaps served only as a passive carrier of blood supply to the overlying fasciocutaneous tissues (fascia, skin, and intervening subcutaneous tissues). Previous to this, it had been deemed necessary to include the muscle for reliable harvest of fasciocutaneous tissues supplied by its musculocutaneous perforators, even if it was not necessary to include that muscle for the reconstruction. This unfortunately caused an unnecessary muscular deficit at the donor site, and for this reason these flaps were sometimes abandoned. The introduction of intramuscular retrograde dissection techniques, however, allowed the skeletonization of a musculocutaneous perforator from its encasement within a muscle belly, which spared that muscle from flap harvest and preserved its donor site function.^{7,11} Further refinement of this concept gave rise to the harvest of cutaneous flaps based on any vessel that penetrated the fascia, which preserved the muscle (when the vessel was a musculocutaneous perforator) as well as the fascia (by suprafascial dissection). Within the last decade, free-style flap harvest has also been introduced.¹² With a handheld Doppler ultrasound probe, the surgeon is able to identify an arterial supply to almost any area of skin with the desired reconstructive characteristics and trace that pedicle in retrograde fashion along whatever direction it takes, preserving donor site fascia and muscle as necessary. Although the exact definition of what a perforator flap is remains contentious, its advantages remain clear: reduced donor site morbidity, reduced flap bulk, and increased flexibility in choosing desired flap components for reconstruction. The circulation of perforator flaps is axial in pattern; consequently, they can be transferred as pedicled island flaps or by microvascular free tissue transfer.

Free Tissue Transfer

A free tissue transfer (or transplantation), often referred to as a *free flap* procedure, is an autogenous transplantation of vascularized tissues. Any axial pattern flap with pedicle vessels of a suitable diameter can be transferred as a free flap. This involves three main steps: (a) complete detachment of the flap, with devascularization, from the donor site; (b) revascularization of the flap with anastomoses to blood vessels in the recipient site; and (c) an intervening period of flap ischemia. Flap circulation must be restored within a tolerable ischemia time.

Given the small diameter of most flap pedicle vessels (usually between 0.8 and 4.0 mm), these anastomoses are usually performed using an operative microscope that provides dedicated illumination and between 6x and 40x magnification. Any surgery performed with the aid of an operative microscope is termed *microsurgery*; such anastomoses are therefore termed *microvascular anastomoses*. High-magnification surgical loupes are usually used for flap harvest, especially for dissecting the flap pedicle, because they allow greater operator freedom. Aside from microvascular anastomosis, microsurgical techniques include microneural coaptation, microlymphatic anastomosis, and microtubular anastomosis.

The first successful free tissue transfer in humans was transfer of a jejunal free flap for cervical esophagus reconstruction performed in 1957; however, the surgeons did not use microvascular surgery for the anastomoses. The first *microvascular* free tissue transfers in humans were carried out during the late 1960s and early 1970s. Free flaps were initially considered to be a last-resort option to reconstruct the most complex defects. However, as a result of improved microsurgical techniques and microinstrumentation, as well as proper patient and free flap selection and effective postoperative monitoring methods, the success rates have increased to exceed 95%.¹³ Today, free tissue transfer is often the first-choice treatment for many defects and is no longer considered the last-ditch effort. It is now ubiquitously used in appropriate patients by reconstructive plastic surgeons worldwide.

The predetermining factor in free flap failure is occlusion of its anastomotic lifeline blood supply due to thrombosis. As enumerated by Virchow's triad, any factors that alter normal laminar blood flow, cause endothelial damage, or change the constitution of blood (producing hypercoagulability) increase the risk of thrombosis (Table 45-8).¹⁴ Avoidance of this complication therefore begins with a thorough patient evaluation for the presence of acquired or inherited thrombophilic tendencies. The patient's hemodynamic status

influences that of the free flap and should be optimized. The effect of tobacco smoking on free flap success has been debated, with some larger retrospective studies reporting no difference in thromboembolic complications; however, smoking is well known to affect wound healing.^{13,15} Smoking, and the use of potentially vasoconstrictive agents, such as caffeine, should be avoided for several weeks before a free flap procedure. The restoration of normal laminar blood flow and avoidance of endothelial damage are addressed principally by careful flap inseting and meticulous microvascular surgical technique.

Table 45-8 Thrombogenic Factors That Can Affect Free Flap Pedicles and Anastomoses		
Altered Laminar Blood Flow	Endothelial Damage	Hypercoagulability
Tension or intimal malalignment at the anastomosis site; twisting, kinking, compression, or vasospasm of pedicle vessels	Iatrogenic damage (e.g., back-walled anastomotic suture, poor vessel handling, too many sutures)	Acquired thrombophilic tendency (e.g., pregnancy, paraneoplastic Trousseau's syndrome, antiphospholipid antibody syndromes)
Nearby intraluminal structures (e.g., atherosclerotic plaque, venous valves, back-walled anastomotic suture)	Previous vessel damage (e.g., atherosclerosis, trauma)	Hereditary thrombophilias (e.g., activated protein C resistance, protein C/protein S deficiency, hyperhomocysteinemia)

Planning a free flap goes beyond a simple calculation of matching flap and defect dimensions and tissue characteristics. The surgeon must, in addition, consider several important technicalities: what flap pedicle length and size are required (affected by flap choice), which recipient vessels to use, how to orient anastomoses (end to end or end to side), how to deal with mismatched donor and recipient vessel dimensions, how to overcome unhealthy donor and/or recipient vessels (e.g., traumatic dissection, scarred surgical field due to previous operation or radiotherapy), how to inset flap tissues (to maximize functional and cosmetic results without detriment to flap circulation), how to route the pedicle (to restore normal blood flow without pedicle kinking, twisting, or compression), how to position the patient (especially if the flap is to be inset over mobile soft tissue or joints), how to place postoperative dressings (so as to produce no compression of the flap or pedicle), and what donor site morbidity will likely result (there is a risk-benefit decision between defect severity and flap choice).¹⁶ In addition, the surgeon must have a suitable backup plan to overcome intraoperative troubles; for example, insufficient pedicle length can be addressed with an interpositional vein graft adjoining the donor and recipient vessels, and iatrogenic vessel injury or severely aberrant anatomy may necessitate use of a backup flap or backup recipient vessels.¹³

A clear understanding of the blood supply to the free flap and its tissue components is a prerequisite to harvesting a viable free flap. Pedicle vessels must be identified and protected, and handled minimally and atraumatically to avoid thrombogenic factors (see Table 45-8). Meticulous technique also reduces the risk of vasospasm, but the latter can be ameliorated by topical lidocaine or papaverine should it occur. Critical vessels connecting flap components must also be recognized and preserved. Under microscope magnification, the donor and recipient vessels should be dissected back to health. The presence of, for example, venous valves, atherosclerotic plaques, intimal trauma, and intraluminal prolapse of adventitial tissue at or adjacent to the anastomosis site increases the risk of thrombosis. The vessel ends should be cleared of periadventitial tissues for 3 to 5 mm with sharp dissection under the microscope. Periadventitial dissection should be limited to this extent, so as to avoid potential devascularization of the vessel wall by removal of the vasa vasorum and prevent the subsequent delayed development of a perianastomotic pseudoaneurysm. Adventitiectomy also helps relieve vasospasm by increasing compliance of the vessel wall and by inducing a local sympathectomy effect. The vessel ends usually are stabilized with a double approximating microvascular clamp for anastomosis. Interrupted sutures or, less commonly, continuous sutures can accomplish the anastomosis. The microneedle typically has a three eighths circle curvature and is between 30 and 150 μm in size. Its monofilament microsuture is usually between 9-0 and 11-0 caliber. The dimensions of the vessels to be anastomosed define the choice of microneedle and microsuture. Less commonly, suture alternatives such as fibrin adhesives or laser welding (these remain largely experimental) and mechanical anastomotic devices (e.g., venous couplers) may be used. Triangulating or bisecting suturing techniques can help to achieve an even placement of sutures. Normally, each suture should include the full thickness of both vessel walls, none should catch the opposite vessel wall (which causes disastrous luminal occlusion and intimal trauma), and the size of each bite should approximate the vessel wall thickness. The configuration of the anastomosis can be either end to end (Fig. 45-10), if the distal circulation can be adequately preserved, or end to side (Fig. 45-11) if the distal circulation must be preserved, as in the case of an arterially compromised

extremity supplied by one dominant vessel. An end-to-side orientation may also be useful to overcome dramatically mismatched donor-recipient vessel dimensions. Whatever the method chosen, microanatomic differences between the vessels should be respected so as to achieve accurately approximated intimal surfaces in a tension-free anastomosis, devoid of redundancy that might promote kinking.¹³

A through D. End-to-end anastomosis.

Fig. 45-11.

The clinical monitoring of a free flap should start during flap harvest, especially before its pedicle is divided. A free flap that is struggling to maintain normal perfusion characteristics during harvest most likely has insufficient circulation, which may be due to arterial or venous compromise, or a combination of both (Table 45-9). Flap compromise may be due to reversible factors such as pedicle kinking, tensioning, or twisting; patient hemodynamic compromise; or an overly large flap harvest for the chosen pedicle vessels. If poor flap perfusion continues despite the absence or correction of all these factors, an inherent flap problem or a critical vascular injury to the flap or its pedicle must be considered, and it may not be safe to continue its harvest. This is one clear example of a situation in which a backup plan may require execution.

Table 45-9 Clinical Signs of Arterial and Venous Compromise in a Free Flap^a

Clinical Sign	Arterial Compromise	Venous Compromise
Color	Becoming paler	Increasingly reddish or purplish
Temperature	Becoming cooler	Becoming warmer
Tissue turgor	Reducing	Increasing
Capillary refill time	Becoming slower	Becoming faster
Pinprick bleeding	Increasingly sluggish	Quickening (and darkening)

^aNote that venous and arterial compromise may coexist, and one may lead to the other.

Clinical flap monitoring continues after successful restoration of arterial inflow and venous outflow. The mainstay of postoperative free flap monitoring is clinical assessment (see Table 45-9), although supplementary instrument monitoring also can be helpful. Doppler ultrasound assessment of arterial and venous signals is useful for monitoring buried or concealed flaps. If flap perfusion was healthy before division of its donor site pedicle, then poor perfusion after anastomoses is likely due to either a technical error or insufficient systemic hemodynamics. The latter usually is correctable by ensuring that the patient and the patient's environment are suitably warm and by initiating IV colloid challenge or, if indicated, blood transfusion. Numerous potential technical errors, which have been described in the earlier paragraphs on planning and anastomosis technique, may occur. Routine postoperative patient monitoring includes

measurement of total fluid inputs, urinary catheter output (which should be >1 mL/kg per hour), core temperature, and arterial blood pressure (systolic pressure should be >100 mmHg), as well as pulse oximetry. The patient and free flap are best monitored in an intensive care setting by experienced staff until both are stable enough for routine ward assessments.¹³

Occlusion of the anastomosis most commonly arises from internal thrombosis or from external compression of the pedicle, such as from surrounding tissues, fluid accumulation (e.g., hematoma and tissue edema), or overly tight dressings or skin sutures. Because there is a threshold of ischemia beyond which a flap will sustain irreversible tissue and/or microcirculatory damage, it is important that the early signs of flap circulatory compromise be recognized as quickly as possible and the underlying problem diagnosed and corrected promptly if flap health is to be restored successfully. Different tissues tolerate differing durations of ischemia in correlation with their tissue-specific basal metabolic rate. Although cooling free flaps (to reduce basal metabolic rate) has a variably protective effect in experimental settings, it appears that this practice contributes little to improving free flap success in the clinical setting as long as warm ischemia times are kept to <4 hours for most tissues; exceptions include bowel flaps, which are more susceptible to ischemia.¹³

Given that the predisposing factor for free flap failure is thrombosis formation, it is understandable that plastic surgeons have looked to anticoagulant therapies in an effort to improve success rates. The routine use of anticoagulants remains controversial. Although such drugs, including the dextrans, aspirin, heparin, and also some fibrinolytics, appear beneficial in experimental settings, large clinical trials have failed to show any conclusive associations between their use and either free flap success or failure rates.¹⁷ It seems intuitive to use these drugs for failing free flaps as an adjunctive measure alongside operative re-exploration and surgical intervention. The surgeon must be aware of their contraindications and recognize that their side effects, apart from bleeding, are occasionally serious. Venous congestion may be addressed by surgical measures as well as by application of medicinal *Hirudo medicinalis* leeches (with concomitant *Aeromonas hydrophilia* prophylaxis) or by chemical "leeching" (topical heparin combined with dermal punctures).

Unfortunately, the "no-reflow" phenomenon is occasionally witnessed and leads to irreversible flap failure. This describes a situation in which no venous return drains into the pedicle vein of the flap, even though adequate arterial inflow passes the arterial anastomoses and is seen to enter the flap tissues. The no-reflow phenomenon sometimes follows an extended ischemic insult and appears to be a self-perpetuating cycle of endothelial cellular swelling, inflammatory vasoconstriction, impaired microcirculatory flow, stasis, microcirculatory thromboses, progressive ischemia, and flap failure.¹³

Despite these potential problems, free flap success rates exceed 95% in experienced hands.¹⁸ There is no doubt that increasing microsurgical experience is critical to improving free flap success rates. The laboratory setting is an excellent environment in which to progress beyond the early portion of one's learning curve through supervised microsurgical training and execution of microvascular anastomoses and microvascular free flap procedures in small animals.

Tissue Expansion

Although skin grafts and local flaps are very useful in reconstructing many superficial defects, they are not without their drawbacks. Both leave donor site defects with cosmetic and/or functional sequelae. Grafts are limited in color match and durability, whereas local flaps may supply insufficient tissue and produce contour irregularities. The advent of tissue expansion has created the potential to greatly increase the amount of local, well-matched tissue that can be advanced or transposed as a flap while decreasing donor site morbidity.

The most common method of skin expansion involves the placement of an inflatable silicon elastomer balloon with an integrated or remote port beneath the skin and subcutaneous tissue followed by serial inflation with saline. After completion of expansion, usually over weeks to months, the expander is removed and the redundant overlying skin may be advanced into an adjacent defect. Expanders are now available in a multitude of shapes and sizes that can be tailored to the reconstruction. In breast reconstruction the tissue expander is replaced with a permanent implant instead of using the tissue as a flap to re-create the volume of the breast mound. Histologically, expanded skin demonstrates thickened dermis with enhanced vasculature and diminished subcutaneous fat. Studies have shown that the skin expansion is due not merely to stretch or creep but also to actual generation of new tissue.¹⁹

The technique of tissue expansion comes with its share of potential complications, including infection, hematoma, seroma, expander

extrusion, implant failure, skin necrosis, pain, and neurapraxia. Furthermore, an inflated expander is certainly a very visible, albeit temporary, deformity that may cause patients much distress.

Despite these imperfections, tissue expansion has become a major treatment modality in the management of giant congenital nevi, secondary reconstruction of extensive burn scars, scalp reconstruction, and breast reconstruction. The technique has permitted the plastic surgeon to perform reconstructions with tissue of similar color, texture, and thickness with minimal donor site morbidity.

PEDIATRIC PLASTIC SURGERY

Cleft Lip and Palate

Orofacial clefting is the most common congenital anomaly and is known to occur in 1 in 500 live white births.²⁰ The incidence is lower in African Americans and higher in Native Americans and Asians. Clefting of the lip and/or palate is felt to occur around the eighth week of embryogenesis, either by failure of fusion of the medial nasal process and the maxillary prominence or by failure of mesodermal migration and penetration between the epithelial bilayer of the face. The cause of orofacial clefting is felt to be multifactorial. Factors that likely increase the incidence of clefting include increased parental age, drug use and infections during pregnancy, smoking during pregnancy, and a family history of orofacial clefting. The increased chance of clefting when there is an affected parent is approximately 4%.

The *primary palate* is defined as all tissue anterior to the incisive foramen, including the anterior hard palate (premaxilla), alveolus, lip, and nose. The secondary palate includes everything posterior to the incisive foramen, including the majority of the hard palate and the soft palate (velum). Clefting can involve the lip and nose, with or without a palatal cleft. Clefts of the lip and/or palate are first classified as unilateral or bilateral, and then as complete or incomplete (Fig. 45-12). Complete clefts of the lip affect the entire lip and extend up into the nose. Incomplete clefts affect only a portion of the lip and contain a bridge of tissue connecting the central and lateral lip elements, referred to as *Simonart's band*.

TREATMENT PROTOCOL

Considerable controversy remains over the details of the timing, technique, and protocol for treating children with orofacial clefting. The treatment protocol described in this chapter is accepted at many large cleft centers around the United States. All infants born with cleft-craniofacial anomalies benefit from care by a specialized team dedicated to the treatment of congenital anomalies. Today, this is widely accepted as the standard of care. Often, patients are seen prenatally after a diagnosis is made using sophisticated antenatal ultrasonography. The prenatal consultation has proven to be beneficial to parents, serving to dispel fears and uncertainties, and assuring them that treatment exists. After the infant's birth, a team evaluation occurs, and input is obtained from the surgeon, speech and

language pathologist, social worker, craniofacial orthodontist, geneticist, otorhinolaryngologist, and pediatrician. For infants born with orofacial clefting, initial concerns relate to successful feeding and breathing. Infants with palatal clefts cannot generate negative pressure when suckling and therefore need milk dispensed into their mouths from a specialized nurser when they make suckling motions. Once adequate nutrition and a safe airway are ensured, attention is turned to the cleft anomaly. Attempts to lessen the deformity and set the stage for the surgical repair of the lip and nose begin with a process known as *presurgical infant orthopedics (PSIO)*, which includes procedures such as nasoalveolar molding (NAM) (Fig. 45-13). NAM repositions the neonatal alveolar segments, brings the lip elements into close approximation, stretches the deficient nasal components, and turns wide complete clefts into the morphology of narrow "incomplete" clefts. After PSIO with NAM, the definitive single-stage cleft lip and nose repair is performed at 3 to 6 months of age. With this initial operation, the lip deformity is repaired and a primary nasoplasty reconstructs the cleft lip nasal deformity. If the family does not have access to PSIO or have the resources for this time-intensive therapy, a cleft lip adhesion can be performed as an initial stage in the repair. The preliminary cleft lip adhesion unites the upper lip and nasal sill, truly converting complete clefts into incomplete clefts. A cleft lip adhesion is performed in the first or second month of life, and the definitive cleft lip and nose repair follows at 4 to 6 months. After the definitive cleft lip and nose repair, the cleft palate is repaired in a single stage at 9 to 12 months of age.

UNILATERAL CLEFT LIP

The unilateral cleft lip is classically associated with a cleft lip nasal deformity. The cleft lip nasal deformity includes lateral, inferior, and posterior displacement of the alar cartilage. This results from the deficient and clefted underlying skeleton as well as the unopposed pull of the clefted orbicularis oris muscle abnormally inserted on the alar base (Fig. 45-14A). The maxillary minor segment (the smaller alveolar/maxillary segment on the clefted side) is collapsed medially. The process of unilateral cleft lip repair can be thought of as "philtral subunit reconstruction." The goal of the operation is to level Cupid's bow and reconstruct the central philtrum of the lip, ideally placing the incision and subsequent scar as close to the normal philtral column as possible. The surgical repair is performed under general anesthesia, and local anesthesia containing epinephrine is used. Many different techniques of cleft lip and nose repair have been proposed; however, most of the commonly used procedures are variations of a "rotation-advancement" procedure.²¹ The rotation-advancement procedure, as championed by Millard (Fig. 45-14B), rotates the philtral subunit of the central lip downward to level Cupid's bow as the lateral lip element is advanced into the defect created by the downward rotation of the philtrum. Some surgeons choose to perform primary closure of the alveolar cleft at the time of primary lip and nose repair, called a *gingivoperiosteoplasty*. If the alveolar cleft is to be repaired, the gingivoperiosteoplasty is performed by raising mucoperiosteal flaps within the alveolar cleft margin and reapproximating them across the alveolar cleft defect. This creates a bony tunnel closed with periosteal flaps and facilitates the generation of bone in the alveolar defect. It is accepted today that some form of primary nasoplasty should be performed at the time of primary definitive lip repair. Techniques to release and reposition the nasal tip cartilages, as well as the ala, are performed with variations of tip rhinoplasties using suture methods. Some surgeons choose to use postoperative internal and/or external splints to maintain the nasal correction achieved at surgery during the healing process.

A. Unilateral cleft lip and nose deformity. **B.** The rotation-advancement repair.

BILATERAL CLEFT LIP

In the complete bilateral cleft lip and nose deformity, the central lip element, called the *prolabium*, is entirely separate from the rest of the upper lip. The prolabium is displaced on top of the central alveolar segment, called the *premaxilla*, containing the unerupted four central incisors. Often, the premaxilla and prolabium are outwardly displaced. This is referred to as a *flyaway premaxilla*. For the child with a complete bilateral cleft lip and nose, PSIO is a very important step in preparing the child for definitive lip and nose surgery by retracting the premaxilla into the maxillary arch, repositioning the lip segments, and stretching the rudimentary columella. Bilateral cleft lip and nose repairs often are versions of straight-line repairs, with the Mulliken technique being the more commonly performed (Fig. 45-15). In the bilateral cleft lip deformity, the new philtrum is made from the prolabium and is united to the lateral lip elements on top of the repaired orbicularis oris muscle.²²

CLEFT PALATE

During the eighth to twelfth weeks of gestation, the mandible becomes more prognathic, the tongue drops from beneath the clefted lateral palatine processes, and the palatal shelves migrate upward into a more horizontal position and fusion occurs. A cleft palate results from the failure of fusion of the two palatal processes. As with labial clefing, isolated clefts of the palate are multifactorial in etiology, and isolated clefts of the palate are more likely to be associated with other anomalies. Between 8 to 10% of isolated clefts of the palate are associated with the 22q deletion of velocardiofacial syndrome.²³

The main goal of cleft palate surgery is to help the patient attain normal speech, which results from velopharyngeal competence. During speech, the soft palate, or velum, is moved posteriorly and superiorly, primarily by the levator palatini muscle sling that suspends the velum from the skull base. Velopharyngeal competence is obtained during attempted speech when the velum approximates the posterior pharyngeal wall, preventing air and liquid from regurgitating into the nasal cavity. Velopharyngeal competence allows intraoral pressure to be built up for speech sounds. A cleft palate precludes this from occurring and results in velopharyngeal incompetence, or VPI.

Because it is impossible for the oral and nasal cavities to be partitioned in the patient with a cleft palate, it is also difficult for the patient to develop negative intraoral pressure for an effective suck. Therefore, specialized nursers are used to dispense liquid into the infant's mouth during the suckling motions. Children with clefts of the palate have an increased incidence of otitis media; this may be related to the abnormality of the velar musculature and ineffective function of the eustachian tube. The increased incidence of otitis media can result in hearing loss if not treated appropriately. In addition, VPI and nasal air escape during speech results in hypernasal speech.

As with the repair of cleft lip and nose, the timing, technique, and protocols for cleft palate repair are controversial. Most agree that palate repair should be performed before the development of speech. The cleft palate usually is repaired when the infant is between 6 and 18 months of age. Cleft palate repair also is performed under general anesthesia, with the head slightly hyperextended and a retractor, such as the Dingman mouth gag, placed intraorally to retract the tongue and endotracheal tube. An epinephrine solution is injected into the palate. Techniques of hard palate closure include the use of unipedicled hard palate mucoperiosteal flaps as in the Wardill-Veau-Kilner repair or bipedicled hard palate mucoperiosteal flaps as in the von Langenbeck repair. Both the unipedicled and bipedicled hard palate palatoplasty techniques rely on the greater palatine neurovascular pedicle. Soft palate or velar closure techniques are divided into straight-line and Z-plasty procedures. With either a straight-line or Z-plasty velar repair, the levator palatini muscle should be independently repaired; this is called an *intravelar veloplasty*. The clefted levator is identified coursing sagittally in an anterior-posterior direction, abnormally inserted onto the posterior edge of the hard palate. In intravelar veloplasty, it is released from the posterior edge of the hard palate in the midline and dissected free from abnormal attachments to the aponeurosis of the tensor veli palatini muscle and superior constrictor laterally. After its complete release, the levator palatini muscle is united in the midline, with reconstruction of the levator muscle sling that suspends the velum from the skull base and aids in velopharyngeal competence.

The authors prefer the double opposing Z-plasty technique of soft palate or velar reconstruction known as the *Furlow palatoplasty*.²⁴ The procedure uses four triangular flaps, two oral and two nasal, with the posteriorly based flaps containing the released levator muscles. The Z-plasty lengthens the soft palate, prevents longitudinal scarring from a straight-line repair, and produces a secondary pharyngoplasty effect by narrowing the velopharyngeal port (Fig. 45-16).

A. Markings for the Furlow double opposing Z-plasty palatoplasty. **B.** Raising the oral flaps in a Furlow palatoplasty. **C.** The complete dissection of a Furlow palatoplasty.

Complications of palatoplasty include wound-healing problems resulting in a breakdown of the suture line and the development of a fistula. The literature reports fistula rates ranging from approximately 1 to 20%. Treatment of palatal fistulae is particularly challenging, because the recurrence rates have been noted to approach 96%. The second most common complication of palatoplasty is the incomplete correction of speech and the development of postoperative VPI. The literature reports postoperative VPI rates ranging from 10 to 40%. Some of the best rates of velopharyngeal competence have been reported with the Furlow double opposing Z-plasty palatoplasty. Postoperative VPI is treated with pharyngoplasty: either a posterior pharyngeal flap pharyngoplasty or a sphincter pharyngoplasty. A posterior pharyngeal flap is a static flap formed from the posterior pharyngeal wall including mucosa and a portion of the superior constrictor muscle. The midline superiorly based pharyngeal flap is inset into the posterior free edge of the soft palate, permanently attaching it to the posterior pharyngeal wall. The sphincter pharyngoplasty has been reported to involve creation of a dynamic sphincter made with the bilateral posterior tonsillar pillars containing the palatopharyngeus muscle. The superiorly based tonsillar pillars are elevated from the lateral pharynx and inset into a horizontal incision on the posterior pharyngeal wall at the level of the adenoid pad.

Craniofacial Anomalies

HISTORY, OVERVIEW, AND CLASSIFICATION SYSTEM

Craniofacial surgery is the subspecialty of plastic surgery dealing with hard and soft tissue deformities of the craniofacial skeleton, treating the congenital, developmental, and acquired defects of the cranial and/or facial skeleton. Craniofacial surgery addresses the functional and equally important appearance-related issues surrounding these deformities. Attempting to separate the functional impairment from the appearance-related issues is arbitrary, because it can be argued that the most important function of a face is to look like a face.²⁵ Numerous studies have established the importance of facial form and the significant emotional impact that facial

deformities have on a person's life and sense of self.

The field of craniofacial surgery finds its origins in the aftermath of the world wars and the need to treat massive facial injuries. In 1967, Dr. Paul Tessier, now recognized as the father of craniofacial surgery, first publicly presented his concepts of using wide exposure and a transcranial route to treating craniofacial deformities with large segmental movements of bone. An American disciple of Dr. Tessier, Dr. Linton Whitaker of the Children's Hospital of Philadelphia, working with the Committee on Nomenclature and Classification of Craniofacial Anomalies of the American Cleft Palate-Craniofacial Association, presented a simple and practical classification system for craniofacial anomalies (Table 45-10).

Table 45-10 Classification of Craniofacial Anomalies
I. Clefts

b. Acentric
II. Synostoses
a. Symmetric
b. Asymmetric
III. Atrophy, hypoplasia
IV. Neoplasia, hypertrophy, hyperplasia
V. Unclassified

It is the standard of care today that an interdisciplinary team of experts with specialized knowledge and training in treating children with craniofacial anomalies care for children who have such anomalies. The preoperative work-up and evaluation must be thorough and should include imaging (computed tomography, or CT; magnetic resonance imaging, or MRI; cephalography), photography, blood work, anesthesia consultation, and other components as the condition dictates. Craniofacial procedures are often long, complicated surgeries of significant magnitude, with an attendant risk of blood loss, serious morbidity, and even mortality. Significant blood loss is a realistic possibility, and preparation for blood conservation and transfusion must be made. The routine surgical approach to the craniofacial skeleton can be via a coronal incision, and after a bifrontal craniotomy, the orbital and facial skeleton can be addressed. Bone grafts for reconstruction can be split calvarial grafts or, alternatively, grafts from the ribs or iliac crest. Rigid fixation is obtained with bioresorbable plates, screws, and sutures. Despite the magnitude of the procedures, significant morbidity (blindness, brain injury, significant infection, cerebrospinal fluid leak, intracranial hematoma) or mortality is rare.

CRANIOFACIAL CLEFTS

The rare craniofacial clefts have been subclassified by Tessier (Fig. 45-17). The Tessier classification of craniofacial clefts considers the orbit as the center around which the clefts radiate as the spokes of a wheel, numbered from 0 to 14. The facial clefts (0 to 7) and their cranial extensions (8 to 14) are often associated and total 14 (Fig. 45-18). Treacher Collins syndrome (Fig. 45-19), also known as *mandibulofacial dysostosis*, is a type of craniofacial clefing disorder representing bilateral 6-7-8 clefts. This autosomal dominant disorder with variable penetrance has the following manifestations: hypoplasia of the zygomas, asymmetry and hypoplasia of the mandible, ear anomalies, and colobomas of the lower eyelids. Craniofacial microsomia, also known as *hemifacial microsomia*, can be classified as a form of clefing as well (Fig. 45-20). Manifestations of this anomaly usually involve the hard and soft tissue of one half of the craniofacial skeleton. Deformities range in severity from complete absence of an affected facial component (globe, mandible, ear) to mild asymmetries. Ear deformities range from complete absence of the ear to only preauricular skin tags. Similarly, the eye deformities range from complete absence of the globe to various anomalies including epibulbar dermoids. Hypoplasia of the temporal skull, maxilla and zygoma, and orbit are seen in varying degree and affect the underlying skeleton as well as the overlying soft tissues. The classical deformity of hemifacial microsomia affects the mandible. Hypoplasia of the hemimandible, as well as the maxilla, results in dental malocclusions (Fig. 45-20C). Mandibular hypoplasia may range from minor underdevelopment of otherwise normal components to

complete absence of the condyle, ramus, and proximal body. Treatment of hemifacial microsomia includes management of the airway and attention to other functional conditions. Treatment of the mandibular deformity includes distraction osteogenesis during growth and orthognathic procedures at skeletal maturity. Ear deformities are reconstructed with techniques using costal cartilage and local soft tissue. Soft tissue deficiencies of the hemiface can be treated with fat injections, dermal-fat grafts, or free tissue transfer. Orbital hypertelorism is yet another type of midline craniofacial (0-14) clefting. *Orbital hypertelorism* is defined as a lateralization of the entire orbit, increasing the intraorbital distance and resulting from midline conditions such as encephaloceles, frontonasal dysplasia, and syndromic craniosynostosis. The treatment of severe orbital hypertelorism includes a transcranial approach to four-wall orbital box osteotomies, resection or treatment of the abnormal midline process, mobilization, medialization of the orbital complexes, and nasal reconstruction with a cantilever nasal bone graft.

CRANIOSYNOSTOSIS

The craniosynostoses are a group of disorders that result from the abnormal obliteration or premature fusion of the cranial sutures. The craniosynostoses can be subdivided into simple or single-suture craniosynostoses, and complex, syndromic, or multiple-suture craniosynostoses. The cranial sutures allow for the normal growth of the skull, and therefore the classic presentation of craniosynostosis is an abnormal head shape. The resultant abnormal head shapes are secondary to an inhibition of skull growth at right angles to the fused suture and a compensatory overexpansion of the skull perpendicular to the fused suture into areas with open sutures. These abnormal head shapes provide a basis for the classification of craniosynostoses. In addition to appearance-related deformities resulting from craniosynostosis, important functional aspects include the potential for intracranial hypertension, which may result from brain growth restricted by an unyielding skull. The chances of intracranial hypertension increase with the number of sutures affected. Blindness and mental deficiencies secondary to an increase in intracranial pressure can likely be prevented by the surgical expansion of the cranium to release the fused suture, correct the abnormal head shape, and remodel the skull. The standard procedure used today in the correction of these synostotic deformities is fronto-orbital advancement. Fronto-orbital advancement, performed using a transcranial approach, includes a frontal craniotomy and orbital repositioning. The complex or multisutural synostoses are often syndromic, resulting from gain-in-function mutations of the fibroblast growth factor receptors (FGFR1, FGFR2, FGFR3). These syndromes of craniosynostosis include the Apert, Crouzon, Pfeiffer, and Saethre-Chotzen syndromes. The syndromic craniosynostoses not only include bicoronal synostosis but also involve the midface with resulting exorbitism and midface hypoplasia. Multilevel airway anomalies, obstructive sleep apnea, corneal exposure, intracranial hypertension, feeding difficulties, and severe malocclusion are some of the associated anomalies found in children with syndromic craniosynostoses. In addition to fronto-orbital advancement, facial osteotomies (i.e., Le Fort III craniofacial dysjunction) are required to treat the orbital, midfacial, and occlusal deformities.

ATROPHY AND HYPOPLASIA

The categories of craniofacial atrophy and hypoplasia encompass many conditions such as Pierre Robin sequence and Romberg's

progressive hemifacial atrophy. Pierre Robin sequence is characterized by three pathognomonic findings: microretrognathia, glossoptosis, and respiratory distress. Pierre Robin sequence may or may not be associated with a palatal cleft. It is thought by some to occur secondary to a fixed and flexed fetal head position that inhibits mandibular growth and results in micrognathia. The micrognathia prevents the natural caudal migration of the tongue from between the clefted palatal shelves, and the resulting deformity as described earlier. The functional consequences include intermittent respiratory obstruction and obstructive sleep apnea that may affect feeding, growth, and safety of the airway. Treatment of a child mildly affected with Pierre Robin sequence may include simply positioning the child prone until the child "grows out" of the condition. However, if the child is severely affected and unable to feed adequately or has an unsafe airway, surgical intervention is required. For decades, tracheotomy was the initial and definitive treatment of choice; however, today many initially attempt a tongue-lip adhesion, treating the glossoptosis and alleviating respiratory obstruction by suturing the tongue tip to the lower lip. The tongue-lip adhesion is taken down at the time of palatoplasty. Should the tongue-lip adhesion not adequately correct the obstruction, then neonatal mandibular distraction can be used to correct the underlying microretrognathia and relieve the obstructive symptoms (Fig. 45-21). Another syndrome of atrophy and hypoplasia is Romberg's progressive hemifacial atrophy, also known as *Parry-Romberg syndrome* (Fig. 45-22). Romberg's disease is a disorder of unknown etiology, beginning in childhood or adolescence, in which hemifacial atrophy of the skin, subcutaneous fat, muscle, bone, and cartilage progresses for a variable period of time before spontaneously ceasing or "burning out" 2 to 10 years after beginning. Most believe treatment should be delayed until at least 1 year after the process of atrophy has ceased. Some hematologists and oncologists have treated the early presentation of Romberg's disease with chemotherapy. After the cessation of atrophy, reconstruction of the craniofacial skeleton and soft tissues may begin with bone and/or cartilage grafts, alloplastic implants, dermal-fat grafts, fat grafting, and possibly free tissue transfers.

HYPERPLASIA, HYPERTROPHY, AND NEOPLASIA

The categories of craniofacial hyperplasia, hypertrophy, and neoplasia encompass a wide variety of conditions affecting the craniofacial skeleton. These include vascular anomalies (discussed later in this chapter), neurofibromatosis, hemifacial hypertrophy, and bony conditions such as osteomas and fibrous dysplasia. Fibrous dysplasia can be monostotic, affecting a single location, or polyostotic, affecting more than a single location in the skeleton; it may be associated with skin pigmentation abnormalities and endocrine involvement, and be termed *polyostotic* or *McCune-Albright syndrome*. Treatment of fibrous dysplasia of the craniofacial skeleton includes block resection and reconstruction with bone grafts. If extensive involvement exists and block resection is not possible or feasible, partial resection and contouring of the affected bone is possible, as long as there is the understanding that long-term outcomes and the behavior of the disease are unpredictable.

Vascular Anomalies

Vascular anomalies are vascular birthmarks that all appear similar: flat or raised, in various shades of red and purple.²⁶ For centuries, they have been named by similarly colored food and drink (i.e., strawberry hemangioma, port-wine stain). Today these vascular birthmarks have been biologically classified as either *hemangiomas* or *vascular malformations*. The Greek suffix *-oma* means "swelling" or "tumor" and today connotes a lesion characterized by hyperplasia. Hemangiomas are congenital vascular anomalies that undergo a phase of rapid growth followed by slow regression, based on endothelial cell kinetics. Malformations are abnormal vascular channels lined with quiescent endothelium, usually are seen at birth, never regress, and have the potential to expand. The differential diagnosis of vascular anomalies is routinely made by a detailed accurate history and clinical examination. For deep lesions, radiographic studies may help determine the diagnosis. Biopsy is used if the diagnosis is uncertain or there is concern over the potential of malignancy.

HEMANGIOMAS

The infantile hemangioma is the most common birthmark, affecting 10 to 12% of whites, with a 3-5:1 predilection for females and an increased incidence in preterm infants (23%) (Fig. 45-23). Hemangiomas are solitary in 80% of cases and multiple in 20%. In children with multiple (more than three) cutaneous hemangiomas, abdominal ultrasound is suggested to rule out hemangiomatosis with visceral

involvement. Hemangiomas do not cause bleeding disorders; however, more invasive lesions such as kaposiform hemangioendothelioma can result in Kasselbach-Merritt syndrome, characterized by platelet trapping and disordered bleeding. Hemangiomas are usually first noted around 2 weeks of life as a flat pink spot, often confused with a superficial scratch. Around the second month of life they enter the *proliferating phase* in which rapid growth is seen caused by plump, rapidly dividing endothelial cells. If the hemangioma is superficial, the skin becomes crimson and raised; if the lesion is deep, a dark blue or purple color is noted with less superficial swelling. Hemangioma growth frequently peaks before the first year, and then the lesions enter the *involuting phase* in which growth is commiserate with the child. The involuting phase is characterized by diminishing endothelial activity and luminal enlargement. The lesion begins to "gray," losing its intense reddish color and taking on a purple-gray shade with overlying "crepe paper" skin. The involution phase continues until 5 to 10 years of age. Regression of the lesion is then complete. The *involved phase* begins in 50% of children by 5 years of age and in 70% by 7 years. If there was cutaneous ulceration during the proliferative phase, a cutaneous scar may persist, along with the yellow-gray crepe paper-like skin with fibro-fatty deposition. In 50% of children, near-normal skin is restored. The treatment of hemangiomas is largely observational, with reassurance of parents that regression and involution will occur. Cutaneous ulceration secondary to a proliferating hemangioma occurs in 5% of cases and more frequently with lip or urogenital lesions. Local wound care, topical application of lidocaine for pain, and laser cauterization may be beneficial treatment modalities. Problematic or endangering hemangiomas (i.e., periocular lesions threatening amblyopia, airway lesions, facially disfiguring lesions) occur in 10% of cases. The first-line treatment for problematic hemangiomas is systemic corticosteroid therapy, which is particularly effective (85% response rate). Second-line therapies include interferon and vincristine, each with its own attendant effectiveness and morbidity. Laser therapy has been claimed by some to be effective in the treatment of early hemangiomas; however, there has been no conclusive proof that laser therapy either diminishes lesion bulk or induces involution. Laser therapy has been effective in lightening affected skin. Surgery for hemangiomas in the proliferating phase is largely limited to treatment of problematic lesions (i.e., eyelid lesions threatening amblyopia). Hemangioma surgery usually is reserved for the treatment of secondary deformities and residual fibro-fatty depositions, among other indications.

VASCULAR MALFORMATIONS

Vascular malformations are subclassified by vessel type, such as lymphatic, capillary, venous, or arterial, and by rheologic characteristics, such as slow flow and fast flow. Slow-flow lesions include capillary malformations (CMs) and telangiectasias, lymphatic malformations (LMs), and venous malformations (VMs). Fast-flow lesions include arterial malformations (AMs) and arteriovenous malformations (AVMs). In addition, there are combined malformations. One such combined lesion occurs in Klippel-Trénaunay syndrome in which CMs, LMs, and VMs are found and may be associated with soft tissue and skeletal hypertrophy in one or more of the limbs (Fig. 45-24A).

A. Klippel-Trénaunay syndrome, with combined vascular anomaly (capillary malformation, lymphatic malformation, venous malformation) of the leg. **B.** Sturge-Weber syndrome, with V1 and V2 capillary malformation of the left face. **C.** Lymphatic malformation of the neck, previously referred to as *cystic hygroma*. **D.** Venous malformation of the forehead.

CMs are pink-red macular vascular stains that are present at birth and persist throughout life. These lesions tend to become more verrucous and darker throughout life. CMs are effectively treated with a pulsed-dye laser, and the results often are better with treatment in infancy and young childhood. Laser therapy often is repetitive and prolonged. CMs of the head and neck, historically called *port-wine stains*, may be associated with Sturge-Weber syndrome, which includes vascular involvement of the leptomeninges and ocular pathology (Fig. 45-24B).

LMs are anomalous lymphatic channels that never regress and have the potential to affect underlying muscle and bone, causing significant swelling and bony overgrowth. They have historically been called *lymphangiomas* or *cystic hygromas* (Fig. 45-24C). LMs can be classified as microcystic, macrocystic, or both. LMs expand or contract with the flow of lymph, infection, or intralesional hemorrhage. Superficial LMs that affect the skin often produce cutaneous vesicles that may coalesce and weep lymph fluid. Sclerotherapy remains a major treatment modality for LMs, and lesions that are macrocystic can be aspirated before sclerotherapy. Although surgery rarely removes the entire lesion, surgical resection is the only possibility for cure. These resections often are challenging, lengthy, and associated with significant blood loss, and the potential exists for regeneration of lymph channels and recurrence of the LMs postoperatively.

VMs are frequently bluish, soft, and compressible, and swell when dependent (Fig. 45-24D). VMs grow with the child, expand slowly, and may enlarge during puberty. Patients often complain about stiffness and pain with thrombosis. VMs can affect the skin, muscle, and bone. MRI is the modality of choice for imaging these lesions. Preoperative sclerosis followed by surgical extirpation is the treatment of choice for VMs that cause functional or appearance-related disability. VMs have the tendency to recanalize and re-expand. Use of elastic support stocking and low-dose aspirin therapy are important adjunctive treatment modalities for VMs involving the legs.

Pure AMs are rare and more commonly present as AVMs. AVMs appear as red violaceous skin with a palpable mass beneath. Local warmth, bruit, and thrill are frequently present. AVMs have the likely consequences of ischemic changes, ulceration, intractable pain, and intermittent bleeding. The natural history of AVMs has been described as consisting of four stages: quiescence, expansion, destruction, and decompensation. Usually, treatment for AVM is initiated when signs and symptoms of ischemic pain, ulceration, bleeding, or

hemodynamic instability (stages 3 and 4) are evident. Surgical treatment includes arterial embolization to temporarily occlude the nidus 24 to 72 hours before surgical extirpation. The nidus and overlying affected skin must be widely excised, and reconstruction can be performed afterward.

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMNs) contain nevus cells and are usually present at birth. Lesions are frequently light to dark brown and round or oval, and vary greatly in size, pattern, and anatomic location. The most common location of CMNs is the trunk, followed by the extremities and head and neck. Frequently, larger lesions are associated with multiple smaller satellite lesions. Over time, these lesions may become less (or sometimes more) pigmented and develop hypertrichosis and a variegated texture, including nodularity. Small CMNs are <1.5 cm in diameter, and large ones are >10 cm. Giant CMNs usually are >20 cm in their greatest dimension in adulthood, and this correlates with a 9-cm scalp lesion or a 6-cm trunk lesion in an infant. All CMNs should be monitored for worrisome changes that indicate the need for biopsy, including ulceration, uneven pigmentation, change in shape, and nodularity. There is controversy over the actual incidence of malignant transformation of CMNs; however, most experts believe that melanoma may arise directly from a CMN. No convincing study to date has proven that excision of a CMN reduces the rate of malignant transformation to melanoma; however, many clinicians feel that excision serves at least to debulk the lesion. The reported lifetime risk for melanoma arising in small or large CMNs is between 0 and 5%; the risk for giant CMNs is estimated to be between 5 and 10%.²⁷ In addition to being at risk for melanoma, patients with large or giant CMNs are at risk for neurocutaneous melanocytosis (leptomeningeal melanosis), and this condition includes collections of melanocytes in the leptomeninges. Neurocutaneous melanocytosis carries a lifetime nonreducible risk of central nervous system melanoma and other morbidity and mortality from seizures, hydrocephalus, and other central nervous system conditions. MRI screening for infants born with large or giant CMNs is recommended to make the diagnosis of neurocutaneous melanocytosis.

Many different treatments have been advocated for the child with CMN; however, the overwhelming goals are to remove (or at least reduce) the risk of malignant transformation, preserve function, and improve cosmesis. Dermabrasion, chemical peels, and laser therapy have been reported to improve the appearance; however, none of these modalities completely removes nevus cells. To address malignant potential, only complete excision is a possible solution, and this is difficult, because nevus cells may extend beyond the skin and into the deep subcutaneous tissue and even the underlying muscle. The surgical options include direct excision and primary closure, serial excision, excision and skin grafting, and staged tissue expansion with subsequent lesion excision and lap reconstruction (Fig. 45-25). Treatment options have particular indications with respect to the location of the nevus. Scalp lesions are best treated with tissue expansion. Full-thickness skin grafting is best used for ear and eyelid reconstruction. Tissue expansion is associated with increased morbidity in lower extremity reconstruction, and therefore excision and grafting, even with previously expanded full-thickness skin grafts, is often the treatment of choice. In summary, CMNs often are treated surgically to decrease the risk of malignant degeneration to melanoma as well as to correct the significant appearance-related deformity.

RECONSTRUCTIVE SURGERY

Facial Reconstruction after Fracture

GENERAL PRINCIPLES

As technologic advances raise the level of energy involved in modern systems of transportation, recreation, and weaponry, so follow increases in the degree of maxillofacial destruction related to misadventures with this technology. The first phase of care for the patient with maxillofacial trauma is activation of the advanced trauma life support protocol. Concomitant injuries beyond the face are the rule rather than the exception. The most common life-threatening considerations in the facial trauma patient are airway maintenance, control of bleeding, identification and treatment of aspiration, and identification of other injuries. Once the patient's condition has been stabilized and life-threatening injuries treated, attention is directed to diagnosis and management of craniofacial injuries.

Physical examination of the face with attention to lacerations, bony step-offs, instability, tenderness, ecchymosis, facial asymmetry, and deformity guides the examiner to underlying hard tissue injuries. Traditional specialized radiography has largely been replaced by widely available high-resolution CT. Coronal, sagittal, and three-dimensional reconstructions of images further elucidate complex injuries.

MANDIBLE FRACTURES

Mandibular fractures are common injuries that may lead to permanent disability if not diagnosed and properly treated. The mandibular angle, ramus, coronoid process, and condyle are points of attachment for the muscles of mastication, including the masseter, temporalis, lateral pterygoid, and medial pterygoid muscles (Fig. 45-26). Fractures are frequently multiple, and disturbances in dental occlusion reflect the forces of the many muscles of mastication on the fracture segments. Dental occlusion is perhaps the most important basic relationship to understand about fracture of the midface and mandible. The Angle classification system describes the relationship of the

maxillary teeth to the mandibular teeth. Class I is normal occlusion, with the mesial buccal cusp of the first maxillary molar fitting into the intercuspal groove of the mandibular first molar. Class II malocclusion is characterized by anterior (mesial) positioning, and class III malocclusion is posterior (distal) positioning of the maxillary teeth with respect to the mandibular teeth (Fig. 45-27).

Nonsurgical treatment may be used in situations in which there is minimal to no displacement, preservation of the pretraumatic occlusive relationship, and normal range of motion. The goals of surgical treatment include restoration of pretraumatic dental occlusion, reduction and stable fixation of the fracture, and repair of soft tissue. Operative repair involves seating of the condyles within the glenoid fossa, achievement of maxillary-mandibular fixation with arch bars or intermaxillary screws to establish proper dental occlusion, and intraoral, extraoral, or combination surgical exposure of fracture lines. The mandibular plating approach follows one of two schools of thought: rigid fixation as espoused by the Association of Internal Fixation group (AO/ASIF) and less rigid but functionally stable fixation (Champy technique). Regardless of the stabilization approach, one of the postoperative objectives is release from maxillary-mandibular fixation and resumption of range of motion as soon as possible to minimize the risk of ankylosis. Other potential complications include infection, nonunion, malunion, malocclusion, facial nerve branch injury, infra-alveolar or mental nerve injury, and dental fractures.

ORBITAL FRACTURES

Treatment of all but the simplest orbital injuries should include evaluation by an eye specialist to assess visual acuity and rule out globe injury. Orbital fractures may involve the orbital roof, floor, or lateral or medial walls. The most common orbital fracture is the orbital floor blow-out fracture caused by direct pressure to the globe and sudden increase in intraorbital pressure. Because the medial floor and inferior medial wall are made of the thinnest bone, fractures occur most frequently at these locations. These injuries may be treated expectantly if they are sufficiently small and without complication. However, larger blow-out fractures and those associated with enophthalmos (increased intraorbital volume), entrapment of inferior orbital tissues (diagnosed via the forced duction test), or diplopia lasting >2 weeks generally require surgical treatment.²⁸ There are many approaches to the orbital floor, including the transconjunctival, subciliary, and lower blepharoplasty incisions. All provide access to the orbital floor and allow for repair with a multitude of different autogenous and synthetic materials. Late complications include persistent diplopia, enophthalmos, ectropion, and entropion.

Lateral and inferior orbital rim fractures also are not uncommon and are often associated with the zygomaticomaxillary complex fracture pattern, as discussed later.

Special mention should be made of two uncommon complications after orbital fracture. Superior orbital fissure syndrome results from

compression of structures contained in the superior orbital fissure in the posterior orbit. These include cranial nerves III, IV, and VI, and the first sensory division of cranial nerve V. Compression of these structures leads to symptoms of eyelid ptosis, globe proptosis, paralysis of the extraocular muscles, and anesthesia in the cranial nerve V1 distribution. If the optic nerve (cranial nerve II) is also involved, symptoms include blindness and the syndrome is dubbed *orbital apex syndrome*. Both of these syndromes are medical emergencies, and steroid therapy or surgical decompression is considered.

ZYGOMA AND ZYGOMATICOMAXILLARY COMPLEX FRACTURES

The zygoma forms the lateral and inferior borders of the orbit. It articulates with the sphenoid bone in the lateral orbit, the maxilla medially and inferiorly, the frontal bone superiorly, and the temporal bone laterally (Fig. 45-28). Zygoma fractures may involve the arch alone or many of its bony relationships. Isolated arch fractures manifest as a flattened, wide face with associated edema and ecchymosis. Nondisplaced fractures may be treated nonsurgically, whereas displaced and comminuted arch fractures may be reduced and stabilized indirectly (Gilles approach) or, for more complicated fractures, directly through a coronal incision.

Fig. 45-28.

A

The zygomaticomaxillary complex (ZMC) fracture involves disruption of the zygomatic arch, the inferior orbital rim buttress, the zygomaticomaxillary buttress, the lateral orbital wall, and the zygomaticofrontal buttress. The fracture segment tends to rotate laterally and inferiorly, creating an expanded orbital volume, limited mandibular excursion, an inferior cant to the palpebral fissure, and a flattened malar eminence. ZMC fractures are almost always accompanied by numbness in the infraorbital nerve distribution and subconjunctival hematoma. Displaced fractures are treated by exposure through multiple incisions to gain access to all of the buttresses requiring fixation. These include the upper eyelid incision (zygomaticofrontal buttress and lateral orbital wall), the subtarsal or transconjunctival incision (orbital floor and infraorbital rim), and the maxillary gingivobuccal sulcus incision (zygomaticomaxillary buttress). Again, significantly complex zygomatic fractures require wide exposure through a coronal approach.⁵

NASO-ORBITAL-ETHMOID FRACTURES

Naso-orbital-ethmoid (NOE) fractures are often part of a constellation of panfacial fractures and intracranial injuries. Anatomically, the fracture pattern involves the medial orbits, nasal bones, nasal processes of the frontal bone, and frontal processes of the maxilla. These injuries result in severe functional deficit and cosmetic deformity from collapse of the nose, ethmoids, and medial orbits; displacement of medial canthal ligament fixation; and nasolacrimal apparatus disruption. Telecanthus is produced by splaying apart of the nasomaxillary buttresses to which the medial canthal ligaments are attached. Treatment typically involves plating or wiring all bone fragments meticulously, potentially with primary bone grafting, to restore their normal configuration. Key to the successful repair of an NOE fracture is the careful re-establishment of the nasomaxillary buttress and restoration of the pretrauma fixation points of the medial canthal ligaments. If comminution is severe, this may be achievable using transnasal wiring of the ligaments.

FRONTAL SINUS FRACTURES

The region of the frontal sinus is a relatively weak structural point in the upper face. For this reason, it is a common location for fracture in facial trauma. The paired sinuses each have an anterior bony table that determines the contour of the forehead and a posterior table that separates the sinus from the dura. Each sinus drains through the medial floor into its frontonasal duct, which empties into the middle meatus within the nose. Treatment of a frontal sinus fracture depends on the fracture characteristics (Fig. 45-29).

NASAL FRACTURES

The nose is the most common facial fracture site due to its prominent location, and such fracture can involve the cartilaginous nasal septum, the nasal bones, or both. It is important to perform an intranasal examination to determine whether a septal hematoma is present. If present, a septal hematoma must be incised, drained, and packed to prevent pressure necrosis of the nasal septum and long-term midvault collapse. Closed reduction of nasal fractures may be performed under local or general anesthesia. Unfortunately, many, if not most, show some deformity upon final healing, requiring rhinoplasty if airway obstruction is present or if improved appearance is desired.

PANFACIAL FRACTURES

Fractures of multiple bones in various locations fall into the category of panfacial fracture. These may involve frontal and maxillary sinus fractures, NOE fractures, orbital and ZMC fractures, palatal fractures, and complex mandible fractures. The difficulty in the repair of these injuries lies not in the technical aspects of fixation but in the re-establishment of normal relationships between facial features in the absence of all pretraumatic reference points. Without proper correction of bony fragment relationships, facial width is exaggerated and facial projection is lost. The key point in approaching the patient with a panfacial fracture is first to reduce and repair the zygomatic arches and frontal bar to establish the frame and width of the face. The nasomaxillary and zygomaticomaxillary buttresses may then be repaired within this correct frame. Next, the maxilla may be reduced to this framework, followed by palatal fixation if needed. Finally, now that the midface relationships have been corrected, maxillary-mandibular fixation can be applied with the mandible in correct occlusion followed by plating of any mandibular fractures.²⁹

Ear Reconstruction

Acquired defects of the auricle have many causes, and many different choices for reconstruction are available. Reconstructive approach often is determined by the size and location of the defect. Small helical lesions may be simply excised as a wedge and closed primarily. Larger defects of the upper and middle thirds of the ear may use antihelical and conchal cartilage reduction patterns to reduce the circumference of the helix to allow primary closure. When helical defects are too large for this solution, local flaps may be used to close or re-create the missing tissue. Postauricular flaps created in staged procedures may be manipulated to create a skin tube mimicking the furled helix and bridging the gap of a defect. Alternatively, use of an Antia-Buch chondrocutaneous advancement flap combined with cartilaginous reduction allows for closure of defects³⁰ (Fig. 45-30). Even larger defects of the upper and middle thirds of the ear may be reconstructed with large local skin flaps combined with contralateral cartilage grafts or contralateral composite grafts. Although ear lobe defects are relatively simple to close primarily, lower third auricular defects that involve more than just the lobe are complex and require cartilaginous support, often combined with local skin flaps.

Nasal Reconstruction

Reconstruction of the nose requires appreciation of the nine aesthetic subunits that are defined by normal anatomic contours and lighting patterns (Fig. 45-31). In general, if a defect involves $\geq 50\%$ of a subunit, the remainder of the subunit should be excised and included in the reconstruction. The nose can be thought of as being composed of three layers: skin cover, structural support, and mucosal lining. When a defect or anticipated defect is evaluated, it is useful to consider what layers of tissue will be missing so that a reconstruction can be devised that replaces each layer. Nasal reconstruction methods draw on the full arsenal of reconstructive techniques. Healing by secondary intention is successfully used in concavities such as the alar groove. Split- or full-thickness skin grafts may be used for superficial defects of the nasal dorsum or sidewall. Composite grafts may be used for the nasal tip or alar rim (see Fig. 45-3). Local random pattern flaps are useful in closing small defects of the dorsum and tip, and may be combined with cartilage grafts if structural support is needed. Axial pattern flaps are commonly used for larger defects. These flaps have the advantage of being able to cover and revascularize underlying cartilage grafts and enjoy a close color match to surrounding skin. Workhorse flaps often used in nasal reconstruction include the nasolabial flap and the paramedian forehead flap (Fig. 45-32). Even larger defects may require scalping flaps or free radial forearm flaps. Split calvarial cantilever bone grafts may provide the nasal dorsum support. Lining is generally achieved with scar tissue turnover flaps, mucoperichondrial flaps from within the nasal vestibule, or skin grafting of the underside of transposed flaps.

Lip Reconstruction

The lips are important for articulate speech, eating and maintenance of oral competence, facial expression, and aesthetic harmony of the lower face. Three layers of tissue form the upper and lower lips: skin, muscle, and mucosa. Blood supply is through the facial artery and its branches to the lip, the superior and inferior labial arteries. Lip defects can arise from trauma, burns, neoplasms, congenital lesions, clefts, or infection. The most common malignancy in the upper lip is basal cell carcinoma, and the most common in the lower lip is squamous cell carcinoma. As with almost all types of reconstruction, choice of technique is heavily dependent on defect size, location, and deficient structures. The goals of lip reconstruction are restoration of the competent oral sphincter with vermillion apposition, preservation of sensation, and avoidance of microstomia, all while preserving a near-normal static and dynamic appearance. In the upper and lower lip, vermillion-only defects can be corrected with advancement of the labial mucosa, often called a *lip shave*. In defects of less than one third the horizontal length, enough redundancy is present to allow primary closure. More complex decisions must be made for defects that are between one third and two thirds of the total lip length. The two categories of lip flap technique are transoral cross-lip flaps and circumoral advancements flaps. Cross-lip flaps include the Abbé flap and the Estlander flap. The Abbé flap was originally designed to reconstruct central upper lip (tubercle) defects with lower lip full-thickness tissue vascularized by one of the labial arteries (Fig. 45-33). The technique requires a second-stage procedure for division of the pedicle. The Estlander flap is similar in principle but is based laterally at the oral commissure and is used to reconstruct lateral upper or lower lip lesions. Both the Estlander and Abbé flaps are denervated, but sensation and perhaps even motor function return over months.³¹ The Karapandzic technique is an advancement-rotation flap technique designed for central lower lip defects. Although good function, sensation, and mobility are

preserved, a side effect is reduction in the size of the oral aperture. The Webster-Bernard technique uses cheek tissue advancement flaps to replace defects with full-thickness or partial-thickness cheek incisions extended laterally from the commissure (Fig. 45-34). When performed bilaterally, both the Karapandzic and the Webster-Bernard methods can be used to reconstruct a complete upper or lower lip.

In addition, microvascular free tissue transfer reconstruction may be necessary in cases where there is no remaining lip. The radial forearm free flap is the most commonly used for this purpose, usually transferred with the palmaris longus tendon for lip support.

Eyelid Reconstruction

The eyelids protect the eye from exposure and are another crucial aesthetic structure of the face. They consist of an anterior lamella (skin and orbicularis oculi muscle) and a posterior lamella (tarsus and conjunctiva). The eyelid blood supply is robust, and ischemia is rarely a concern in reconstruction.

UPPER EYELID

Defects comprising <25% of the upper eyelid can generally be closed primarily in pentagonal approximating fashion (Fig. 45-35). For defects involving 25 to 50% of the upper eyelid, lateral canthotomy (release of the lateral canthal tendon) and cantholysis (release of the superior limb of the lateral palpebral tendon) can be performed to allow advancement and are often combined with use of a lateral semicircular flap (Fig. 45-36). Defects larger than 50% of the upper eyelid may be reconstructed with a Cutler-Beard full-thickness advancement flap or a modified Hughes tarsoconjunctival advancement flap (Fig. 45-37).

LOWER EYELID

Lower eyelid reconstruction considerations parallel those for the upper eyelid. In addition, special attention must be given to the prevention of scleral visibility and ectropion, which can arise from excessive vertical tension due to either technique or scarring. Similar reconstructive methods may be used, including direct closure, semicircular flaps and canthal release, and advancement flaps. Grafts may also be used if the defect is partial thickness. Full-thickness contralateral upper eyelid skin grafts are suitable for replacing the anterior lamella. The posterior lamella requires sturdy, nonkeratinized graft tissue, such as cartilage (tarsal, ear, or nasal septal) or hard palate mucosal grafts, to allow globe apposition.³²

PTOSIS

In the normal eyelid, the orbicularis oculi muscle, Müller's muscle, and levator palpebrae muscle act in concert to open and close the palpebral aperture and to maintain the level of the upper eyelid with respect to the pupil. Eyelid ptosis is created by derangement of this cooperative action. Ptosis may be congenital or acquired. Congenital ptosis is caused by lid anomalies, ophthalmoplegia, and synkinesis, whereas acquired ptosis can be neurogenic, myogenic, or traumatic in nature. Horner's syndrome is a form of neurogenic ptosis caused by interrupted sympathetic innervation that leads to ptosis, miosis, and anhydrosis. A thorough evaluation of the ptotic patient includes a general eye and visual acuity examination, attention to signs of exposure or irritation, measurement of marginal-reflex distance, observation of the height of the supratarsal fold, and assessment of levator function. Severity of ptosis and degree of levator dysfunction are critical in deciding the appropriate corrective procedure (Table 45-11). Mild ptosis may be addressed with the Fasanella-Servat procedure, which involves excision of the superior tarsal edge, conjunctiva, and levator aponeurosis, and mullerectomy. Other corrections of mild ptosis usually involve variations on this procedure. Moderate ptosis with fair to good levator function may be treated with some

form of a levator aponeurosis shortening procedure. Severe ptosis with poor levator function requires use of an alternate eyelid motor. The frontalis muscle fascial sling technique, which uses strips of fascial grafts sutured to the frontalis muscle, is one such solution.

Table 45-11 Eyelid Ptosis Classification	
Classification of ptosis severity	
Mild	1–2 mm
Moderate	3 mm
Severe	4+ mm
Classification of levator function	
Excellent	12–15 mm
Good	8–12 mm
Fair	5–7 mm
Poor	2–4 mm

Skull and Scalp Reconstruction

SCALP RECONSTRUCTION

The scalp is formed of five layers: Skin, subCutaneous tissue, galea Aponeurotica, Loose areolar tissue, and Pericranium (SCALP). The scalp is well vascularized bilaterally by branches of the external carotid artery, including the superficial temporal arteries, the occipital arteries, and the posterior auricular arteries. In addition, the bilateral supraorbital and supratrochlear arteries contribute to the forehead and anterior scalp blood supply. These vessels run in the subcutaneous tissue layer, just superficial to the galea. Because of this rich blood supply, scalp lacerations can lead to dramatic blood loss, an event that usually can be curtailed by a simple running/locking suture closure.

Partial-thickness scalp loss due to trauma usually occurs at the level of the loose areolar tissue plane and is treated initially with débridement of devitalized tissue. If a partial-thickness defect is small enough, primary closure or skin graft can be used. Although the cosmetic result is often less than desirable, all layers of the scalp will accept a skin graft, including the calvaria if it is burred down to its diploë. Grafted areas may be reconstructed later with hair-bearing scalp skin through the use of flaps or tissue expansion. Because the scalp is relatively inelastic, scoring of the galeal layer often facilitates closure of full-thickness defects, but care must be taken to avoid lacerating the blood vessels just superficial to the galea. Larger areas of loss (4 to 8 cm) may be covered with large scalp flaps, as classically described by Orticochea.³³ Grafting of defects or donor sites leaves a visible area of alopecia. Tissue expansion has been very successful in replacing scarred or grafted regions with hair-bearing skin. Defects larger than 8 to 10 cm are best treated with microsurgical free tissue transfer. Total or subtotal scalp avulsions are rare injuries that usually occur when a person's long hair becomes caught in rotating machinery. These potentially devastating injuries are ideally treated by scalp replantation, because the avulsed segment usually has preserved vessels (Fig. 45-38).

CALVARIAL RECONSTRUCTION

Autogenous bone remains the material of choice for reconstruction of skull defects. Its advantages include resistance to infection and ability to heal with strength. All autogenous bone sources have the disadvantage of donor site morbidity. Bone grafts can be harvested from a normal area of the calvaria, of which the outer table may be used as a graft for defects of limited size. Care must be taken during harvest to avoid compromise of the inner table. Rib bone may also be used, either as a split-rib graft or as a microsurgical free osseous flap. Unfortunately, use of ribs to reconstruct the skull may give an unappealing "washboard" appearance to the scalp. Another disadvantage of bone grafts, although not flaps, is graft resorption over time.

Alternative materials to autogenous bone exist for calvarial reconstruction, including methyl methacrylate, titanium, and hydroxyapatite (with or without bone morphogenic protein). Although they have the advantage of no donor site, these plastics and metals are associated with a higher risk of infection necessitating removal. Various formulations of calcium phosphate hydroxyapatites are being actively studied as bone replacement materials.

Head and Neck Reconstruction

The head and neck region has a compact arrangement of critical and complex structures encasing the essential access routes to the GI and respiratory systems. The tissues of the face, mouth, and cavities serve as a primary communication interface with the external environment through facial and verbal expression. Therefore, cancer resections with adequate safety margins can be severely and multiply debilitating. The management of head and neck cancer patients demands an integrated multidisciplinary team approach that includes the skills of ablative and reconstructive surgeons, medical and radiation oncologists, pathologists, nutritionists, and functional and psychologic rehabilitation specialists.

TUMOR-ABLATIVE SURGERY

The freedom available to the ablative surgeon to completely excise a tumor is limited, at least partly, by the capability of the reconstructive surgeon to restore anatomic continuity and achieve successful wound healing. A neck dissection to remove cervical lymphatics and nodes may be performed for prophylactic or curative intent, for more accurate prognostication by operative staging, and/or for solidification of plans for adjunctive treatments. It is important to be familiar with the tumor, nodes, and metastases (TNM) classification and staging of head and neck cancers. The N and M parameters are fairly constant for most head and neck cancers, whereas the T parameter varies according to tumor location.

PRINCIPLES OF RECONSTRUCTION

The reconstructive surgeon aims to restore lost anatomic components adequately. Residual deficits, seemingly inconsequential, may progress to psychologic morbidity, societal malacceptance, and social withdrawal. Uncomplicated and timely wound healing is important to allow radiotherapy when indicated and smooth discharge to home and occupation.

Each defect can be addressed by a number of methods, but the technique must be decided for each individual patient. Although a more complex reconstruction might offer improved outcomes, it may bring an increased risk of complications. Some patients may therefore benefit from use of a simpler method with more acceptable anesthetic and operative risk rather than a gold-standard reconstruction. Such an approach may be appropriate, for example, for an elderly patient with an advanced T4 cancer and short life expectancy. Reconstruction is impossible for some functional losses, such as the enucleation of an eye, but replacement by a reasonably aesthetic prosthesis may be achievable.³⁴

RECONSTRUCTIVE OPTIONS BY REGION

Before the 1970s, autogenous tissue reconstructions were largely restricted to local or regional pedicled flaps, including the trapezius, pectoralis, and deltopectoral workhorse flaps. With microvascular free tissue transplantation, defects that were previously deemed nearly impossible to reconstruct can now be addressed in a single operation. Consequently, head and neck cancers that were historically unresectable have become more operable.

Intraoral Structures

The reconstructive choice for mouth floor, tongue, and other intraoral defects is dictated by the dimension of the defect, the volume of tissue lost, and residual tongue mobility. The tongue and adjacent mucosal surfaces heal exceptionally well, so small defects may be treated by primary closure or even left to heal spontaneously. Smaller defects, less than one fourth glossectomy, may be treated with a skin graft or perhaps primary closure if tongue mobility is preserved. Larger defects, more than one third glossectomy, call for reconstruction by free tissue transfer, commonly a free radial forearm or anterolateral thigh flap for smaller- or larger-volume defects, respectively. Total glossectomy defects are a major challenge, and there exists no ideal method to restore tongue motor functions. The primary goal is to protect the airway from aspiration. Swallowing and articulation are often suboptimal after total glossectomy reconstructions. Options include bulkier myocutaneous free flaps harvested from the anterolateral thigh, the back (latissimus dorsi), or the abdomen (rectus abdominis), or pedicled regional flaps (e.g., latissimus dorsi).³⁵

The reconstructive choice for other intraoral soft tissue defects should also take into consideration the specific characteristics of the

defect, such as its thickness and dimensions, and involvement of the oral commissure, facial skin, and/or neck. Buccal defects, for example, may be adequately treated with a radial forearm free flap or a thin anterolateral thigh flap. Thicker defects may be more appropriately reconstructed with a fasciocutaneous anterolateral thigh free flap. Those that extend through the full thickness of the cheek to involve the external facial skin may be reconstructed with a cutaneous or myocutaneous anterolateral thigh free flap that has been folded to address the internal mucosal, external skin, and intervening soft tissue defects simultaneously.³⁶ When the contour of the neck is sunken and asymmetric after a neck dissection, it is possible to improve symmetry by inseting part of the flap into the neck. This maneuver also obliterates dead space and helps protect the adjacent major neurovascular structures.

Mandible and Midface

Mandibular defects may arise from the ablation of tumors involving the bone itself or from the need to satisfy clearance margins for adjacent soft tissue tumors. Segmental mandibular defects can be classified as isolated bone defects, compound defects (bone and oral lining *or* skin), composite defects (bone, oral lining, *and* skin), or extensive composite defects (bone, oral lining, skin, and soft tissues).³⁷ The primary goals of mandibular reconstruction are to restore bony continuity, masticatory (with accurate dental occlusion) and speech functions, and facial contour, and to maintain tongue mobility. Early mandibular reconstructions involved the use of various prosthetic materials, with or without conventional bone grafts, and accompanying local or regional soft tissue flaps. Although small segmental defects are still reconstructible using autogenous bone grafts, they are not vascularized and therefore may fail, especially if radiotherapy is administered. The best option for most mandibular defects is the fibula bone free flap with an adjoined skin island supplied by reliable septocutaneous vessels (occasionally musculocutaneous perforators) from the peroneal artery and vein; this is termed a *fibula osteoseptocutaneous free flap* (Fig. 45-39).³⁸ Its many desirable characteristics include (a) the ability to withstand multiple osteotomies (as long as the periosteal blood supply is not interrupted) so that the bone can be folded to re-create the contour of any mandibular region, (b) an unmatched supply of sturdy bone length (22 to 26 cm in the adult) sufficient to reconstruct even angle-to-angle mandibular defects, (c) a bicorticocancellous structure that can tolerate the incorporation of osseointegrated dental implants, (d) acceptable donor site morbidity when the flap is appropriately harvested, and (e) a donor site location that allows a two-team approach for simultaneous tumor ablation and flap harvest.^{39,40} Reasonable alternatives include vascularized bone flaps from the iliac crest, radius, or ribs. Extensive composite mandibular defects may demand more than one free flap (such as one anterolateral thigh free flap with one fibula osteoseptocutaneous free flap) to reconstruct the entire anatomy in one operation.⁴¹ These principles are also applicable to other bony defects in the head and neck region, including maxillary and other midfacial defects. The goals of midface reconstruction include the restoration of facial contour and projection, achievement of accurately occlusive maxillary dentition, provision of appropriate infraocular support, and sealed separation of adjacent nasal and oral cavities.

Soft tissue and bony reconstruction of a compound segmental mandibular defect using a fibula osteoseptocutaneous free flap. **A.** Squamous cell carcinoma seen arising from the left buccal mucosa. **B.** Compound segmental left mandibular defect resulting from wide local excision of the neoplasm, which invaded the bone and local soft tissues. **C.** Fibula osteoseptocutaneous free flap; the pedicle artery (*red arrows*), pedicle vein (*blue arrows*), and osteotomy site (*yellow arrow*) are indicated. **D.** After contouring and miniplate fixation, the fibula osteoseptocutaneous free flap was inset into the left mandibular defect, with the skin paddle used to reconstruct the intraoral soft tissues. **E and F.** Four months after reconstruction the patient had good mouth opening and good cosmesis; note the skin paddle of the free flap visible intraorally.

Esophagus and Hypopharynx

The goals of reconstruction for esophageal and hypopharyngeal defects, which may be circumferential or partial, are to maintain luminal patency, restore speech and swallowing, and avoid strictures, fistulas, and GI anastomotic leaks. Reconstructive options for partial defects include primary closure, if luminal narrowing is insignificant, and skin (or dermal) grafts for partial-lining defects. A regional muscle flap may be useful for patching small full-thickness defects, but larger defects call for free tissue transfer of a jejunal flap or a

tubed fasciocutaneous flap. The jejunal flap procedure was the first successful free tissue transfer in humans, performed in 1957 for reconstruction of the cervical esophagus. It has since become a robust option for this purpose. A proximal segment is harvested based on its mesenteric blood supply and inset into the neck in the isoperistaltic direction. Disadvantages of the jejunal flap include halitosis, slow swallowing transit times, and a "wet" voice. Tubed fasciocutaneous free flap options, including the anterolateral thigh and radial forearm flaps, are also popular; however, they may have a greater risk of stricturing than the free jejunal flap. Nevertheless, proponents of such flaps favor the resultant vocal qualities and faster transit times.

Recipient Vessels in the Head and Neck for Free Flaps

Commonly used recipient arteries for free tissue transfer in the head and neck include the ipsilateral superior thyroid, lingual, facial, superficial temporal, and transverse cervical arteries. End-to-side anastomosis with the carotid artery is associated with potentially lethal carotid blow-out injury. Anastomoses with contralateral vessels are useful when ipsilateral vessels are not available, such as in patients with recurrent cancer who have undergone previous free flap procedures or in patients who have an otherwise difficult ipsilateral neck.^{7,12,17,22} Vein grafts may occasionally be necessary to overcome insufficient pedicle length. For venous drainage, tributaries of the superficial and deep jugular systems are convenient. Finally, protection of the major vessels and nerves of the neck is possible after neck dissection by overlaying residual free flap tissues. This also aids in improving the contour and symmetry of the neck for aesthetic purposes and obliterates any dead space.

Complications

Apart from the general complications that may be encountered with any major operation or prolonged anesthesia, there exist several specific potential complications of head and neck ablative and reconstructive surgery. Specific intraoperative complications include air embolus, pneumothorax, and injuries to important vessels, lymphatics, or cranial nerves. Specific perioperative complications include carotid artery blow-out, flap necrosis, infections, saliva or chyle leakage, airway problems, and acute psychiatric disturbances. Examples of later complications are prolonged pain syndromes, fistulas, scar contractures, and problems associated with radiotherapy such as flap shrinkage (potentially with metalwork exposure) and osteoradionecrosis.

Facial Reanimation

Facial nerve paralysis is a debilitating and emotionally depressing condition that presents many functional and aesthetic problems. Loss of mimetic muscle activity leads to poor articulation and drooling from oral incompetence, exposure keratopathy from dysfunctional lacrimation and paralytic ectropion, and impaired socialization from facial disfigurement and difficulty expressing emotion. Facial nerve dysfunction has a number of possible causes, including oncologic resection, temporal bone or skull base surgery, trauma, congenital conditions (Möbius' syndrome), and idiopathic origin. The main considerations in treatment are management of forehead and brow symmetry, eyelid closure, oral competence and symmetry, and smile dynamics. The long-term goals include normal static appearance, symmetry with movement, and restoration of voluntary muscular control. Although the best results usually require multistaged, complex surgeries, the elderly patient is better served by a single-stage procedure that provides immediate improvement.

NEURAL TECHNIQUES

Traumatic injuries to the facial nerve without segmental nerve loss are best treated with primary end-to-end neurorrhaphy of the facial nerve stumps. The success of this repair depends on accurate approximation of nerve ends and achievement of a tension-free epineural repair with fine sutures, usually 8-0 nylon or finer. In segmental facial nerve loss due to trauma or oncologic resection, interpositional nerve grafts lead to the most successful reconstruction and may approach the results of primary repair. Grafting ideally is performed at the time of the injury rather than in delayed fashion. Donor nerves include the cervical plexus, great auricular nerve, and sural nerve. Timing of reanimation after nerve repair depends on distance of the repair from the motor end plates. Axonal regeneration proceeds at approximately 1 mm/d, whereas motor end plates deteriorate at approximately 1% per week and are gone by 2 to 3 years. In general, facial tone returns approximately 6 months after repair and voluntary motion a few months later.⁴³ Problems associated with facial nerve repair and grafting are weakness, mass movement (synkinesia), and dyskinesia. If the proximal facial nerve stump is available but

the distal stumps are not, the cervical plexus can be harvested and proximally anastomosed to the facial nerve stump and distally implanted into the mimetic muscles to allow neurotization and partial restoration of function.

Nerve transfer techniques borrow other local cranial nerves to innervate the distal facial nerve stump if grafting cannot be done. This requires the availability of distal facial nerve or nerve branch stumps. Typically used donor nerves include the ipsilateral hypoglossal nerve, spinal accessory nerve, and cross-face sural nerve graft from a contralateral facial nerve branch (redundant buccal or zygomatic branch). Disadvantages of this technique include those of nerve repair or grafting plus loss of donor nerve function and facial hypertonia. Transfer of the complete hypoglossal nerve creates ipsilateral tongue paralysis and hemitongue atrophy with mild to moderate intraoral dysfunction.⁴³

MUSCLE TRANSPOSITION TECHNIQUES

All of the aforementioned neural techniques rely on the presence of a functional distal neuromuscular unit. When the distal neuromuscular unit is deficient, as in congenital facial paralysis or in situations in which reconstruction is not undertaken until 2 to 3 years after the original insult, muscle transposition is considered. Muscle transposition techniques require intense muscular retraining to achieve the intended dynamics. A classic muscle dynamic facial sling uses the temporalis muscle, innervated by the trigeminal nerve and perfused by the deep temporal branch of the internal maxillary artery. The muscle is released along with its aponeurosis from the temporal fusion line, reflected inferomedially, and attached to the modiolus at the oral commissure, the nasolabial fold, and potentially the orbicularis oculi. Disadvantages include lack of spontaneous movement, temporomandibular joint dysfunction, and soft tissue fullness over the zygomatic arch. Other transferable muscle units include the masseter muscle and the anterior belly of the digastric muscle. The latter is useful in restoring depressor function of the lower lip in cases of isolated paralysis of the marginal mandibular branch of the facial nerve.⁴³

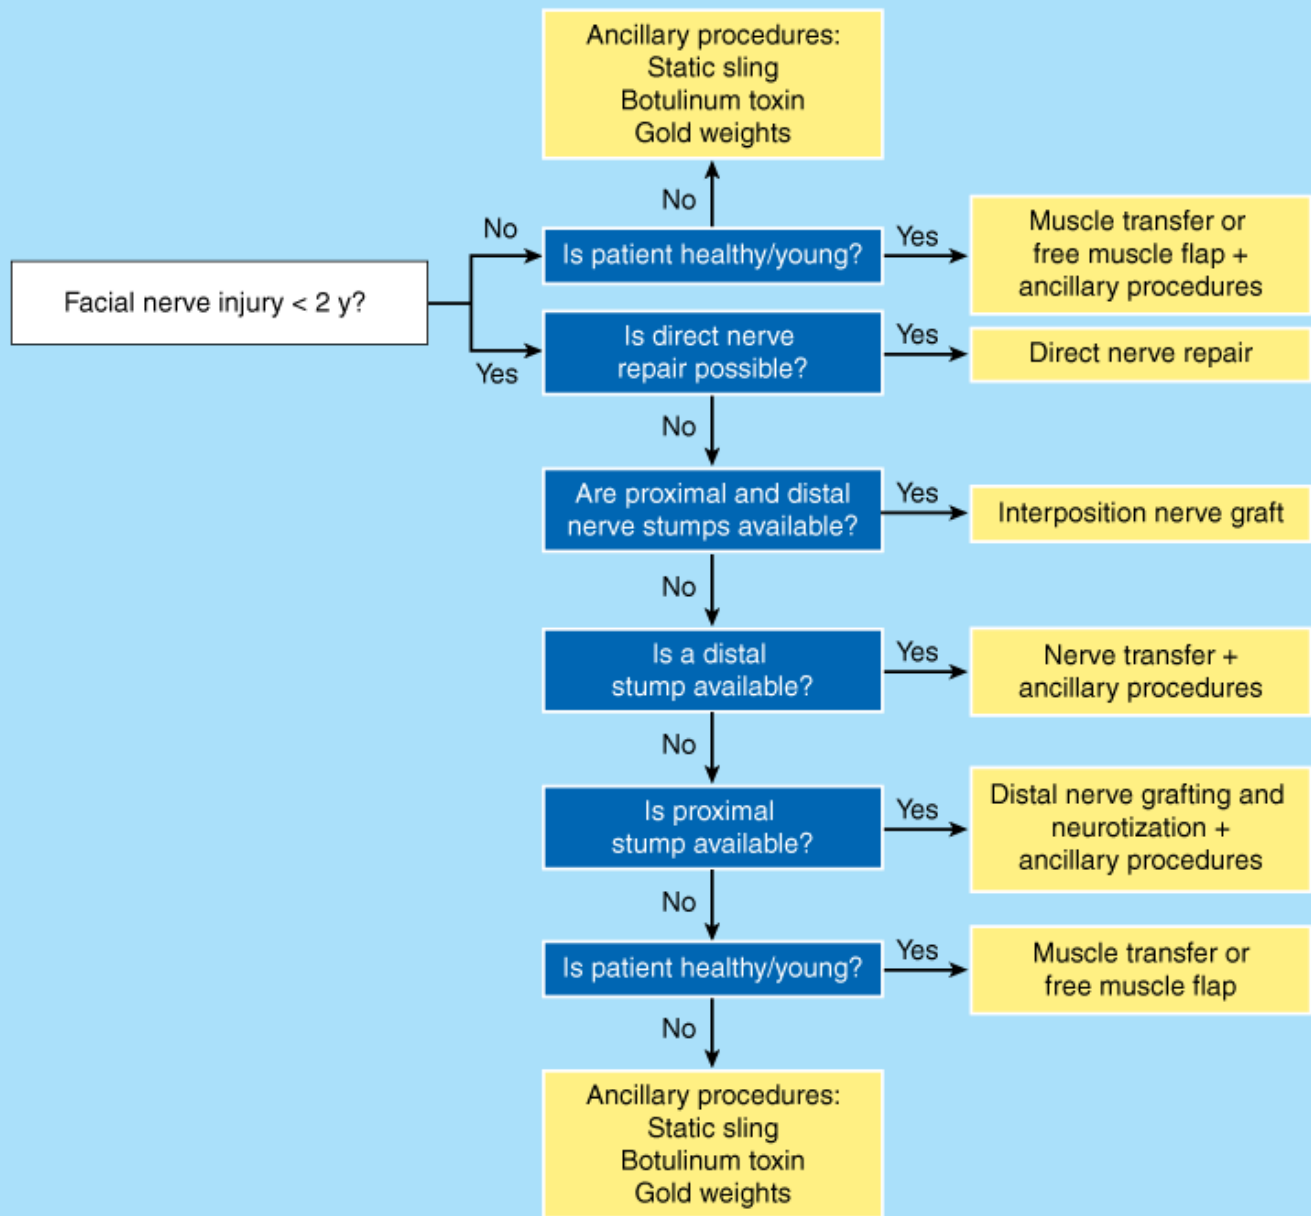

INNERVATED FREE TISSUE TRANSFER

Microsurgical free innervated muscle transfer may be considered in the same situations as local muscle transfers but is especially appropriate when concomitant soft tissue augmentation is needed. Muscles described for this purpose include the gracilis, latissimus dorsi, serratus anterior, and pectoralis minor muscles. The procedure may be performed in a single stage if the proximal facial nerve stump is available for anastomosis or if a long enough donor muscle nerve is present to reach the contralateral facial nerve branches. Often, however, it is a staged procedure beginning with establishment of a local neural source via cross-facial nerve grafting. The extent of axonal regeneration through the graft is monitored using Tinel's test. After sufficient axonal progression, approximately 6 to 12 months, the free muscle transfer is performed via vascular anastomoses to the superficial temporal or facial vessels, recipient and donor nerve coaptation, and fixation of the muscle to the zygoma superolaterally and to the nasolabial fold, upper lip orbicularis, and lower lip orbicularis inferomedially. Disadvantages of free muscle transfer include donor site morbidity, lengthy surgical times, and the need for specialized microsurgical skills.

ANCILLARY PROCEDURES

One of the most important goals of treatment for facial paralysis is rehabilitation of the periocular region. This objective may be simply achieved with implantation of gold or platinum upper eyelid weights, which allows gravity to assist with lid closure. Static fascial slings are used to improve symmetry when comorbid conditions preclude more extensive and staged surgeries. Sling materials include tensor fasciae latae, Gore-Tex, and human acellular dermal allograft. Nonsurgical techniques play a significant role in improving facial symmetry, both as a primary intervention and an adjunct to surgery. Contralateral mimetic muscle hypertonicity is tempered with botulinum toxin injections. Finally, soft tissue rejuvenative techniques such as cervicofacial rhytidectomy, blepharoplasty, browlift, and midface lift can improve the soft tissue effects of facial nerve paralysis (Fig. 45-40).

Breast Reconstruction

Breast cancer is the most common malignancy and the second leading cause of cancer-related death among women in the United States. One in eight women will develop breast cancer sometime during her life (overall lifetime risk). Breast reconstruction began as a means to reduce chest wall complications and deformities from mastectomy. Reconstruction has now been shown to benefit women in terms of psychologic well-being and quality of life.⁴⁴ The goal of breast reconstruction is to re-create form and symmetry while avoiding delay in adjuvant cancer treatment. A number of studies have shown that breast reconstruction, both immediate and delayed, does not impede standard oncologic treatment, does not delay detection of recurrent cancer, and does not change the overall mortality associated with the disease.^{3,45–47}

Preoperative counseling of the breast cancer patient regarding reconstruction options should include discussion of the timing and type of reconstruction, alternatives to surgical reconstruction, and realistic expectations. The plastic surgeon and surgical oncologist must

maintain close communication to achieve optimal results.

TIMING OF RECONSTRUCTION

Immediate reconstruction is defined as initiation of the breast reconstructive process at the time of the ablative surgery. This is usually done in patients with early-stage disease for whom there is low expectation of postoperative radiation therapy. Immediate reconstruction takes advantage of the preserved, supple skin envelope made possible by the skin-sparing mastectomy approach. In general, this allows a more aesthetically pleasing and symmetric reconstruction. It is also psychologically advantageous to the patient to avoid living with the mastectomy deformity, as the patient must with delayed reconstruction. Furthermore, the cost to the medical system is less with immediate reconstruction, because fewer operations are required than for staged procedures. Disadvantages include the potential delay of adjuvant therapy due to surgical site complication, partial necrosis of mastectomy skin flaps, and the possibility that unanticipated postoperative radiation therapy is recommended based on pathology information. Breast reconstructions by all techniques are adversely affected by radiation therapy, and many surgeons feel reconstruction should be delayed until at least 6 months after treatment.

Delayed breast reconstruction is initiated at least 3 to 6 months after mastectomy. This approach avoids mastectomy flap unreliability and radiation therapy unpredictability. However, the patient is subjected to an additional operative procedure, and overall cosmetic result is often worse (especially with autologous tissue reconstruction).

PARTIAL BREAST RECONSTRUCTION

Over the last decade many women have chosen breast conservation therapy (BCT) consisting of segmental mastectomy with sentinel lymph node biopsy and/or axillary lymph node dissection combined with postoperative whole-breast irradiation. Although this less invasive cancer treatment is quite beneficial to many women, significant breast deformity can result from the tissue removal and radiation-induced changes, especially in women with small breasts. *Oncoplastic surgery* refers to the set of techniques developed to lessen breast deformity from partial mastectomy, both in the delayed and the immediate settings. One of the most common methods of minimizing defect visibility in large-breasted women is to rearrange the breast parenchyma at the time of tumor extirpation using reduction mammoplasty techniques. Dermatoglandular pedicles supporting the nipple-areolar complex can be designed in any number of orientations to avoid the defect location. This procedure, combined with traditional contralateral breast reduction, can result in excellent cosmetic outcomes, often better than preoperative appearance (Fig. 45-41). The lateral thoracodorsal flap, based on the lateral intercostal perforators at the inframammary fold, is particularly useful in correcting lateral breast defects⁴⁸ (Fig. 45-42).

Preoperative, intraoperative, and 4-month postoperative photos of a 66-year-old woman with right breast cancer at the 10 o'clock position. Oncoplastic lateral thoracodorsal flap reconstruction was performed simultaneously with a right breast segmental mastectomy of the lesion.

(Photographs reproduced with permission from M. Gimbel.)

One drawback of these oncoplastic techniques when performed at the time of segmental mastectomy is the chance that, if the specimen margins are not clear, the reconstruction must be taken down to allow for re-excision. The oncologic implications of reusing the flap in this setting are unclear. Another shortcoming is the potential for fat necrosis, especially distally, in these nonaxial pattern flaps.

IMPLANT-BASED RECONSTRUCTION

By necessity or patient choice many women undergo mastectomy for local control of breast cancer. In fact, recently in response to the increased recognition of multifocal disease and experience with poor aesthetic results after BCT in small-breasted patients, some women have chosen mastectomy despite being candidates for BCT. The simplest method of reconstructing the breast is placement of an implant into the mastectomy defect. Occasionally an implant may be placed at the time of mastectomy as a one-stage mound reconstruction.

Usually, however, the first stage involves placement of a silicone shell tissue expander under the chest wall musculature (pectoralis major, serratus anterior, superior rectus sheath), followed by expansion of the skin and pocket weekly over the following 3 months. The patient then returns to the operating room for removal of the expander and placement of a saline or silicone breast implant (Figs. 45-43, 45-44). After exhaustive investigation, silicone implants have been proven as safe and effective as saline implants in breast augmentation and reconstruction. After another 3 months, the nipple is reconstructed, usually under local anesthesia.

Bilateral tissue expander/implant-based breast reconstruction. Appearance preoperatively (**A**) and 2 months after saline implant exchange (**B**).

The advantages of the tissue expander/implant-based reconstruction are absence of donor site morbidity, short operative times, and short recovery periods. The disadvantages include the need for more reconstructive stages and longer cumulative time to completion of reconstruction. Implant breast reconstructions tend to lack the natural breast feel and ptotic appearance. This is particularly noticeable in unilateral reconstructions. Complications related to the tissue expander or implant include infection, malposition, hematoma, seroma, and rupture and deflation. Long term the most common problem requiring reoperation is the formation of dense scarring around the implant (capsular contracture) causing firmness, visible deformity, and even discomfort. In addition, implants are medical devices that undergo mechanical wear, which ultimately leads to leakage and deflation. When all reasons are taken into account, the chance that a patient will need additional surgery on her reconstructed breast within 5 years of implant-based reconstruction is approximately 35%.⁴⁹ The results worsen and the rate of complication increases further when implants are placed in an irradiated chest wall, regardless of whether the radiation therapy occurs before or after reconstruction. The use of implants in such cases generally is discouraged.

TOTAL AUTOLOGOUS TISSUE RECONSTRUCTION

An entirely different way to reconstruct the breast mound avoids the placement of implants in favor of using only the patient's own redundant tissue. Indications for total autologous breast reconstruction are many and varied, including patient preference, previous or anticipated chest wall radiation treatment, a ptotic contralateral breast, and previous failed implant reconstruction. Contraindications are lack of a suitable donor site due to scarring or minimal adiposity, morbid obesity, and serious comorbidities that preclude a longer surgery and recovery period.

The most commonly used donor site is the abdomen. Most women in the breast cancer patient population have redundant skin and fat in the lower abdomen that may be transferred to the chest wall and fashioned into a breast mound. Many techniques have been developed to transfer this tissue, both as pedicled myocutaneous flaps and as free flaps. The workhorse abdominal flap for breast reconstruction is the pedicled transverse rectus abdominis myocutaneous (TRAM) flap. This flap is based on the superior epigastric vessels that run on the undersurface of the rectus abdominis muscle. A transversely oriented skin paddle with underlying fat is isolated based on its perforating vessels that course through the rectus muscle to join the main superior epigastric pedicle. The flap, along with the rectus muscle and blood supply, is tunneled under the anterior chest wall and delivered into the mastectomy defect, where it is then shaped into a breast mound. The donor site is closed in a manner similar to an abdominoplasty. The advantages of this and all total autologous reconstruction techniques are creation of a breast that looks and feels natural, that changes volume along with the patient's weight (and the contralateral natural breast), and that avoids the potential complications of breast implants. In addition, patients are often pleased to have the side benefits of an abdominoplasty. The pedicled TRAM flap procedure is also relatively quick for a total autologous reconstruction. Downsides include the potential for partial or complete flap failure, fat necrosis, fullness in the upper abdomen from the tunneled pedicle, abdominal wall bulge or hernia, and abdominal wall weakness.

The free TRAM flap was introduced to improve on the sometimes limited volume of tissue that can be carried by the relatively indirect blood supply of the pedicled TRAM's superior epigastric vessels. The free TRAM flap is similar to the pedicled TRAM flap but is based on the deep inferior epigastric vessels, which are the dominant blood supply to the lower abdomen. The flap is harvested as a free flap and the deep inferior epigastric artery and vein are anastomosed to recipient vessels in the chest, usually the internal mammary or the thoracodorsal vessels. A refinement to this method is the muscle-sparing free TRAM flap procedure, in which less fascia and rectus abdominis muscle is harvested with the flap to minimize donor site morbidity. The ultimate muscle-sparing free TRAM flap is the deep inferior epigastric perforator flap (Fig. 45-45). In this case, the fascia is opened but no muscle is included with the flap, and the perforating vessels of the deep inferior epigastric system are dissected between the muscle fibers to join the main pedicle. When patients are carefully selected, muscle-sparing techniques decrease abdominal wall morbidity and increase useful pedicle length for microsurgery without significantly compromising flap perfusion⁵⁰ (Fig. 45-46A and 45-46B). Finally, in some patients the lower abdominal tissue may be transferred to the breast as a free flap without violating the abdominal wall fascia at all. The superficial inferior epigastric artery is capable of supporting enough abdominal tissue volume to reconstruct the breast. Because this artery and its

accompanying vein do not traverse the anterior rectus sheath, the flap can be harvested with no more abdominal wall morbidity than an abdominoplasty. Unfortunately this artery is frequently absent or too diminutive in size to ensure a reliable anastomosis. Despite the many advantages of microsurgical total autologous breast reconstruction, it is associated with longer operative times than pedicled TRAM procedures, requires expertise in microsurgery, and has the potential for complete flap failure due to microvascular thrombosis.

IMPLANT AND AUTOLOGOUS TISSUE RECONSTRUCTION

The pedicled latissimus dorsi myocutaneous flap procedure is a straightforward, reliable method used for breast reconstruction. It is often reserved for reconstructing breasts when other methods have previously failed. The latissimus flap is relegated to second-choice status because it carries the major disadvantage of autologous tissue reconstruction (donor site morbidity) as well as all of the potential complications associated with breast implants. That aside, the latissimus flap/implant-based reconstruction can produce excellent cosmetic results with relatively low donor site morbidity (Fig. 45-47). The latissimus dorsi muscle with overlying skin paddle is elevated based on its thoracodorsal vessel pedicle, tunneled through the axilla, and delivered into the mastectomy site. After partial inseting, either a tissue expander or permanent implant is placed behind the muscle to give adequate volume to the reconstruction (Fig. 45-48). Drawbacks specific to this method include contour irregularity of the back, high rate of postoperative seroma, and noticeable weakness in

the shoulder (uncommon).

(Illustrations reproduced with permission from M. Gimbel.)

ACCESSORY PROCEDURES

After creation of the breast mound, refinements and accessory procedures are performed after approximately 3 months. These may include mound revision via liposuction or direct excision, scar revisions, fat grafting, and nipple-areola complex reconstruction. Scores of methods have been described for reconstructing the nipple. These include local flap techniques (e.g., star flap, skate flap, C-V flap), grafting techniques (contralateral nipple/areola sharing, groin skin, labia skin), and tattooing. Nipple reconstructions are initially purposefully overprojected in anticipation of approximately 50% loss of projection over the first 6 months.

RADIATION-RELATED CONSIDERATIONS

With some notable exceptions, most surgeons advocate avoidance of implant-based breast reconstruction in chest walls that have previously received radiation or are likely to receive radiation due to the relatively high rate of complications and disappointing results. Delayed total autologous reconstructions bring healthy nonirradiated tissue to replace the damaged fibrotic tissue and are the preferred mode of breast reconstruction in this setting. Similarly, latissimus dorsi/implant reconstructions replace much of the irradiated skin, which probably explains to some degree why, in the face of previous irradiation, implants fair better with an overlying latissimus flap than without.

The question of whether total autologous reconstructions should be done before or after anticipated radiation therapy is still controversial. Those in favor of delaying the reconstruction argue that an irradiated flap will exhibit shrinkage and fibrosis that subtracts from the overall aesthetic result. Those in favor of performing immediate reconstruction in this setting feel that, because immediate reconstructions have inherently better aesthetics, the imperfect result due to irradiation it is still comparable to the result of delayed reconstruction without the additional operation. To date no prospective study has been performed comparing the two approaches.

Trunk and Abdominal Reconstruction

In the trunk, as in most areas of the body, choice of reconstructive method is determined by the location and size of the defect, and the

properties of the deficient tissue. A distinction is made between partial-thickness and full-thickness defects in deciding between grafts, flaps, synthetic materials, or a combination of techniques. Unlike the head and the lower leg, the trunk harbors a relative wealth of regional transposable axial pattern flaps that allow sturdy reconstruction, only rarely requiring distant free tissue transfer. Indeed, the trunk serves as the body's arsenal, providing its most robust flaps to rebuild its largest defects.

THORACIC WALL

The chest wall is a rigid framework designed to resist both the negative pressure associated with respiration and the positive pressure from coughing and from transmitted intra-abdominal forces. Furthermore, it protects the heart, lungs, and great vessels from external trauma. Reconstructions of chest wall defects must emulate these functions.

The pectoralis major muscle is the workhorse pedicled flap for coverage of the sternum, upper chest, and neck. It is a type of V flap with one dominant pedicle (pectoral branch of the thoracoacromial artery) and several secondary segmental pedicles (intercostal perforators and the pectoral branch of the lateral thoracic artery).⁵¹ The muscle may be advanced or transposed on its dominant pedicle or used as a turnover flap based on its internal mammary perforators. Both methods are useful in covering the sternum after dehiscence or infection. Before the turnover flap is elevated previous operative notes should be reviewed carefully to determine whether the internal mammary artery is still a viable perfusion source; the artery, especially the left, is frequently used for heart revascularization. The muscle may also be used for obliteration of intrathoracic dead space infections and as a myocutaneous flap for head and neck reconstruction. Although it is a reliable flap, the loss of the pectoralis major muscle results in upper extremity weakness and cosmetic deformity from loss of the anterior axillary fold.⁵²

The rectus abdominis muscle is a type III axial pattern flap that can be based on the superior epigastric vessels or the deep inferior epigastric vessels.⁵¹ When elevated as a myocutaneous flap it can be designed with a transverse (TRAM) or vertical skin paddle. Although the vertical rectus abdominis muscle flap has better vascularized skin due to its multiple longitudinally oriented perforators, the TRAM flap provides a larger area of donor skin that can be primarily closed with an easily concealable scar. The rectus abdominis muscle is frequently used for lower sternum reconstruction when the pectoralis muscle is insufficient. It can also be used in pedicle or free flap configuration for repair of large chest wall defects from cancer resection (Fig. 45-49).

(Photographs reproduced with permission from M. Gimbel.)

The latissimus dorsi myocutaneous flap is probably the most widely used flap in nonsternal chest wall reconstructions due to its broad size, location, reliability, and pedicle length. The flap is based on the thoracodorsal vessels arising from the subscapular system. Its secondary blood supply comes from the posterior intercostal and lumbar vessels.⁵¹ The arc of rotation of this flap can extend to most areas on the ipsilateral torso as well as to the abdomen, head and neck, and upper arm. The serratus anterior muscle can be included on the same vascular pedicle to further increase its surface area. Use of this donor site is relatively well tolerated, but shoulder weakness can be significant. The major drawbacks of the latissimus flap are its conspicuous scar and the high risk of seroma.⁵²

The trapezius muscle flap, based on the transverse cervical vessels, is generally used as a pedicled flap to cover the upper midback, base of neck, and shoulder. The superior portion of the muscle along with the acromial attachment and spinal accessory nerve are preserved to maintain shoulder elevation function. Other useful flaps of the thoracic region include the scapular/parascapular fasciocutaneous flap, the external oblique flap, the medially or laterally based thoracoepigastric skin flaps, and the omental flap.

When a full-thickness defect of the chest wall involves more than two adjacent ribs, the inherent rigidity of soft tissue flaps may provide insufficient chest wall integrity. Although cadaveric bone and autologous bone grafts have been used in the past to lend structural support, the availability of well-tolerated synthetic and biologic materials has become more common. These materials include polypropylene (Prolene), polyethylene (Marlex), and polytetrafluoroethylene (Gore-Tex) meshes, methyl methacrylate, and acellular dermal allograft. Even if these avascular foreign bodies must be removed due to chronic infection, often a thick fibrous layer of tissue will

have formed that can maintain chest wall stability.⁵²

ABDOMINAL WALL

The abdominal wall also protects the internal vital organs from trauma, but with layers of strong torso-supporting muscles and fascia rather than with osseous structures. The goals of reconstruction are restoration of structural integrity, prevention of visceral eventration, and provision of dynamic muscular support. Defects in the abdominal wall may arise from trauma, oncologic resection, congenital deformities, and infection. By far the most common reason for abdominal wall deficiency, however, is incisional fascial dehiscence and herniation after laparotomy. When a reconstruction plan is being formulated, careful physical examination and review of the medical history will help prevent selection of an otherwise sound strategy that, because of previous incisions and trauma, is destined for failure.

PARTIAL DEFECTS OF THE ABDOMINAL WALL

Large defects of the abdominal skin and subcutaneous tissue are usually easily controlled with skin grafts, local advancement flaps, or tissue expansion. Myofascial defects are more difficult to manage. The abdominal wall fascia requires a minimal-tension closure to avoid dehiscence, recurrent incisional hernia formation, or abdominal compartment syndrome.⁵³ Prosthetic meshes are frequently used to replace the fascia in clean wounds and in operations that create myofascial defects. When the area of fascial deficiency is contaminated, as in infected mesh reconstructions, enterocutaneous fistulas, or viscous perforations, prosthetic mesh is avoided because of the risk of infection. A delayed reconstruction can be performed by inseting a resorbable polyglactin (Vicryl) mesh that will eventually granulate to allow skin grafting. The ensuing hernia is repaired later with prosthetics under cleaner conditions. The separation-of-components procedure has enjoyed much success in closing large midline defects without resorting to mesh. This procedure involves advancement of bilateral myofascial flaps consisting of the anterior rectus fascia/rectus abdominis/internal oblique/transversus abdominis muscle complex. Mobility of this myofascial unit is created by release of the external oblique muscle at the semilunate line. Midline defects measuring up to 10 cm superiorly, 18 cm centrally, and 8 cm inferiorly can be closed using separation of components.⁵⁴ This technique is less effective in closing lateral defects, for which regional muscle and fascial flaps are usually better suited (rectus abdominis flap, internal oblique flap, external oblique flap).⁵³

Full-thickness abdominal defects and large myofascial defects require large robust pedicled flaps or free flaps for closure. The tensor fasciae latae pedicled flap, based on the ascending branch of the lateral circumflex femoral vessels, is useful in reconstructing the lower two thirds of the abdomen. Bilateral flaps can be used for very large defects, although the skin-grafted donor site is unsightly. The rectus femoris flap and the vastus lateralis flap can be used for smaller lower abdominal defects. The "mutton-chop" flap, which is an extended rectus femoris flap with fascia lata included distally, has been used successfully in closing massive defects.^{55,56} Large defects of the upper abdominal wall may be repaired with pedicled extended latissimus dorsi flaps with attached pregluteal fascia. Very large full-thickness defects, especially superiorly, are best treated with free tissue transfer of large myofascial units such as the latissimus dorsi or the tensor fasciae latae. These can also be innervated flaps to re-establish contractile force and strength in the abdominal wall.

Extremity Reconstruction

POSTTRAUMATIC RECONSTRUCTION

Historically, significant advances in the treatment of traumatic wounds have occurred during those times of greatest need—wars. World War I was closely predated by the beginnings of aseptic surgery and anesthesia, and marked a turning point in wound management and trauma surgery. With the beginnings of modern orthopedic and plastic surgery; improvements in the understanding of anesthesia, trauma resuscitation, and infection; and the availability of early antibiotics, these times witnessed a move away from amputation for all compound extremity fractures toward an increase in attempts at limb salvage. The introduction and maturation of microsurgical techniques brought increasingly successful distal extremity replantations and free flap reconstructions. Soft tissue reconstruction thus advanced alongside evolving techniques of bone fixation, joint reconstruction, and general vascular surgery. Current lower extremity reconstruction incorporates the use of vascularized bone, composite tissues, and functioning muscle transfers tailored to the given defect.⁵⁷ The future may behold the use of tissue-engineered vascularized composite tissue constructs and cadaveric composite tissue

allotransplantation.

Common causes of high-energy lower extremity trauma, outside of wartime, include road traffic accidents, falls from a height, direct blows, sports injuries, and gunshots. Understanding the anatomy of the lower limb compartments, nerve and vascular supplies, muscle functions, skeletal structure, and mechanics is essential for accurate bony and soft tissue restoration for function and appearance. Several limb-salvage scoring systems have been suggested to aid in the decision regarding whether to amputate or attempt limb salvage, but their routine use remains controversial; nevertheless, they can provide guidance during this life-altering decision process.⁵⁸ Open (compound) fractures are often classified according to the system devised by Gustilo and colleagues (Table 45-12).⁵⁹

Table 45-12 Gustilo and Anderson Classification of Compound Fractures	
Classification	Description
Grade I	Wound <1 cm; minimal contamination, comminution, and soft tissue damage
Grade II	Wound >1 cm; moderate soft tissue damage and minimal periosteal stripping
Grade IIIa	Substantial contamination and severe soft tissue damage but adequate fracture coverage; usually due to high-energy trauma
Grade IIIb	Substantial contamination, periosteal stripping, severe soft tissue damage, and inadequate fracture coverage; usually due to high-energy trauma
Grade IIIc	Any open fracture with an associated arterial injury requiring repair

In addition to following standard multiple trauma evaluation and resuscitation guidelines, the multidisciplinary team must assess the peripheral neurovascular status, soft tissue defects, and configuration of fractures.^{57,60} Bony stabilization may be critical to controlling fracture hemorrhage. Angiography or Doppler ultrasound examination may help assess vascular integrity. Compartment syndrome must be monitored for, and fasciotomies performed when necessary. Antitetanus vaccine and antibiotics should be provided as soon as possible according to contemporary guidelines.⁶¹ An evaluation of the patient as a whole allows treatment to be planned within the context of comorbidities, socioeconomic considerations, and rehabilitative potential. The loss of plantar sensation may favor below-knee amputation. Revascularization of a mangled major extremity brings a risk of massive reperfusion injury and multiple organ failure.

In terms of surgical management, the order of repair is fracture stabilization followed by vascular repair and reconstruction of a stable soft tissue envelope. The choice of method for soft tissue coverage is determined by the location and extent of the injury (Table 45-13). Coverage for weightbearing areas should be durable, stable (nonshearing), and sensate. Properly fitted footwear provides essential protection against pressure-related complications. Split-thickness skin grafts are reasonable for coverage of exposed healthy muscle or soft tissue. Local flaps may be used to cover smaller defects. Free tissue transplantation is preferred for larger or more complex defects with bony exposure, particularly in the middle and lower thirds of the leg where limited local soft tissues are available for reconstruction. Free flaps need not be limited to providing only soft tissue coverage; incorporation of vascularized bone, such as of fibula or iliac crest, can aid in fracture management. Chimeric flap configurations can improve flap inseting into composite defects. Flow-through designs, such as the anterolateral thigh flow-through free flap, can be used to bridge segmental vascular defects to revascularize the distal extremity. Muscular flaps can be motor innervated to restore lost muscle functions at the recipient site (Fig. 45-50).^{62–64} Other techniques, such as tissue expansion and vacuum-assisted closure, may be indicated in select circumstances. Traditional cross-leg flaps are almost never used nowadays; they cause complete immobilization and increase the risk of deep vein thrombosis and contracture formation.

Table 45-13 Some Lower Extremity Reconstructive Options for Soft Tissue Coverage after Fracture	
Area of Defect	Reconstructive Options
Femur	Sartorius muscle/MC flap (anterior defects)
	TFL muscle/MC flap (posterior defects)
	Vastus lateralis/medialis muscle/MC (mid to lower thigh defects)

	ALT for fasciocutaneous flap
	Free osseous flaps useful for segmental femur defects
Knee and proximal third of tibia	Gastrocnemius muscle (medial or lateral head, or both) with SSG
	Distally based ALT flap
	Free tissue transfer for larger defects
Middle third of tibia	Soleus muscle with SSG
	Gastrocnemius head(s) with SSG
	Flexor digitorum longus muscle
	Tibialis anterior muscle "book flap" (preserves function)
	Free tissue transfer for larger defects
Distal third of tibia	Free tissue transfer usually the first choice
	Reversed sural artery flap
	Peroneal perforator fasciocutaneous flap
	Local muscle flaps for smaller defects

ALT = anterolateral thigh; MC = myocutaneous; SSG = split-thickness skin graft; TFL = tensor fasciae latae.

Soft tissue and bony reconstruction of a Gustilo IIIb open segmental fracture of the right femur using a double-barreled fibula osteoseptocutaneous free flap. **A.** Antibiotic-impregnated beads were placed as a temporary spacer in the segmental femur bone gap after primary débridement; an external fixator is in place. **B.** Two weeks later, a free left fibula osteoseptocutaneous flap was harvested, osteotomized into a double-barreled configuration, and transferred as a microvascular free flap to the contralateral limb. **C.** The skin paddle of the free flap provides a useful means for postoperative clinical monitoring of the viability of the underlying fibula bone. **D** and **E.** The patient is shown fully weightbearing without assistance 20 months after reconstruction; hypertrophy of the double-barreled fibula was noted on the radiographs.

With the availability of microvascular free tissue transplantation, radical débridements can be adequate even for the largest wounds. Early one-stage wound coverage and bony reconstruction is generally advocated whenever possible.^{2,57,60,61} It is reasonable for reconstruction to be deferred briefly, however, if there remain tissues of questionable viability, so that these can be reassessed and débrided as required. Temporary placement of a biologic dressing is one method to assess the viability and cleanliness of questionable tissues; a skin graft will fail if laid onto an unhealthy graft bed. If débridement produces an irregular dead space that cannot be completely obliterated, or if débridement remains questionable even after a second look, the resultant cavity may be filled with antibiotic-impregnated beads or available vascularized soft tissues to act as a spacer until definitive reconstruction is possible. This applies also to segmental bone losses within a soft tissue envelope of doubtful viability. In these situations, soft tissue coverage preferably is still achieved early; bony reconstruction can be completed at a later date, when both the bone and soft tissue envelope are stable and healthy. Although it remains debated whether fasciocutaneous or muscular (musculocutaneous or muscle alone) flaps are superior for treating compound fractures, it is critical to obliterate dead space with fresh tissue, and this is often more easily achieved using muscle.

Osteomyelitis often complicates inadequately débrided compound leg fractures. Delayed coverage also appears to increase the risk of this dreaded complication. Generous irrigation, débridement, removal of dead bone (even in a segment), expedient antibiotic therapy, and healthy soft tissue coverage are important in both acute compound fracture and established posttraumatic osteomyelitis. Large segmental bone losses can be addressed with microvascular free transplantation of osseous flaps or distraction lengthening.^{57,60}

When limb salvage either is not possible or is not in the best interests of the patient, attention is directed to providing soft tissue stump

coverage suitable for weightbearing and allowing ambulation with a properly fitted prosthesis. Ideally, local tissues are used; however, when they are unavailable or inadequate, the amputated part can be a useful source of skin grafts or tissues for microvascular free transfers to the stump, which preserves length and avoids a more proximal amputation.

RECONSTRUCTION AFTER ONCOLOGIC RESECTION

The refinements in surgical ablation techniques, in adjuvant radiation therapy and chemotherapy, and in limb reconstruction methods have opened the possibility for curative limb-sparing treatments instead of amputation. Extensive soft tissue and segmental long bone defects from radical tumor resection and radiation-compromised wound healing can often be reconstructed nowadays by liberal importation of fresh tissues through microvascular free tissue transplantation tailored to the defect.

DIABETIC ULCERATION

The pathophysiology of primary diabetic lower limb complications has three main components: peripheral neuropathy (motor, sensory, and autonomic), peripheral vascular disease, and immunodeficiency. Altered foot biomechanics and gait caused by painless collapse of ligamentous support, foot joints, and foot arches change weightbearing patterns. Blunted pain allows cutaneous fissuring and ulceration to progress. Multiflora infections are established amid local immunodeficiency and microvasculopathy. Frank neuroarthropathic Charcot's foot deformities may ultimately result. Cutaneous ulcerations may chronically deteriorate relatively painlessly, involving deeper tissues, including bone. Persistent soft tissue infection and osteomyelitis, worsened by peripheral vascular compromise and immunodeficiency, traditionally ends in gangrene and amputation. Previously, 50 to 70% of lower extremity amputations performed for nontraumatic causes were due to diabetes.^{13,31} Improved patient education and medical management, timelier detection of diabetic foot problems and referral for treatment, and the use of more refined techniques for wound management have helped increase the chances of limb preservation.

Diabetic patients with lower limb disease often have significant multisystemic comorbidities that must be optimized for surgery; strict perioperative control of blood glucose levels is mandatory. Clinical examination must include documentation of sensory deficits, vascular insufficiencies, and evidence of osteomyelitis. Plain radiographs, MRI, nuclear bone scans, and angiography or duplex imaging may be indicated. A patient with significant vascular disease may be a candidate for lower extremity bypass. Nerve conduction studies may diagnose surgically reversible neuropathies at compressive sites and aid in decisions about whether to perform sensory nerve transfers to restore plantar sensibility. Antibiotic and fungal therapies should be guided by tissue culture results.

Plastic surgical management starts with thorough débridement of devitalized or infected tissues, purulent cavities, and osteomyelitic bone. Methods of wound closure are dictated by the extent and location of the postdébridement defect (Table 45-14). Vacuum-assisted closure may be appropriate for superficial defects. Skin grafts should be used cautiously and not in weightbearing areas. Local and regional flaps can be used after careful evaluation of their vascularity given concurrent peripheral vascular disease and possible recent distal vascular bypass procedures. Microvascular free tissue transfers are appropriate when defects are large or when local flaps are not available. Combination lower extremity bypass and free flap coverage has proved beneficial for the treatment of the diabetic foot in terms of healing and reduction of disease progression. Orthopedic surgeons should be consulted to improve foot biomechanics and address bony prominences to reduce the risk of recurrent ulceration. Proper footwear (including orthotic devices and off-loading shoe inserts), hygiene, and toenail and skin care are essential.⁶⁵

Table 45-14 Some Reconstructive Options for the Diabetic Foot	
Area of Defect	Reconstructive Options
Forefoot	V-Y advancement
	Toe island flap
	Single toe amputation
	Lisfranc's amputation
Midfoot	V-Y advancement

	Toe island flap
	Medial plantar artery flap
	Free tissue transfer
	Transmetatarsal amputation
Hindfoot	Lateral calcaneal artery flap
	Reversed sural artery flap
	Medial plantar artery flap ± flexor digitorum brevis
	Abductor hallucis muscle flap
	Abductor digiti minimi muscle flap
	Free tissue transfer
	Syme's amputation
Foot dorsum	Supramalleolar flap
	Reversed sural artery flap
	Thinner free flaps (e.g., temporoparietal fascia, radial forearm, groin flaps)

LYMPHEDEMA

The lymphatic system provides a high-volume transport mechanism, clearing proteins and lipids from the interstitial space to the systemic vasculature by means of differential pressure gradients. Factors that contribute to circulatory lymphatic flow include segmental lymphangion contractility, skeletal muscle activity, and one-way valves that prevent backflow.^{66,67} The lymphatics course throughout the body alongside the venous system, into which they eventually drain via the major thoracic and cervical ducts. With lymphatic obstruction, abnormal connections form between the superficial and deep lymphatics and between the lymphatic and venous systems. Lymphatic stagnation, hypertension, and valvular incompetence contribute to edema, inflammatory fibrovascular proliferation, and collagen deposition, causing firm, nonpitting swelling with peau d'orange cutaneous changes. Lymphoscintigraphy reveals the lymphatic anatomy and quantifies lymphatic flow. MRI provides anatomic information regarding lymphatic trunks, nodes, and obstructive lesions. It is essential to rule out neoplastic lymphatic invasion, especially after oncologic ablation, as a cause of secondary lymphedema. Lymphangiosarcoma is a rare cause of lymphedema that is deadly if diagnosed late.⁶⁸

Primary lymphatic obstruction may arise from congenital malformations of the lymphatic system such as lymphatic hypoplasia, functional insufficiency, or absence of lymphatic valves. Identified genetic causes include the autosomal dominant Milroy disease. Lymphedema praecox accounts for >90% of cases of primary lymphedema, generally appears during puberty but sometimes as late as the third decade, and occurs more commonly in females. It is usually unilateral and limited to the foot and calf. Lymphedema tarda appears after the age of 35 years and is relatively rare. Secondary (acquired) lymphedema is much more common, with filariasis being the leading cause worldwide. In Western countries, secondary lymphedema is more commonly the result of neoplasms and their surgical treatments and radiotherapy.^{13,67}

The mainstay of treatment for lower extremity lymphedema is nonsurgical measures, including one or more of the following: use of external compressive garments and devices, limb elevation, administration of antibiotics for episodes of cellulitis, and specialized complex physical therapy.⁶⁹ The efficacy of available surgical options is generally poor, and these are reserved for cases in which aggressive nonsurgical measures have failed. The classic Charles procedure involved radical excision of lymphedematous fascial and suprafascial tissues with skin grafting for coverage; cosmetic outcomes were often disastrous, and functional problems arose due to high rates of contracture, wound breakdown, and ulcerations. This method was later modified into multiple staged excisions of subcutaneous tissues. Other techniques include liposuction and bridging procedures. Microsurgical lymphatic-lymphatic, lymphatic-venous, lymphatic-venous-lymphatic, and lymph node–venous anastomoses have all been tried to relieve obstructive lymphedema, and all techniques show some efficacy early on; however, longer-term results are highly variable.⁷⁰ Nonsurgical techniques can be, and usually are, combined with any of the surgical methods.

Pressure Sore Treatment

A *pressure ulcer* is defined as tissue injury, usually over a bony prominence, due to pressure or a combination of pressure and shear forces. These wounds occur in patients debilitated by age, illness, immobilization from orthopedic injuries, or spinal cord injury.

Prevention of pressure ulcers first requires identification of susceptible patients. Once such patients are identified, measures to prevent development of ulceration include frequent position changes (by both the patient and caretakers), use of pressure reduction equipment (low air loss mattresses and seat cushions, heel protectors), nutritional optimization, hygienic control of incontinence, and medical and/or surgical treatment of muscle spasm and joint contracture. Once an ulcer has developed these same factors must be carefully evaluated and deficiencies corrected before embarking on a complex reconstructive treatment plan. Successful reconstruction also requires a medically stable, cooperative, motivated patient with adequate social support.

Pressure ulcers are described by their stage, based on depth of tissue injury (Table 45-15).⁷¹ Stage I and II ulcers are treated conservatively with dressing changes and basic pressure ulcer prevention strategies as already discussed. Patients with stage III or IV ulcers should be evaluated for surgery. The wound is examined for soft tissue infection or abscess, osteomyelitis, and involvement of deeper structures or spaces (e.g., joint space, urethra, spinal canal) to determine the urgency and specific requirements of the problem. Blood laboratory work and imaging studies are performed to help establish whether soft tissue or bone infection is present. Radiographs are usually adequate to rule out osteomyelitis; CT and MRI are helpful when plain films are equivocal. Wet gangrenous tissue and abscesses should be surgically débrided without delay to prevent or treat sepsis. In patients who do not meet the strict reconstruction criteria, débridement to healthy tissue without subsequent reconstruction may be the optimal treatment. If bone is present at the wound base, it should be débrided only to bleeding bone and left with a smooth contour. Complete ischiectomy should not be performed for ischial decubitus ulcers, because removal of one ischium only transfers subsequent pressure trauma to the contralateral ischium or the perineum. If osteomyelitis is present, which is best proven by culture of specimens obtained by intraoperative bone biopsy, long-term antibiotic therapy guided by microorganism sensitivity is indicated. A special note should be made regarding surgical treatment of spinal cord injury patients with T5 or higher injuries. In these patients, manipulation of a pressure ulcer and even simple urinary retention can trigger autonomic hyperreflexia. This dangerous condition is characterized by critically high blood pressure elevation and sympathetic discharge. Effective management is immediate recognition and reversal of trigger factors along with prompt administration of pharmacologic agents to prevent complications such as intracranial and retinal hemorrhage, seizure, cardiac irregularities, and death.

Table 45-15 National Pressure Ulcer Advisory Panel Staging System

Classification	Description
Stage I	Intact skin with nonblanchable redness
Stage II	Partial-thickness loss of dermis; may present as blister
Stage III	Full-thickness loss of dermis with visible subcutaneous fat (no deeper structures exposed)
Stage IV	Full-thickness loss of dermis with exposed bone, tendon, or muscle
Unstageable	Full-thickness loss of dermis with ulcer base obscured by eschar

Direct closure of a pressure ulcer is rarely performed because it usually creates tension in the healing tissues already stressed by nonphysiologic external pressure, predisposing the closure to breakdown. Skin grafting is useful for shallow ulcers with well-vascularized beds that are not subjected to high mechanical shear. Unfortunately, these requirements remove most pressure ulcers from skin graft candidacy. The mainstay of deep pressure ulcer reconstruction is coverage with well-vascularized local flaps. There is debate over whether myocutaneous flaps are better than fasciocutaneous flaps for resurfacing regions prone to excess pressure and shear. Although myocutaneous flaps have excellent bulk and blood supply, muscle has low tolerance for ischemic injury. From an anatomic viewpoint there is no pressure point on the human body where bone is padded by muscle. On the other hand, although fasciocutaneous flaps provide reasonable bulk and are teleologically appropriate, some argue that subcutaneous fat and fascia have low resistance to pressure and shear forces, and have less robust perfusion than muscle.⁷²

The anatomic location of the pressure ulcer naturally has a profound impact on flap choice. Regardless of the wound site, however, the flap design should be very large, more than needed for closure, so that if the ulcer recurs the flap can be readvanced. In addition, care should be taken to place suture lines, the weakest part of the reconstruction, away from pressure points. Over the last few decades, patterns have developed in the selection of particular flaps for particular pressure sores. Sacral decubiti are well treated with gluteus maximus myocutaneous flaps (Fig. 45-51). In ambulatory patients, either the superior or the inferior gluteus muscle is spared to preserve hip extension function. The downside of using the gluteal muscle is the relatively bloody dissection. A common alternative is the gluteal fasciocutaneous advancement or rotational flap. Ischial pressure sores are generally due to sitting in a wheelchair with improper cushioning or insufficient position changes. A good first-choice flap for ischial wound reconstruction is the hamstring V-Y myocutaneous flap. The gluteus maximus flap may also be transposed inferiorly to cover this wound. A fasciocutaneous alternative is the posterior thigh flap, based on the continuation of the inferior gluteal artery. Trochanteric ulcers develop from prolonged positioning in the lateral decubitus position or from poorly fitting seat or wheelchair equipment. The tensor fasciae latae myocutaneous flap is an expendable muscle unit in ambulatory patients that has a reliable blood supply. It can be advanced superiorly or transposed on its long arc of rotation (see Fig. 45-51). Good second-choice flaps are the rectus femoris muscle flap and the vastus lateralis myocutaneous flap. When pressure sores are neglected they can become confluent, forming large areas of deep tissue destruction. This dire situation may require hip disarticulation and use of the upper leg soft tissue as a total thigh flap for coverage.

Flap reconstruction of pressure ulcers. *Top row*: Preoperative and 1-month postoperative photos of a stage IV sacral decubitus ulcer treated with a myocutaneous gluteus maximus flap. *Bottom row*: Preoperative and 1-month postoperative photos of a stage IV trochanteric ulcer treated with a myocutaneous V-Y tensor fasciae latae flap.

(Photographs reproduced with permission from M. Gimbel.)

The postoperative care after flap reconstruction of pressure ulcers is as important for success as the surgery itself. The authors recommend transfer of the patient from the operating room table onto an air-fluidized bed, where the patient will remain for the next 7 to 10 days in the hospital. Meticulous instructions must be given to the nursing staff and therapists regarding the positioning and rolling of the patient to prevent stressing the suture lines during these maneuvers. Nutrition and muscle spasm control are carefully maintained. The posthospitalization care plan, which should have been arranged preoperatively, is confirmed to avoid lapses in proper care. Patients with ischial sores are advised to abstain from sitting for 6 weeks to allow for sufficient healing. Care of the pressure ulcer patient is a labor-intensive process that requires attention to detail by the surgeon, nurses, therapists, caseworkers, and family. Unfortunately, small gaps in care inevitably lead to large gaps in the debilitated patient's integument.

Reconstructive Transplant Surgery

Composite tissue allotransplantation (CTA), such as hand and face transplantation, has become a clinical reality and offers enormous potential for many reconstructive problems, including amputation of extremities. However, as with solid organ transplantation, there remains the issue of allograft rejection. In contrast to visceral organ transplantation, which involves homogeneous tissues, CTA may involve a combination of skin, subcutaneous tissue, nerve, blood vessels, muscle, tendon, and bone, and thus carry the antigenicities of all these tissue types. The basic principles of immunosuppression for solid organ transplantation have been applied to CTA and include therapy with a variety of combinations of T-cell-depleting agents, monoclonal antibodies, calcineurin inhibitors, antimetabolites, and rapamycin. The complications associated with immunosuppression are well known, including opportunistic infections, metabolic disturbances, and malignancies. Patients selected to undergo CTA, specifically hand transplantation, are young and healthy and therefore more resistant to immunosuppressive side effects than typically less robust solid organ recipients.

As with any surgical procedure the benefits, success rate, and complications must be understood. Unlike solid organ transplantation, CTA is not a lifesaving procedure. There remains much debate over the risks associated with lifelong administration of potentially dangerous immunosuppressive agents to patients who have no life-threatening illness. The ultimate goal in CTA research is immune tolerance in which the recipient of the allograft remains fully immunocompetent yet does not mount an immunologic response to the transplanted allograft. Accomplishment of this goal would allow the decrease or possible elimination of immunosuppressive medications. If immune tolerance is achieved, CTA clinical applications will broaden dramatically as they become the next frontier in reconstructive surgery⁷³ (Fig. 45-52).

AESTHETIC SURGERY

The American Medical Association defines *cosmetic surgery* as "surgery performed to reshape normal structures of the body to improve the patient's appearance and self-esteem." *Reconstructive surgery* is performed on structures of the body that are abnormal due to congenital defects, developmental abnormalities, trauma, infection, tumors, or disease. It is generally performed to improve function but may also be done to approximate a normal appearance.⁷⁴ In practical terms, there are both reconstructive and cosmetic elements to almost every plastic surgery case, and the definition of "normal" structure is sometimes unclear. Nevertheless, there are patients for whom it is a priority to make surgical changes to their bodies in the clear absence of a functional deformity. Aesthetic surgery patients present a unique challenge to the plastic surgeon, because the most important outcome parameter is not truly appearance, but patient satisfaction. Optimally, a good cosmetic outcome will be associated with a high level of patient satisfaction. For this to be the case, the plastic surgeon must do a careful analysis of the patient's motivations for wanting surgery, along with the patient's goals and expectations. The surgeon must make a reasonable assessment that the improvements that can be achieved through surgery will meet the patient's expectations. The surgeon must appropriately counsel the patient about the magnitude of the recovery process, the exact location of scars, and potential complications. If complications do occur, the surgeon must manage these in a manner that preserves a positive doctor-patient relationship.

Assessment of Facial Aesthetics

A thorough evaluation of the patient who presents for facial aesthetic surgery should start with elicitation of the patient's chief complaint, and the examination should be focused on that region. Physical examination of the entire face should note skin quality as well as the

presence of redundant skin on the neck, jowls, and eyelids. Depth of the nasolabial folds and the presence of "marionette" lines on the chin should be noted. Brow position should be evaluated, along with the distance from brow to hairline. Bulging fat in the lower eyelid region and the presence of a "tear trough" deformity, or deep fold at the lid-cheek junction, should be evaluated. Facial fat atrophy and descent, a hallmark of facial aging, should be noted.

Blepharoplasty and Browlift

Excess skin and adipose deposits of the upper eyelid are approached through an incision based on the supratarsal crease. Careful attention to marking will avoid the complication of overresection. A strip of orbicularis muscle is often excised to accentuate the supratarsal fold. Fat deep to the orbital septum is resected selectively. In the lower lid, excess skin is removed through a subciliary incision. Lower eyelid fat may be either excised or repositioned. Complications can include hematoma, lower lid retraction, and injury to ocular muscles. If a hematoma forms in the retro-orbital region, a true surgical emergency exists. Permanent vision loss can occur if it is not immediately decompressed. Brow ptosis, judged relative to the superior orbital rim, can be corrected through a number of incisions (Fig. 45-53).⁷⁵

Incisions for browlift. *A*, Temporal scalp incision; *B*, temporal hairline incision; *C*, midline scalp incision; *D*, mid-hairline incision; *E*, direct eyebrow incision; *F*, direct forehead incision.

Facelift

Correction of jowls, nasolabial folds, and redundant neck skin can be accomplished with a facelift procedure that both removes skin and tightens the superficial musculoaponeurotic system (SMAS) layer. The SMAS lies deep to the subcutaneous tissue and contains the muscles of facial expression. The facial nerves are in a plane just deep to the SMAS. The SMAS can be simply plicated or a portion of it excised and closed. A sub-SMAS dissection technique can help to elevate and develop this layer in separate fashion, with care being

taken to avoid injury to the underlying facial nerves. The incisions for most facelift techniques are preauricular with extension into the temporal hairline superiorly and into the retroauricular region posteriorly and inferiorly (Figs. 45-54, 45-55). The platysmal layer is continuous with the SMAS layer and can be plicated through a small neck incision to eliminate the appearance of vertical bands along the muscle edge. The most common facelift complication is hematoma, which may require operative drainage to prevent skin flap necrosis. Injury to facial nerves, most often temporal branch and marginal mandibular branch, is seen in approximately 1% of cases.⁷⁶

Facelift. **A.** Preoperative appearance. **B.** Postoperative appearance.

Rhinoplasty

The key to understanding rhinoplasty is appreciating the complex nasal anatomy (Fig. 45-56) and the way in which altering this framework will impact the appearance of the nose. Evaluation of the rhinoplasty patient not only should include the aesthetic complaints, but also should consider the function of the nasal airways. Nasal airway obstruction can occur from several structural problems. A deviated septum can severely impede airflow, as can problems with the internal nasal valve. Obstruction at the internal nasal valve, which is the junction of the upper lateral cartilage and septum, can be identified by applying lateral traction on the cheek skin to open the valve and observing whether airflow improves (Cottle sign). Airway obstruction can be addressed surgically at the time of rhinoplasty. Aesthetic deformities of the dorsum of the nose are treated by a combination of osteotomies, which serve to reposition the nasal bones, and rasping of the bone. Aesthetic deformities of the tip of the nose are treated by reducing the width of the lower lateral cartilages and/or sewing the cartilages together to reduce tip width. Small tips can be augmented with cartilage grafts harvested from septum or auricle (Fig. 45-57). Complications of rhinoplasty include induction of new nasal airway obstruction and a variety of aesthetic deformities.⁷⁷

Rhinoplasty. **A.** Preoperative appearance. **B.** Postoperative appearance.

Suction Lipectomy

Liposuction involves the removal of adipose tissue through minimal incisions using a hollow suction cannula. Although the scarring is quite innocuous, a key principle of liposuction is that fat is being removed without skin tightening. Therefore, one relies on the patient's inherent skin elasticity to provide retraction over the treated adipose depot. Assessment of skin tone is a vital part of the patient evaluation. If there is skin laxity in the area to be treated, it may worsen after liposuction. Importantly, liposuction should be used as a tool for contouring prominent adipose depots and is not considered a weight loss treatment. The best candidates for liposuction are individuals who are close to their goal weight and have focal adipose deposits that are resistant to diet and exercise (Fig. 45-58). The suction cannula removes fat by avulsing small parcels of adipose tissue into small holes at the cannula tip. With standard suction lipectomy, fat is removed only when the cannula is actively moved through the tissue planes. Minimal tissue effects are seen when the cannula is stationary. In general, larger-diameter cannulas remove adipose tissue at a faster rate but carry a higher risk of causing contour irregularities such as grooving and uneven removal of fat. Newer liposuction technology uses an ultrasonic probe to emulsify the fat via cavitation before suction. Advocates of ultrasonic liposuction report that the technique provides a more even and uniform removal of adipose tissue. Recognizing that no one technique is best for all patients and all anatomic regions, many surgeons use ultrasonic energy selectively.

A and B. Preoperative photos of a 22-year-old woman with focal adipose deposits on the trunk and extremities. **C.** Patient 3 months after surgery.

A major advance in the field of liposuction was the development of tumescent local anesthesia. This method involves the infiltration of very dilute lidocaine and epinephrine (lidocaine 0.05% and epinephrine 1:1,000,000) in large volumes throughout the subcutaneous tissues. Tumescent volumes may range from one to three times the anticipated aspirate volume. The dilute lidocaine provides sufficient anesthesia to allow the liposuction to be performed without additional agents, although many surgeons prefer to use sedation or even general anesthetic when large volumes of fat are to be removed. When general anesthesia is used, the lidocaine dose may be reduced or even eliminated. With tumescent anesthesia, the absorption of the dilute lidocaine from the subcutaneous tissue is very slow, with peak plasma concentrations occurring approximately 10 hours after the procedure.⁷⁸ Therefore, the standard lidocaine dosing limit of 7 mg/kg may be safely exceeded. Current recommendations suggest a limit of 35 mg/kg of lidocaine with tumescent anesthesia.⁷⁹ A very important component of the tumescent anesthetic solution is the dilute epinephrine, which limits blood loss during the procedure.

Safety issues are paramount for liposuction because of potential fluid shifts postoperatively and hypothermia. If 5000 mL of aspirate is to be removed, the procedure should be performed in an accredited acute care hospital facility. After the procedure, vital signs and urinary output should be monitored overnight in an appropriate facility by qualified and competent staff who are familiar with perioperative care of the liposuction patient.⁷⁹

Excisional Body Contouring

When significant skin laxity is present, improvement in contour can be achieved only through skin excision. Therefore, all body-contouring surgery represents a trade of excess skin for scar, and this must be emphasized during patient consultation. The patient willing to accept scars in exchange for improved contour is likely to be satisfied with the procedures. With the increased number of bariatric surgery procedures over the past decade, body-contouring surgery has become very popular and is emerging as a new subspecialty of plastic surgery.

ABDOMINOPLASTY/PANNICULECTOMY

Abdominoplasty/panniculectomy is the most common body-contouring procedure and can range from a limited-incision skin removal in the lower abdomen to a major skin excision with transposition of the umbilicus and plaction of the rectus muscles to further enhance contour.⁸⁰ Some patients may benefit from a concurrent vertical incision to remove skin in two vectors (Fig. 45-59). Possible complications include skin necrosis, persistent paresthesias of the abdominal wall, seroma, and wound separation. Necrosis of the umbilicus may complicate preservation of that structure if the stalk is excessively long or an umbilical hernia is repaired. Adding a vertical resection increases the incidence of skin necrosis, especially at the confluence of scars in the lower abdomen.

A. Preoperative photo of 35-year-old woman after gastric bypass and massive weight loss. **B.** Patient 12 months after a fleur-de-lis abdominoplasty.

BRACHIOPLASTY (ARM LIFT)

Brachioplasty, or arm lift, leaves a visible longitudinal scar on the upper arm. Therefore, it is reserved for patients with excessive skin in that region. The patient willing to accept the scar can be happy with the results. Complications include distal seroma and wound separation. Paresthesias in the upper arm and forearm may occur secondary to injury of sensory nerves passing through the resection area, although this rarely affects function. Scar contracture in the axilla may limit shoulder excursion in rare cases and require revision.

THIGH AND BUTTOCK LIFT

Treatment of loose skin on the thighs and buttocks involves a spectrum of operations customized to the individual patient. The outer thighs can be lifted at the same time that an abdominoplasty is performed with one continuous scar along the belt line. The same scar can be continued all the way around the back to lift the buttocks as well. This combination of abdominoplasty, thigh lift, and buttock lift is commonly referred to as a *circumferential lower body lift*. The inner thighs can be contoured by lifting the skin and placing the incisions along the groin crease. Firmly anchoring the deep thigh fascia to Colles' fascia is essential to help prevent spreading of the labia. In cases of severe excess skin on the inner thighs, a long vertical incision is necessary. Complications of thigh and buttock lift include seroma, wound separation, skin necrosis, and change in the shape of the genital region (with possible sexual dysfunction). Blood loss during the procedure may necessitate transfusion.

Reduction Mammoplasty

Breast reduction is performed to treat symptoms of macromastia, most commonly consisting of the triad of upper back pain, bra strap grooving, and rashes under the fold of the breasts. Although this procedure has reconstructive indications, the aesthetic outcome is of considerable importance. Fundamental to the success of the procedure is the establishment of symmetric and proper nipple position. Nipple ptosis is graded by the nipple position relative to the inframammary fold (IMF). Grade 1 ptosis describes a nipple ≤ 1 cm below the IMF. Grade 2 ptosis describes a nipple 1 to 3 cm below the IMF. Grade 3 ptosis describes a nipple position >3 cm below the IMF. *Pseudoptosis* or *bottoming out* is a term used to describe the descent of the breast tissue below the nipple and is a potential long-term complication of breast reduction. In addition to classification of nipple ptosis, a thorough preoperative evaluation also includes measurement of the distance from sternal notch to nipple bilaterally, as well as measurement of the distance from nipple to IMF. The base width of the breast should also be considered. Many patients are found to have significant baseline asymmetries in these measurements. Preoperative breast cancer screening consistent with current American Cancer Society guidelines should be performed for all patients undergoing elective breast reshaping surgery. The planned new nipple position should be symmetrical at the IMF along the breast meridian. There are many technical variations of the breast reduction procedure, but nearly all of them have common elements of reshaping the skin envelope in three dimensions and moving the nipple to a new location on a vascularized tissue pedicle. The pedicle is de-epithelialized to preserve the subdermal vascular plexus. Figure 45-60 shows the classic "keyhole" Wise pattern reduction technique. The skin resection is designed to create a conical shape, and the nipple is transposed on an inferiorly based pedicle.⁸¹ This results in an inverted T-shaped scar. Figure 45-61 shows a patient treated using this technique. All breast reduction techniques keep the scars on the lower half of the breast so they are covered by clothing. Techniques have been designed to minimize scar length and even eliminate the horizontal component in the IMF. Figure 45-62 depicts a vertical scar skin resection pattern with the nipple preserved on a superior pedicle.^{82,83} For excessively large breasts, the required pedicle length may be too long to provide adequate blood supply to the nipple. In such cases, the nipple is removed and replaced onto a viable tissue bed as a full-thickness skin graft. Complications of breast reduction include decreased nipple sensation, nipple loss (rare), skin necrosis, hematoma, and fat necrosis. This last complication can result in a firm mass of scar within the breast that may need careful evaluation and follow-up to distinguish it from a neoplastic mass. Long-term complications include inability to breastfeed and pseudoptosis, as mentioned earlier.

Vertical reduction mammoplasty, Lejour technique. **A.** Markings for vertical reduction. **B.** Purple area is region to be de-epithelialized. **C.** Dark blue region represents inferior pole to be resected. The shaded regions are the lateral and medial segments that are to be undermined; these areas can also be liposuctioned. The superior pedicle is de-epithelialized and dissected to the chest wall. The tissue

and parenchyma from the inferior pole are resected. The pillars from the lateral and medial segments are sewn together. The nipple is transposed on its pedicle to its new position. **D.** Closure of the vertical mammoplasty. There is bunching up of skin and tissue along the vertical limb that will resolve over time; in addition, the new inframammary fold will declare itself superior to the original one.

Mastopexy

In contradistinction to breast reduction, in which patients are treated for symptoms related to heavy breasts, mastopexy is a three-dimensional reshaping of the breast performed with no or minimal volume removal. The principles are the same, however: The skin envelope is contoured and the nipple location optimized. Because the degree of ptosis may be less severe than in breast reduction cases, the patterns of skin resection can vary widely. Minimal patterns may involve excision of just a crescent of skin from above the areola or a periareolar ("donut") resection. The Wise keyhole pattern can be used for larger skin excisions.

Augmentation Mammoplasty

Although the use of prosthetic implants can successfully increase breast size, the surgeon must fully understand both the risks of the biomaterials and the way in which a specific implant of given shape and size can be surgically integrated into the existing breast mound to achieve the desired result.⁸⁴ To address the latter point, the surgeon must first consider the possible surgical approaches for implant placement. The three commonly used incisions for placement of cosmetic breast implants are inframammary, periareolar, and axillary (Fig. 45-63).⁸⁵ A transumbilical breast augmentation technique has been advocated by some surgeons more recently, but critics of this approach point out that there is poor control over the dissection of the implant pocket and that direct access to the tissues of the breast is inadequate to control bleeding vessels. In addition, only saline implants can be used with transumbilical breast augmentation because the prefilled silicone implants are too large to pass through the incision and narrow tunnel. The implants may be placed in a subglandular or subpectoral position (Fig. 45-64). Many surgeons prefer the subpectoral placement because it provides greater soft tissue coverage in the upper pole of the breast and can hide contour irregularities related to the implant. This soft tissue coverage is especially important with saline implants, because visible rippling can occur. The next issue to consider is existing nipple position. If a patient has mild ptosis, the sheer volume of the implant may raise the nipple to an acceptable level. For more severe ptosis, a concurrent mastopexy is necessary. Some surgeons advocate performing the mastopexy as a second stage after the implant has settled into position.

Placement of breast implant. A. Subglandular. B. Subpectoral.

Potential complications related to the implant itself are numerous, and the patient must be fully informed of these possibilities before undergoing surgery. One important point is that there is a high likelihood that the patient will require a second operation to address an implant problem. The implant complications are essentially all local. Although there was concern in the past that implants might be associated with systemic connective tissue disorders, large epidemiologic studies have not supported such a link. The fears over implant safety were so strong that the Food and Drug Administration (FDA) declared a moratorium on the use of silicone gel implants in 1992. At

that time, saline-filled implants were still allowed for general cosmetic use. Data were compiled on silicone gel implants, and these devices were approved by the FDA for general use in 2006.⁸⁶ Potential implant complications include rupture of the device. For saline implants, this results in rapid deflation. For silicone gel implants, the rupture may be not be obvious and can be confirmed by MRI. Another complication is capsular contracture, which results in a tight envelope of scar that can distort the shape of the implant and cause pain in severe cases. A complication more common to saline devices is the appearance of rippling in the upper pole of the device. Implant malposition can also distort the breast shape and require reoperation. Safety data printed on the official FDA-approved package insert from one of the device manufacturers show the incidence of reoperation to be 29.9% over 7 years in a study of 901 women undergoing primary breast augmentation with saline-filled implants (postapproval study). The rate of severe capsular contracture (grade 3 or 4 on a 4-point scale) was 15.7%, and the rate of implant rupture was 9.8%.⁸⁷ For silicone gel-filled implants, the reoperation rate was observed to be 23.5% over 4 years in a study of 455 women undergoing primary breast augmentation. The rate of severe capsular contracture (grade 3 or 4 on a 4-point scale) was 13.2%, and the rate of implant rupture (evaluated by MRI) was 2.7%. The three most common reasons for operation, in order, were capsular contracture (28.9%), implant malposition (15.6%), and ptosis (14.1%). For secondary augmentation, complication rates were much higher, with the reoperation rate over 4 years rising to 35.2%. The rate of capsular contracture was 17.0%, and the rate of implant rupture was 4.0%.⁸⁸

Another concern regarding breast implants is the issue of whether adequate mammography can be performed after augmentation. Displacement techniques can be used by the mammographer to view the breast tissue. Although patients are advised that implants may affect mammography, a study surveying women who did and did not undergo breast augmentation found no statistical difference in survival or detection of carcinoma between the two cohorts.⁸⁹

Gynecomastia

Male breast excess or gynecomastia can be caused by a host of medical diseases and pharmacologic agents. Medical conditions associated with gynecomastia include liver dysfunction, endocrine abnormalities, Klinefelter's syndrome, renal disease, testicular tumors, adrenal or pituitary adenomas, secreting lung carcinomas, and male breast cancer. Causative pharmacologic agents include marijuana, digoxin, spironolactone, cimetidine, theophylline, diazepam, and reserpine. Although these numerous causes must be considered, a majority of patients present with either idiopathic enlargement of the breast parenchyma (more common in teenagers) or simple skin ptosis and excess adipose deposits on the chest wall (considered pseudogynecomastia; more common in adult males). To obtain a flat chest, both liposuction and/or skin excision techniques can be used.⁹⁰

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 46. Surgical Considerations in the Elderly >

KEY POINTS

1. Emergency surgery in the elderly carries a mortality rate that is 3–4 times that seen after elective surgery.
2. Physiologic age, not chronologic age, is the consequence of diminished functional reserve due to comorbid conditions, and is the major predictor of perioperative morbidity and mortality in the elderly.
3. Impaired cardiac function is responsible for more than half of the postoperative deaths in elderly patients, so careful attention must be paid to intravascular volume status in the perioperative period.
4. In addition to cardiac impairment, deficiencies in pulmonary, renal, nutritional, and cognitive function are major factors in the development of postoperative complications in the elderly.
5. In elderly patients with acute appendicitis or acute cholecystitis, one third lack fever, one third lack an elevated white blood cell count, and one third lack physical findings of peritonitis.
6. Laparoscopic approaches to surgical management, including the use of exploratory laparoscopy to rule out surgical disease, is associated with fewer complications and more rapid recovery in the elderly.
7. Analgesic doses should be reduced and titrated carefully in the elderly to avoid delirium; meperidime (Demerol R) should not be used for pain control in elderly patients.
8. The goal of palliative care is to relieve symptoms and preserve physical and mental well-being.

GENERAL CONSIDERATIONS

The old pediatric surgery adage that children are not just "small people" holds true for the other end of the age spectrum, the growing geriatric surgery population. With the aging and expanding U.S. population, a dramatic increase is anticipated in the number of geriatric patients that will require various surgical interventions. By 2030, people >65 years of age will account for 20% of the overall population.¹ Furthermore, half of all Americans currently alive can expect to reach the ninth decade of life.² Elderly patients represent a unique surgical challenge due to the complexity of comorbid conditions and physiologic changes that occur with aging. These physiologic changes, inherent to the aging process, result in decline of physiologic reserve, development of cognitive and functional impairments, and, not uncommonly, development of multiple comorbid conditions. Physiologic age is of greater importance in perioperative management of elderly surgical patients than chronologic age because it takes into account the burden of comorbid disease. It is, therefore, an accurate predictor of postoperative morbidity and mortality. The hallmark of physiologic aging or "senescence" is decreased functional reserve of critical organ systems, resulting in the decreased ability of these systems to cope with challenge, with surgical stress being a prime example. The age of 70 years typically is accepted as the start of senescence because age-related organ dysfunction and development of comorbid conditions sharply increases between ages 70 and 75 years.³ With improved technologies and expanded criteria for surgical interventions in extremely aged patients, increased awareness of the special needs of this population is required to ensure a comprehensive preoperative assessment, delivery of optimal surgical care, and minimization of postoperative complications. Most importantly, the ability to perform an intervention must be balanced with retention of postoperative physical and cognitive function. It is, therefore, crucial to deliver quality surgical care to an elderly patient using a multidisciplinary approach involving the patient and their family, geriatric medical physician, surgeon, and at times, intensivists.

It is estimated that, by the year 2030, there will be 70 million people >65 years old, a stark increase over the 35 million in 2000.⁴ This ever growing elderly population will increasingly require surgical consultation and intervention. Patients >65 years old account for approximately 60% of the current general surgeon's workload.⁵ Patients >65 years old account for approximately 50% of all emergent operations and 75% of operative mortality.⁴ These statistics challenge a surgeon to have an in-depth understanding of the careful perioperative evaluation required in elderly patients and the tailoring of surgical interventions based on unique changes in physiologic reserve of the patients and comorbid conditions that make elderly patients more susceptible to postoperative complications. After all, elderly patients may tolerate the surgical interventions but not the complications. Therefore, the careful perioperative assessment will lead to improved outcomes in progressively older age cohorts, thereby increasing the upper age limits of surgical candidacy.

The importance of this chapter is to highlight salient management strategies for aged surgical patients to provide optimal care and reduce postoperative complications. A particular problem in the elderly population is the potential delay in surgical treatment either from missing a diagnosis secondary to atypical presentations or postponing elective operations because of the misconception that elderly patients will suffer increased complications and poor outcomes as a result of advanced age alone. For example, elective inguinal and umbilical hernia repairs are often postponed due to age bias; these can lead to potentially devastating consequences of bowel ischemia, gangrene, and perforation, to which elderly patients respond poorly (Fig. 46-1). Emergency hernia repairs are one of the most common procedures performed in older patients. Approximately 40% of hernia repairs are performed for incarceration or bowel obstruction in patients >65 years old.⁵ Emergency repair of hernias is associated with an increased morbidity rate of approximately 50% and a mortality rate ranging between 8 to 14%; a significant increase from the 2% mortality rate following elective repair.⁵ One can argue that proper preoperative assessment and timely intervention would have prevented the complicated course that is marked by a need for intensive care resuscitation for intra-abdominal sepsis, a prolonged hospital course, and a requirement for physical rehabilitation secondary to progressive debilitation from prolonged immobilization. This chapter explores the physiologic changes associated with aging and the importance of the perioperative assessment and the tailored management of specific surgical diseases in this population.

Fig. 46-1.

Timely surgical intervention for a medically optimized elderly surgical candidate cannot be overemphasized. Elective procedures can be carried out safely in elderly patients avoiding the potentially devastating consequences of emergency surgery: ischemia, perforation, or death. This is an example of an umbilical hernia resulting in bowel strangulation in an elderly patient with devastating consequences.

PHYSIOLOGY OF AGING

Elderly surgical patients are a heterogeneous cohort with varying degrees of functional impairments and comorbid burdens. The "young old patient" may lead an active lifestyle with few, if any, comorbid conditions. But even for this seemingly healthy group, it is crucial to remember that there are inherent physiologic changes that occur with aging and affect every organ system. These physiologic changes may become more apparent and clinically consequential with the additional stressor of major illness and operative interventions. Therefore, chronologic age is rarely an accurate predictor of morbidity and mortality from surgical interventions. It is, however, an accurate marker for declining physiologic reserve and the presence of comorbid conditions. These, in turn, place elderly patients at higher risk because of impaired cardiac, pulmonary, renal, and neurological reserves, thereby increasing the morbidity and mortality of surgical interventions. Physiologic age, in addition to comorbid conditions, more accurately predicts surgical outcomes in the elderly than chronologic age. The physiologic changes of aging are summarized in Table 46-1.

Table 46-1 Physiologic Limitations of Aging, Their Clinical Consequences, and "Best Practices" in the Elderly Surgical Patient		
Age-Related Changes	Clinical Consequences	Best Practices
Body composition		
Significantly decreased muscle mass, accounting for much of decreased lean tissue mass	Erosion of muscle mass during acute illness may result in strength rapidly falling below important clinical thresholds (e.g., impaired coughing, decreased mobility, increased risk of venous thrombosis)	Maintain physical function through effective pain relief, avoiding tubes, drains, and other "restraints," early mobilization, and assistance with mobilization.
Increased fat mass		
	Altered volumes of drug distribution	Minimize fasting, provide early nutritional supplementation or support (both protein-calorie and micronutrient).
		Adjust drug dosages for volume of distribution.
Respiratory		
Decreased vital capacity	Less effective cough	Provide early mobilization, assumption of upright rather than supine position.
Increased closing volume	Predisposition to aspiration	
Decreased airway sensitivity and clearance	Increased closure of small airways during tidal respiration, especially postoperatively and when supine, leading to increased atelectasis and shunting	Ensure effective pain relief to allow mobilization, deep breathing.
Decreased partial pressure of oxygen		Provide routine supplemental oxygen in the immediate postoperative period, and then, as needed.
	Predisposition to hypoxemia	Minimize use of nasogastric tubes.
Cardiovascular		
Decreased maximal heart rate, cardiac output, ejection fraction	Greater reliance on ventricular filling and increases in stroke volume (rather than ejection fraction) to achieve increases in cardiac output	Use vigorous fluid resuscitation to achieve optimal ventricular filling.
Reliance on increased end-diastolic volume to increase cardiac output	Intolerant of hypovolemia	Nonvasoconstricting inotropes and afterload reduction may be more effective, if pharmacologic support is required.
Slowed ventricular filling, increased reliance on atrial contribution	Intolerant of tachycardia, dysrhythmias, including atrial fibrillation	
Decreased baroreceptor sensitivity	Predisposition to hypothermia (e.g., decline in body temperature during surgery is more marked unless preventive measures are taken)	
Thermoregulation		
Diminished sensitivity to ambient temperature and less efficient mechanisms of heat conservation, production, and dissipation	If there is hypothermia, shivering may result, associated with marked increases in oxygen consumption and cardiopulmonary demands.	Maintaining intraoperative normothermia reduces wound infections, adverse cardiac events, and length of hospital stay.

Febrile responses to infection may be blunted in frail or malnourished elderly and those at extreme old age.	Fever may be absent despite serious infection, especially in frail elderly.	Be aware of hypothermia in trauma resuscitation.
Renal function, fluid-electrolyte homeostasis		
Decreased sensitivity to fluid, electrolyte perturbations	Predisposition to hypovolemia	Pay meticulous attention to fluid and electrolyte management.
	Predisposition to electrolyte disorders, (e.g., hyponatremia)	
Decreased efficiency of solute, water conservation, and excretion	Predisposition to hyperglycemia	Recognize that a "normal" serum creatinine value reflects decreased creatinine clearance because muscle mass (i.e., creatinine production) is decreased concurrently.
Decreased renal mass, renal blood flow, and glomerular filtration rate	Predisposition to hyperosmolar states	
Increased renal glucose threshold		Select drugs carefully: Avoid those that may be nephrotoxic (e.g., aminoglycosides) or adversely affect renal blood flow (e.g., NSAIDs).
		Adjust drug dosages as appropriate for altered pharmacokinetics.

SURGERY IN THE ELDERLY

It is critical in the assessment of an elderly surgical candidate to evaluate physiologic age and to maintain a high index of suspicion for surgical pathology, keeping in mind that elderly patients often present with atypical symptoms and can present with vague abdominal examinations that may effectively mask intra-abdominal catastrophe. This is worsened by coexistent medical problems and altered mentation that may be the result of organic brain disease such as dementia, drugs, infection, or dehydration. Acute appendicitis and acute cholecystitis are examples of common acute surgical pathologies with which elderly patients present late or have delayed diagnosis or misdiagnosis. This often leads to higher rates of perforation and complications that adversely affect morbidity and mortality.⁶ In fact, biliary tract disease, including acute cholecystitis, is the most common indication for surgical intervention in the elderly. This is likely related to age-related changes within the biliary system, specifically increased lithogenicity of bile and increased prevalence of cholelithiasis.⁷ Delayed diagnosis may lead to complications such as ascending cholangitis and gallstone ileus.

Elderly patients may not present with typical symptoms of acute abdominal pain, fever, or leukocytosis, likely secondary to depressed immune response of elderly patients. A careful assessment is crucial to timely operative intervention. In fact, in older patients presenting with acute appendicitis, the initial diagnosis is correct in less than half of the patients.⁷

Assessment of an elderly patient presenting with abdominal pain should begin with assuring stable hemodynamics and initiating appropriate resuscitation, as these patient are often profoundly dehydrated. As with most initial evaluations, airway, breathing, and circulation are initial priorities. A careful history and physical examination should follow and provide invaluable clues to the underlying disease process. The chief complaint should be elicited as well as a history of previous admissions, which may alert to recurrent diseases such as acute diverticulitis or previous operations that may draw focus to adhesive small-bowel obstruction. It is also important to obtain a detailed history regarding comorbid conditions and current medications. Initial evaluation may include electrocardiogram to rule out coronary ischemia and chest x-ray to rule out congestive heart failure (CHF) or pneumonia. Basic laboratory evaluation will help to rule out common medical etiologies for abdominal pain, such as coronary ischemia, acute pancreatitis, hepatitis, or urinary tract infections. Then careful referral for radiographic imaging will help to confirm the diagnosis and allow timely operative intervention. Regardless, the importance of a high degree of clinical suspicion cannot be overemphasized.

PREOPERATIVE ASSESSMENT

Surgical risk increases with advancing age as a consequence of physiologic decline and the development of comorbid conditions that make the elderly surgical patient more susceptible to postoperative complications. These complications are, in turn, poorly tolerated because of decreased physiologic reserve. Comorbid illness serves as the basis for the

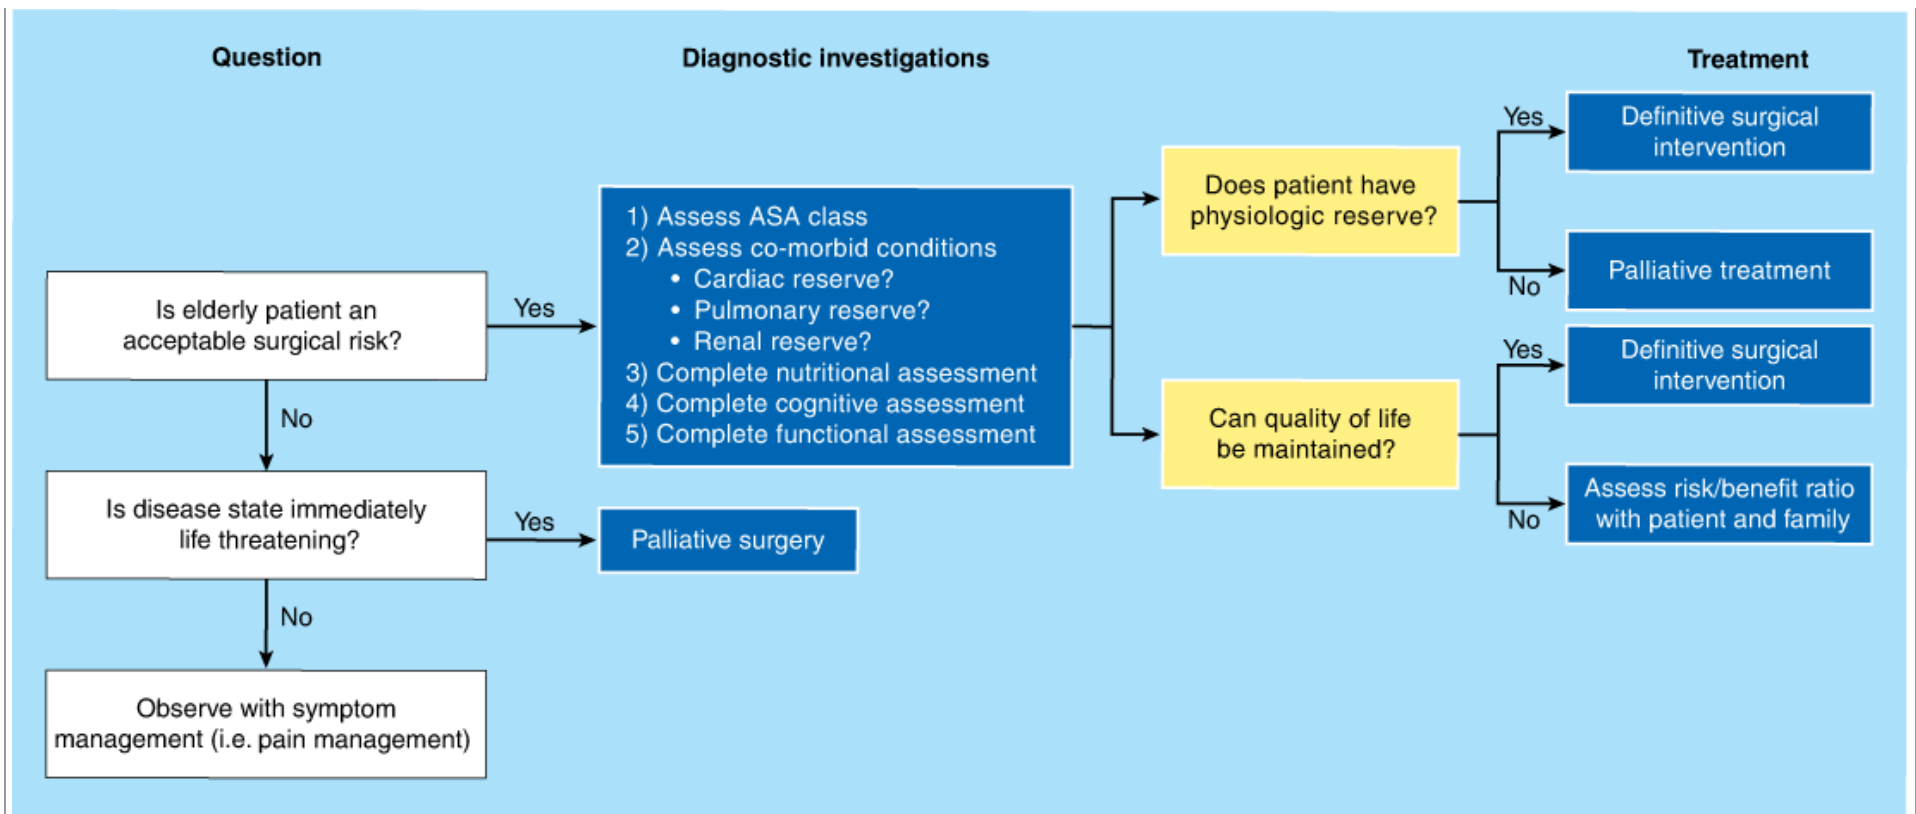

American Society of Anesthesiologists' (ASA's) physical status classification⁸ (Table 46-2). This is a valuable tool for identifying elderly patients who are at high risk for postoperative complications because it is based on organ system dysfunction and severity of functional impairment. It helps to identify subgroups of patients in whom appropriate measures should be taken to reduce the risk of adverse outcomes. Importantly, it also identifies emergency surgery as a dangerous risk factor for perioperative morbidity and mortality. The physiologic changes that occur with normal aging result in increased risks associated with anesthesia and surgery, but careful assessment of potential problems in the perioperative period combined with implementation of preventative measures can significantly reduce complications associated with general anesthesia in the elderly patient.⁹ Adequate control and understanding of the potential negative impact of comorbid conditions on surgical outcomes allows an appropriate preoperative evaluation that, in turn, leads to acceptable morbidity and mortality. A useful algorithm for the preoperative assessment of an elderly surgical patient is provided in Fig. 46-2.

Table 46-2 American Society of Anesthesiologists' Physical Status Classification ASA Risk Stratification of Anesthetic/Surgical Risk	
Class 1	Healthy patient
Class 2	Mild systemic disease
Class 3	Severe (but not incapacitating) systemic disease
Class 4	Severe systemic disease posing a constant threat to life
Class 5	Moribund with life expectancy <24 h, independent of operation
Class 6	Organ donor

Note: Suffix "e" is added to the class for emergency operations.

Useful preoperative algorithm to determine elderly patient's suitability for definitive surgical intervention balancing therapeutic goals, physiologic reserve, and quality of life with palliative treatment and surgery as viable options. ASA = American Society of Anesthesiologists.

Cardiac complications are the leading cause of perioperative complications and death in surgical patients of all age groups, but particularly among the elderly. This is because they likely have existing cardiac dysfunction, combined with normal physiologic decline and poor functional reserve. The combined effect of depletion of intravascular volume, age-related impairment of response to catecholamines, and increased myocardial relaxation time adversely affects the functioning of an elderly patient under stress in the perioperative period.¹⁰ Aging has been demonstrated to cause a decrease in cardiac output by approximately 1% per year. Older individuals fail to augment heart rate to the same extent as younger individuals. More importantly, the ability to increase cardiac output with aging is dependent on ventricular dilatation, which is determined by preload.¹¹ This is precisely the reason that careful attention must be paid to volume status in the perioperative period. Dehydration or poor resuscitation may occur in elderly surgical patients for a variety of reasons, and both are poorly tolerated. Over one half of all postoperative deaths in elderly patients and 11% of postoperative complications are a result of impaired cardiac function under physiologic stress. Incomplete emptying of the ventricle at end systole and subsequent reduction in ejection fraction is characteristic of the aging heart.¹⁰ Reduced distensibility (i.e., preload), in addition to acute stressors, could lead to impaired coronary perfusion and cardiac ischemia.

As a result, the physiologic stress of general anesthesia and surgical interventions can unmask the limited cardiac reserve of the elderly patient. For example, poor reserve may become evident with increased myocardial oxygen demand resulting from tachycardia or loss of vascular tone from the vasodilatory effects of many general anesthetic agents.¹ Another important predictor of surgical outcomes and cardiac complications in the elderly is the presence of CHF. CHF is present in approximately 10% of patients >65 years old and is the leading cause of postoperative morbidity and mortality.¹² This number will likely rise over the next few years as percutaneous intervention and statin drugs prevent and

prolong survival from acute myocardial infarction. Therefore, identifying correctable and uncorrectable cardiovascular disease is critical before elective surgical interventions. Simple steps such as maintaining proper fluid balance and limiting myocardial work will aid in minimizing complications.

Pulmonary complications are a major source of morbidity and mortality in elderly surgical patients. The result of the changes that occur with the respiratory system with aging limits the maximal breathing capacity by age 70 to 50% of the capacity present at age 30.¹² In addition, there is a decline in the forced expiratory volume in 1 second (FEV1) with advancing age. It is estimated that humans lose 35 mL of their FEV1 per year over the age of 35 years old. There is a slow decline between ages 35 and 65 years old followed by a much more progressive decline at approximately 75 years of age.¹³ Pulmonary complications account for up to 50% of postoperative complications and 20% of preventable deaths.¹⁴ Risk factors for pulmonary complications include a positive smoking history, presence of shortness of breath, or clinical evidence of chronic obstructive pulmonary disease. All elderly patients undergoing major surgical interventions should have a baseline chest radiograph. Screening spirometry can be performed to determine forced vital capacity and FEV1. A baseline arterial blood gas measurement also will help to identify hypoxemia and hypercapnia, both of which may increase postoperative complications. If abnormalities are found, perioperative use of bronchodilators and incentive spirometry may be invaluable. When possible, regional anesthetic techniques may provide excellent analgesia while helping to reduce the postoperative pulmonary complications associated with general anesthesia and endotracheal intubation.

Elderly surgical patients are also at increased risk of renal compromise in the perioperative period. Renal size and volume decrease with age, accompanied by intrarenal vascular changes. There is a decrease in the number of glomeruli and nephron mass, resulting in decreased filtration area. Subsequently, serum creatinine concentration is an insensitive indicator of renal function in the elderly.¹⁰ The physiologic changes in renal function in elderly patients increase susceptibility to renal ischemia as well as to nephrotoxic agents. Age-related changes in renal function result from progressive glomerulosclerosis and reduction in renal mass resulting in decreased creatinine clearance and glomerular filtration rate. This is worsened by a decline in cardiac output with increasing age and subsequent decrease in renal blood flow. It has been shown that patients with impaired glomerular filtration rate are more susceptible to volume changes that occur in the perioperative period. Furthermore, decreased drug elimination can potentiate the effects of nephrotoxic drugs and prolong the sedative effects of anesthetics and narcotic used for postoperative pain management.¹² Acute renal failure is proven to dramatically increase morbidity and mortality in elderly patients. The mortality of perioperative renal failure is approximately 50% and may be even higher in elderly patients. Therefore, careful management of fluid and electrolyte status is prudent to avoid imbalances and limit exposure to nephrotoxic diagnostic studies and medications in the perioperative period. Patients >70 years old may be susceptible to the nephrotoxic effects of certain drugs, including certain anesthetic agents, and thus should be protected by hydration and diuresis, as long as they can tolerate the fluid load.¹⁰ Prompt recognition of renal compromise, marked by an elevation of blood urea nitrogen or creatinine levels, or oliguria requires aggressive correction of underlying causes. Furthermore, electrolyte imbalances can lead to potentially devastating cardiac complications, specifically, conduction abnormalities and arrhythmias.¹² Although not routinely advocated in younger patients, elderly patients should have routine electrolyte panels and urinalysis before all surgical interventions to identify potential renal dysfunction.¹⁵ Underlying causes of abnormalities found on screening should be corrected before surgery and necessitate intravascular volume repletion to ensure adequate renal perfusion perioperatively.

It is important that a thorough preoperative evaluation include an accurate assessment of the functional status of surgical candidates as well as their cognitive level of functioning. This ensures that operative intervention will not significantly impair the quality of life of an elderly surgical candidate. The ability to withstand the stress of surgical interventions is dependent on functional reserve and ability to build an appropriate response to perioperative stress.¹⁰ The ability to perform activities of daily living (ADL) such as feeding, dressing, bathing, and toileting have been correlated with postoperative morbidity and mortality. Preoperative functional assessment can be measured by hand grip strength, timed up and go, and functional reach tests. All of these tests independently predicted better recovery and shorter time to recover ADL after major surgery. In addition, these tests provide an accurate assessment of a patient's muscle mass, nutritional status, coordination, gait speed, balance, and mobility.⁵ Proper functional assessment will accurately predict rehabilitation needs, estimate biologic reserve, and even signal complications.¹⁰

The functional status of an elderly patient is related to and predictive of pulmonary and cardiac complications that may ensue following surgical interventions. For example, functional impairment often leads to immobility, which can lead to increased risk of postoperative atelectasis, pneumonia, deep vein thrombosis (DVT), and pulmonary embolism. Furthermore, proper functional assessment has been shown to improve diagnostic and therapeutic outcomes as well as lead to identification of previously undiagnosed conditions that may be treatable preoperatively or managed perioperatively.¹⁰

Cognitive function often is overlooked in the preoperative assessment of patients, because patients are not typically formally evaluated before surgical intervention (i.e., mini-mental state examination). However, knowledge of baseline cognitive function provides invaluable information because subtle changes in cognition often herald postoperative complications, such as underlying infection. Cognitive impairment including delirium and confusion commonly occur in the elderly patient during the early postoperative period and can result in increased morbidity, delayed functional recovery, and prolonged hospitalizations. The etiology of this postoperative cognitive dysfunction may be multifactorial. Advanced age, history of alcohol abuse, baseline cognitive disturbance, hypoxia, and hypotension have all been shown to be contributing factors.¹⁶ It is crucial that careful attention be paid to adequate postoperative analgesia to improve recovery while avoiding compromise of cognitive function. Finally, dementia is a known predictor of poor long-term survival.

Formal nutritional assessment is invaluable in the perioperative assessment of elderly patients. Poor nutritional status in elderly patients is more common than previously believed and results from the interplay between physiologic, psychosocial, and economic changes that accompany the aging process. Elderly patients may have poor nutritional status because of either poor intake from the underlying illness or pre-existing comorbid conditions. It is estimated that approximately 9 to 15% of persons >65 years old are found to be malnourished in an outpatient setting. This increases to 12 to 50% and 25 to 60% in the acute inpatient hospital setting and chronic institutional settings, respectively.¹⁷ The cycle of frailty that occurs with chronic undernutrition or malnutrition can lead to progressive functional decline, loss of muscle mass, and decreased oxygen consumption and metabolic rate among several other potentially debilitating consequences to this population.¹⁷ Therefore, adequate assessment of nutritional status of these patients preoperatively and the prompt institution of nutritional support is of utmost importance. This is an integral component of the preoperative assessment, considering that nutritional status is a proven independent predictor of surgical outcomes. Allowing a patient's nutritional state to deteriorate throughout the perioperative period leads to adverse outcomes, specifically increased nosocomial infections, multiorgan system dysfunction, poor wound healing, and impaired functional recovery. Therefore, nutritional assessment and support, if necessary, not only gives patients additional reserve to minimize postoperative complications, it aids in appropriate wound healing, functional recovery, and rehabilitation.

Protein energy malnutrition (PEM) also can result from keeping surgical patients who may already have inadequate nutritional reserve NPO. This may occur in a short period in the elderly, malnourished surgical patient in a hypermetabolic state induced by stress of illness and surgery. The physiologic consequences of PEM are multiple and include anorexia, hepatic dysfunction, decreased mucosal proliferation, and sarcopenia.¹⁷ A good marker of PEM is hypoalbuminemia, also shown to be an extremely accurate predictor of surgical outcomes. The incidence of postoperative complications was increased in patients with serum albumin levels <3.5 g/L.¹⁷ In fact, current recommendations indicate that if patients demonstrate compromise of nutritional status as defined by >10% weight loss and serum albumin level <2.5 g/dL, they should be considered for a minimum of 7 to 10 days of nutritional repletion prior to surgery.¹⁰

The significant impact of nutritional status on surgical outcomes and functional recovery in the elderly population after surgical intervention underscores the importance of an accurate assessment preoperatively. In busy surgical practices, the question arises as to whether this can be done in a fairly easy, quick, reproducible, and cost-effective manner while obtaining vital information. There are several methods of assessing nutritional status including anthropomorphic measures (i.e., body mass index), biochemical laboratory values (i.e., transferring, albumin and prealbumin), and clinical assessments.¹⁷

The Mini Nutritional Assessment (MNA) is a validated nutritional assessment tool that has been used for several years, which can be a valuable tool for the preoperative assessment of the elderly surgical candidate. The MNA is depicted in Fig. 46-3, and as demonstrated, it can be completed in a relatively short time. The MNA consists of a screening portion assessing the patient's current body mass index, food intake and weight loss, mobility, and presence of stressors, depression, or dementia, all of which can exacerbate undernutrition or malnutrition in the elderly patient. This is aimed at identifying patients at risk for malnutrition and subsequent need for further evaluation involving a more complete psychosocial assessment and determination of mode of feedings, as well as objective measurements of midarm and calf circumferences. This tool helps to identify undernutrition and malnutrition in older individuals, >65 years old, helping to direct timely interventions. This, in turn, may help to decrease postoperative complications and result in improved functional recovery in these patients.

Fig. 46-3.

Last name:	First name:	Sex:	Date:
Age:	Weight, kg:	Height, cm:	I.D. Number:

Complete the screen by filling in the boxes with the appropriate numbers.

Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a malnutrition indicator score.

Screening	
A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties? 0 = severe loss of appetite 1 = moderate loss of appetite 2 = no loss of appetite	<input type="checkbox"/>
B Weight loss during the last 3 months 0 = weight loss greater than 3 kg (6.6 lbs) 1 = does not know 2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs) 3 = no weight loss	<input type="checkbox"/>
C Mobility 0 = bed or chair bound 1 = able to get out of bed/chair but does not go out 2 = goes out	<input type="checkbox"/>
D Has suffered psychological stress or acute disease in the past 3 months 0 = yes 2 = no	<input type="checkbox"/>
E Neuropsychological problems 0 = severe dementia or depression 1 = mild dementia 2 = no psychological problems	<input type="checkbox"/>
F Body Mass Index (BMI) (weight in kg) / (height in m ²) 0 = BMI less than 19 1 = BMI 19 to less than 21 2 = BMI 21 to less than 23 3 = BMI 23 or greater	<input type="checkbox"/>
Screening score (subtotal max. 14 points) 12 points or greater Normal – not at risk – no need to complete assessment 11 points or below Possible malnutrition – continue assessment	<input type="checkbox"/> <input type="checkbox"/>

Assessment	
G Lives independently (not in a nursing home or hospital) 0 = no 1 = yes	<input type="checkbox"/>
H Takes more than 3 prescription drugs per day 0 = yes 1 = no	<input type="checkbox"/>

J How many full meals does the patient eat daily? 0 = 1 meal 1 = 2 meals 2 = 3 meals	<input type="checkbox"/>
K Selected consumption markers for protein intake • At least one serving of dairy products (milk, cheese, yogurt) per day yes <input type="checkbox"/> no <input type="checkbox"/> • Two or more servings of legumes or eggs per week yes <input type="checkbox"/> no <input type="checkbox"/> • Meat, fish or poultry every day yes <input type="checkbox"/> no <input type="checkbox"/> 0.0 = if 0 or 1 yes 0.5 = if 2 yes 1.0 = if 3 yes	<input type="checkbox"/> . <input type="checkbox"/>
L Consumes two or more servings of fruits or vegetables per day? 0 = no 1 = yes	<input type="checkbox"/>
M How much fluid (water, juice, coffee, tea, milk...) is consumed per day? 0.0 = less than 3 cups 0.5 = 3 to 5 cups 1.0 = more than 5 cups	<input type="checkbox"/> . <input type="checkbox"/>
N Mode of feeding 0 = unable to eat without assistance 1 = self-fed with some difficulty 2 = self-fed without any problem	<input type="checkbox"/>
O Self view of nutritional status 0 = views self as being malnourished 1 = is uncertain of nutritional state 2 = views self as having no nutritional problem	<input type="checkbox"/>
P In comparison with other people of the same age, how does the patient consider his/her health status? 0.0 = not as good 0.5 = does not know 1.0 = as good 2.0 = better	<input type="checkbox"/> . <input type="checkbox"/>
Q Mid-arm circumference (MAC) in cm 0.0 = MAC less than 21 0.5 = MAC 21 to 22 1.0 = MAC 22 or greater	<input type="checkbox"/> . <input type="checkbox"/>

0 = yes 1 = no

I Pressure sores or skin ulcers
0 = yes 1 = no ☐

The combined effects of poor nutrition, decreased cognition, and immune impairments due to nutritional or pharmacologic factors create a treacherous tendency for elderly patients to have more poorly defined symptoms or to present with more advanced disease. In acute abdominal conditions, such as acute appendicitis and acute cholecystitis, one third of elderly patients will lack an elevated white blood cell count, one third will lack fever, and one third will lack physical findings of localized peritonitis. These deficits contribute to a threefold higher rate of perforated appendicitis and gangrene of the gallbladder in elderly patients compared to young patients. An "unimpressive" physical exam in an elderly patient with acute onset of abdominal symptoms should never be taken as a sign of the absence of surgical disease.

SPECIFIC CONSIDERATIONS

Cardiovascular

It is estimated that approximately 40% of the projected 25 million octogenarians comprising the U.S. population by the year 2025 will have serious cardiovascular symptoms.¹⁸ With the aging of the population, undoubtedly, many patients will require cardiovascular surgical interventions. With advances in cardiopulmonary bypass technique, myocardial protection, and improved perioperative care, coronary artery bypass grafting (CABG) and valve replacement operations can be safely performed in elderly patients. Senile calcific aortic stenosis is common within this population, and referral for aortic valve replacement is increasing, encompassing many patients who are extremely aged, >75 years old (Fig. 46-4). Interestingly, despite some degree of age bias in referral patterns for elderly patients to undergo major cardiac surgery, advanced age alone is not a predictor of poorer outcomes or increased mortality when compared to younger patients. It has been demonstrated that emergency operations, preoperative New York Heart Association (NYHA) functional class 3 or greater, and chronic renal failure were the main predictors of increased operative mortality.¹⁸ In one study, preoperative renal dysfunction, cerebrovascular disease, valve surgery, and catastrophic state were independent predictors of increased mortality in elderly patients.¹⁹ Elderly patients with nondialysis-dependent renal dysfunction had a 60% chance of death during a 5-year follow-up period compared to 25% in elderly patients without a history of renal dysfunction. Similarly, the presence of cerebrovascular disease resulted in a twofold increase in mortality among elderly patients.¹⁹ Even patients who were 80 years of age or more did not have any significant increase in surgical risk and within this population, the 4-year actuarial survival was 70.5% with an event-free survival of approximately 60.6%.¹⁹

There has been a significant trend in providing definitive operative intervention to elderly patients requiring CABG. Although older patients have higher morbidity and mortality rates after cardiac surgery than do younger patients, these rates are significantly decreasing. The Society of Thoracic Surgeons reports perioperative mortality rates ranging from 1.6% in patients 51 to 60 years of age to 7.7% in those 81 to 90 years of age.²⁰ This decline in morbidity and mortality rates likely reflects better preoperative assessment and patient selection. Furthermore, this decline has occurred despite the advancing age of cardiac patients at time of referral, advanced disease, and greater comorbid disease burden. Elderly patients are more likely to have significant triple-vessel disease accompanied by poor ejection fraction, left ventricular hypertrophy, significant valvular disease, and previous history of myocardial infarction than are younger patients.²⁰ Elderly patients also are more likely to be classified as NYHA functional class 3 or higher and are more likely to present on an emergent basis, in part because of reluctance to provide elective intervention in these patients because of presumptive poorer outcome. Despite the increased risk of morbidity and mortality compared to younger patients, elderly patients, including those >80 years old, can undergo CABG with acceptable mortality risk. The overall mortality rate is approximately 7 to 12% for elderly patients, including those CABGs performed under emergency conditions. This figure decreases to approximately 2.8% when CABG is performed electively with careful preoperative evaluation.²¹

Valve Replacement

There also is an increasing percentage of the geriatric population presenting with symptomatic valvular disease requiring intervention. The most common valvular abnormality present in elderly patients is calcific aortic stenosis, which can lead to angina and syncope.²² The operative mortality from aortic valve replacement is estimated to be between 3 and 10%, with an average of approximately 7.7%.²⁰ If aortic stenosis is allowed to progress without operative intervention, CHF will ensue. The average survival of these patients is approximately 1.5 to 2 years. If a patient is a candidate for operative intervention, age should not be a deterrent, especially considering the potential to increase life expectancy. It has been recommended that the minimally symptomatic octogenarian with aortic stenosis should be considered a low-risk patient and expected to experience an uneventful operative course and expedient recovery, especially with carefully selected patients. More importantly, if these elective procedures are delayed until symptoms or left ventricular dysfunction develop, patients may suffer from unnecessary increased operative risk and mortality.¹⁸ Furthermore, there is a demonstrable improvement in quality of life in these

patients, with many improving their NYHA functional classification.

Elderly patients require surgery for mitral valve disease when ischemic regurgitation is present. Surgery for mitral valve disease carries a higher morbidity and mortality than for aortic intervention, with an estimated mortality rate as high as 20%.²⁰ Left ventricular function usually is compromised in patients requiring intervention, leading to a poorer outcome in these patients. The surgical outcome for mitral valve procedures depends on the extent of the disease, age of the patient, presence of pulmonary hypertension, and extent of coronary artery disease. The presence of comorbid conditions combined with the emergent nature of surgery in a large percentage of elderly patients further worsens the outcome. Therefore, a decision regarding management of mitral valve disease should be individualized to each patient with the above factors considered. Another concern regarding elderly patients who require surgery for valve disease is the additional requirement for coronary revascularization. This increases the morbidity and mortality from surgical intervention. An elderly patient with many comorbid conditions in need of a combined procedure should only have critically stenosed vessels bypassed.²² Therefore, advanced age is not a contraindication to performing combined procedures; however, a higher mortality rate should be expected. Neurologic complications from valve surgery are particularly common in elderly patients. It has been estimated that approximately 30% of patients >70 years old who undergo valve procedures develop either transient or permanent neurologic dysfunction.²² This often is a result of embolism from debris dislodged from the valve during the procedure or from a formed thrombus in the right atrium.

An important consideration in valve replacement procedures in elderly patients is the type of prosthesis to be used. Elderly patients are at increased risk from bleeding-associated anticoagulation complications. This is especially significant in patients who have experienced falls and minor trauma that have resulted in significant intracranial hemorrhage. To avoid the lifelong requirement for anticoagulants, bioprosthetic valves should be used in place of mechanical valves whenever possible.²² Although the bioprosthetic valves are not as durable as mechanical valves, studies demonstrate excellent structural integrity 10 years postprocedure, making it an appropriate choice in an elderly patient.

Kidney Transplantation

The number of patients requiring treatment for end-stage renal disease (ESRD) continues to dramatically increase, with a disproportionate increase in older ESRD patients. In 2000, more than 51% of hemodialysis patients in the United States were ≥65 years old.²³ Although there is currently no age limitation for access to transplantation within the United States, there has been a hesitancy to transplant kidneys from older donors as well as to transplant scarce organs to elderly patients for fear of increased graft loss. Therefore, there have been limited data on short- and long-term outcomes of renal transplantation in elderly patients until recently.

Successful kidney transplantation is preferred treatment for ESRD and long-term patient survival is higher in elderly patients who have been transplanted compared to those that remain on hemodialysis. The projected life span for patients currently on the transplant waiting list who are age 60 to 74 years old is approximately 6 years. This increases to 10 years posttransplantation.²³ For comparison, the expected life span of a 70-year-old patient in the general population is 13.4 years. Kidney transplantation affords all patients, including those in the elderly cohorts, improved quality of life with greater longevity without a significant difference in overall patient morbidity, mortality, or graft survival. Among dialysis patients ages 70 years and older, renal transplantation was associated with a 41% lower risk of death compared to age matched wait-listed patients. A clear survival advantage also has been demonstrated in carefully selected patients 75 years and older. A benefit is observed among patients whose life expectancy is expected to exceed 1.8 years.²⁴ Although the literature on long-term outcomes is still inconclusive, it has been demonstrated that there is no statistically significant difference in short-term outcomes, specifically, primary nonfunction, delayed graft function, in-hospital mortality, and length of stay, among elderly patients undergoing renal transplantation.²³

In the last decade, there has been a shift favoring the transplantation of kidneys from older donors as well as transplantation of donor grafts to older recipients. A new strategy is the use of "extended criteria donors" (ECDs) for elderly recipients, using dual kidney transplantation to increase the net total nephron mass, resulting in favorable outcomes. One such patient was a 70-year-old male who received a dual ECD renal transplant with return of creatine to normal levels shortly after surgery (Fig. 46-5). There has been a progressive increase in the use of ECD kidneys, which accounted for 16% of all transplants from deceased donors in 2003; approximately 33% of these organs were used for transplantation in elderly recipients. The adoption of dual kidney donation from elderly patients with depressed renal function expanded the donor population to patients >75 years of age, >15% of whom demonstrated evidence of glomerulosclerosis.²⁵ The increased nephron mass achieved with dual kidney transplantation compensated for the possible decreased renal function with advancing age. The net result is that recipients demonstrate similar postoperative graft function when compared to single kidney transplantation. Elderly recipients of ECD kidneys demonstrated a 25% decrease in risk of mortality compared to wait-listed patients on hemodialysis.²⁴

Elderly patients have better graft function, with decreased incidence of delayed graft function and fewer episodes of acute rejection, than do younger patients. This may be the result of decreased immune competence with aging. With the lower occurrence of both acute and chronic rejection in elderly patients, it has been suggested that elderly patients would benefit from lower doses of immunosuppressive agents. However, this decreased competence is balanced by the increased incidence of infections from viruses such as herpes zoster, cytomegalovirus and Epstein-Barr, as well as posttransplant neoplasia, including lymphoproliferative disorders.

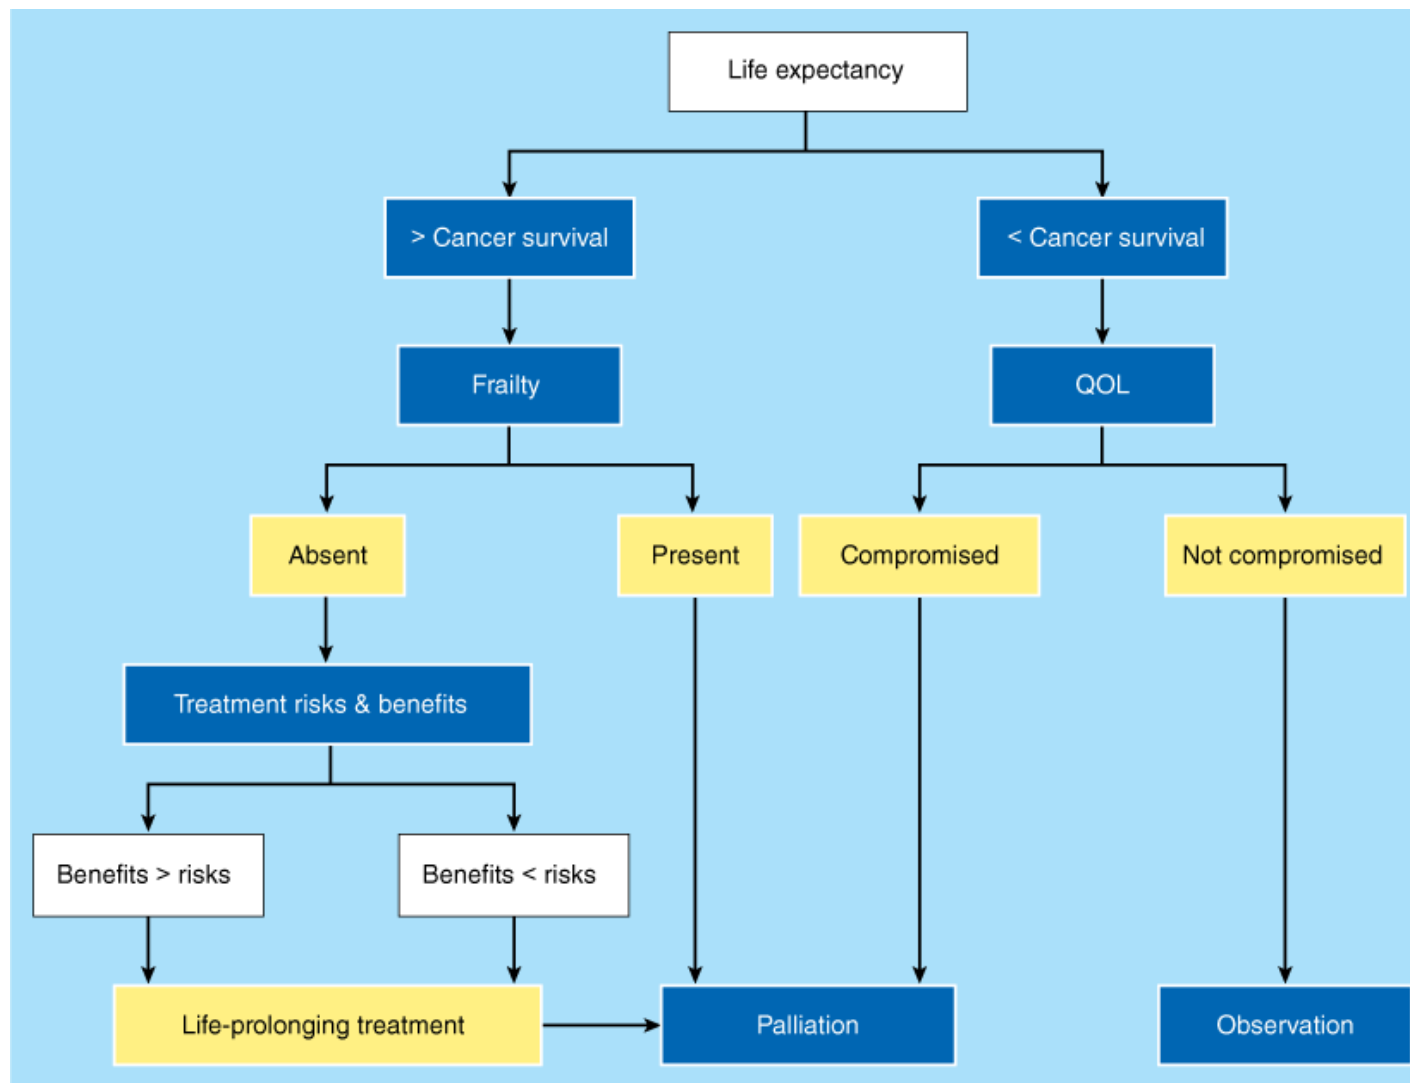

Interestingly, graft loss in the elderly population is mostly attributable to the patient's death, primarily secondary to cardiovascular disease. Pre-existing cardiovascular disease may be worsened by the use of corticosteroids and calcineurin inhibitors, both of which are essential to the antirejection regimen posttransplantation. It must be kept in mind, however, that age-related mortality due to cardiovascular disease is double for patients on the transplant list compared to those who receive a transplant. Other main causes of patient death posttransplantation with graft survival are infection and malignancy. The decreased immune competence with advanced age combined with powerful immunosuppressive drugs places the elderly patient at greater susceptibility to infection and increased risk of morbidity and mortality. However, modification of current immunosuppression regimens may lead to a decrease in infection complications among elderly patients.²³ Careful preoperative assessment for these conditions minimizes postoperative complications and graft loss in this population.

Cancer

The incidence of most cancers is age dependent, and the exponentially expanding aged population is rapidly increasing the number of elderly patients requiring multimodal therapy for various oncologic diseases, primarily lung, breast, pancreas, esophagus, stomach, and colorectal malignancies. Approximately 50% of cancer diagnoses are currently made in patients aged 70 years or older.¹⁰ According to predicted estimations, the increase in the elderly population will account for up to a 51% increase in the number of patients

undergoing oncologic procedures by the year 2020. The increased life expectancy of the geriatric patient coupled with the increasing incidence of cancer with advancing age will most definitely lead to an increased prevalence of malignant disease amenable to surgical intervention within this population. This is an area of great interest given that randomized clinical trials to determine the outcomes of elderly patient undergoing curative resections as well as neoadjuvant and adjuvant chemotherapy and radiation are lacking. In addition, rarely are elderly patients included in clinical trials; therefore, treatment decisions often are based on surgeon experience that may be flawed with inherent biases regarding the outcome of complete oncologic resections in elderly patients. Given the sparse outcomes data, many surgeons also may be reluctant to expose older patients to the toxic effects of chemotherapy and radiation without proven efficacy in this geriatric population. This highlights the need for research targeting the specific needs of elderly patients with malignancy to aid in the development of specific treatment guidelines for various cancers within this age cohort. In fact, the oncogeriatric population may be undertreated for malignant diseases and not receive curative resections as well as neoadjuvant and adjuvant therapies afforded to younger patients.¹¹ Potential reasons include poorer functional status compared to younger patients, patient and family preference, age bias, life expectancy, and concerns regarding quality of life after major operative interventions.²⁶ Surgeons will be challenged to decide whether major surgery is justified in elderly patients, especially those with limited life expectancy. Effectiveness of oncologic surgery in elderly patients depends on whether a cure can be achieved safely without compromise to functional status or quality of life. Postoperative life expectancy should be improved by surgery, or, at the very least, not diminished. A useful treatment algorithm is provided in Fig. 46-6. A study undertaken using the Surveillance, Epidemiology and End Results database assessing cancer-directed surgery (CDS) for localized disease for solid malignancies found that the rates of CDS declined with increasing age for all cancers, especially noted for the aged elderly >70 years old. In addition, CDS was less likely to occur with patients found to have lung, esophagus, stomach, liver, or pancreatic cancer.¹ A careful assessment of the general and cancer-related condition of the patient is crucial to planning the best surgical intervention and postoperative adjuvant therapy.

Formulating a comprehensive, multimodal treatment plan for an elderly patient with a malignancy amenable to surgical intervention is based on careful consideration of the patient's expected life span, specifically if the life span is expected to exceed survival from the malignancy. Additionally, considerations include the patient's ability to tolerate the surgery and any complications that may ensue, as well as the likelihood that the patient would suffer a complication from the cancer which would adversely impact quality of life.²⁷ There is an ongoing international study that is titled "Preoperative Assessment of Cancer in the Elderly (PACE)" that is attempting to determine a scoring system that aids in assessing the oncogeriatric patient for surgical intervention. The PACE study incorporates several validated instruments that assess the functional and physiologic status of patients including the Mini Mental State Examination, ADL, Geriatric Depression Scale, and the ASA classification among other useful instruments. Interestingly, the PACE assessment also includes The Physiological and Operative Severity Score for enumeration of Mortality and Morbidity, which has been shown to predict morbidity and postoperative mortality in general

surgery and in patients with lung and colorectal malignancy. This score factors in the age of the patient and gives consideration to operative factors, including the type of surgical procedure used, the presence and extent of malignancy, and the timing of the operation (i.e., planned elective procedure or an emergency intervention).¹⁰ Palliative interventions are a part of the therapeutic armamentarium; however, a surgeon must weigh these variables carefully to determine if surgical intervention is appropriate.

Breast

It is projected that there will be a 72% increase in the number of elderly women diagnosed with breast cancer in the United States by 2025. Furthermore, 50% of breast cancers occur after the age of 65 years old and 25% after the age of 75 years old.²⁸ The estimated risk for development of new breast cancer is one in 14 women aged 60 to 79 years old compared to one in 24 in women aged 40 to 59 years old.²⁸ Mortality rates following breast cancer surgery in elderly women is <1%, and therefore, surgical interventions remain the cornerstone of therapy for breast cancer in elderly women. However, as expected, the presence of comorbid conditions affects clinical outcomes in elderly patients with breast cancer. A recent study demonstrated the presence of comorbid conditions in patients with breast cancer rose to as high as 55% in patients >80 years of age, with cardiovascular disease, diabetes, and previous cancer being most common.²⁹ As expected, the resulting 5-year survival rate was lower in patients with two or more comorbid conditions.

A recent study on risk factors for breast cancer in patients >75 years of age showed similarity to younger women and included obesity, nulliparity, family history, and advanced age at menopause.³⁰ Interestingly, although breast cancer presentation in elderly patients may be diagnosed at more advanced stages, both clinical and pathologic data demonstrate less aggressive disease in elderly women with more favorable biologic characteristics. Elderly breast cancer patients are more likely to have estrogen-positive tumors and increasing endocrine responsiveness.³⁰ Large percentages of elderly women are not offered conventional therapies for breast cancer, and the management of the axilla is frequently omitted. For example, elderly patients who are offered breast conservation surgery for breast cancer are less likely to have axillary dissection, postoperative radiation, and chemotherapy. This will undoubtedly influence surgical outcomes in elderly patients with breast cancer considering that local recurrence rates after conservative surgery without radiotherapy are reported from as low as 3% to as high as 47%. Advancing age has been demonstrated to be an independent predictor of concordance with treatment guidelines for definitive surgical therapy and adjuvant chemotherapy, as well as hormonal therapy. A study demonstrated that the odds of receiving a recommendation for chemotherapy decreased by 22% for each year of advancing patient age.²⁶ The concept of nonsurgical management of breast cancer in elderly patients is falling out of favor because there is currently no rationale for denying surgical therapy for elderly breast cancer patients. Surgery and hormonal therapy were the best options for overall survival, breast cancer-specific survival, and disease-free survival. A Cochrane Review concluded that treatment with tamoxifen alone is not the best option because of higher local progression of disease; 81% compared to 38% with surgical intervention. Furthermore, the response rate only lasts for approximately 18 to 24 months.²⁶ The final conclusion is that surgery remains the standard of care for elderly patients with breast cancer. Alternative therapies should be reserved for patients who have multiple comorbid conditions leading to poor candidacy for operative intervention, those who are frail, or those who refuse surgery.

A timely study comparing the mortality after breast-conserving surgery (BCS) alone, BCS plus radiation therapy, mastectomy, and the receipt of adjuvant tamoxifen in elderly breast cancer patients determined less than standard treatment for these patients resulted in increased mortality. Elderly women receiving BCS without radiotherapy have more than twice the rate of breast cancer mortality compared to women undergoing mastectomy. In addition, in older women with estrogen receptor and progesterone receptor positive tumors receiving tamoxifen, the rate of breast cancer death increased substantially with the decreasing duration of tamoxifen use.³¹ The standard of treatment for elderly patients with breast cancer should be the same as younger patients; BCS plus radiotherapy when indicated. If patients decline postoperative radiotherapy or are medically unfit for radiotherapy, mastectomy should be performed. Furthermore, elderly patients with tumor size <2 to 3 cm and no clinical evidence of axillary involvement should be offered sentinel node biopsy.³²

One of the most interesting controversies surrounding breast cancer in elderly women is the appropriate age limits of screening. A retrospective study demonstrated a decline in cancer-related mortality among women who underwent regular screening mammography up to 75 years of age.³⁰ Women who underwent at least two mammographic examinations between the ages of 70 to 79 years experienced a two-and-one-half-fold reduction in breast cancer mortality compared to elderly women who did not undergo screening.²⁶ Current recommendations are to offer yearly mammography to women up to age 75, which should be continued after age 75 in women without severe comorbid conditions. In women with multiple comorbidities, the decision to perform screening should be based on estimated life expectancy. Screening benefits depend on life expectancy. People with <5 to 10 years of life expectancy are unlikely to benefit from screening. The American Geriatric Society recommends that screening should be individualized rather than set by age-specific guidelines.

The current recommendation is that no upper age limit for screening be set as long as the estimated life expectancy is 4 or more years.

Colorectal

The incidence of colorectal cancer (CRC) increases with advancing age, similar to most other malignant conditions. Approximately 90% of cases of CRC are diagnosed in patients >55 years old.³³ Of concern is the increased postoperative morbidity and mortality following extensive surgical resections in elderly patients, with a significant increase in patients >70 years old. In fact, inhospital mortality for patients >85 years old undergoing surgery for colorectal malignancy is estimated to be ninefold greater than for younger patients.³³ Furthermore, elderly patients often have decreased cancer-specific survival when compared to younger patients. It has been proven that the 5-year cancer-specific survival for CRC is similar among the age cohorts. Therefore, age is not an independent factor accounting for the decreased survival among elderly patients. It is rather a consequence of comorbid conditions and impaired physical capacity necessary for recovery from perioperative physiological stress.³³ This leads to bias regarding poorer outcomes in elderly patients. For this reason, many elderly patients are receiving suboptimal cancer therapy and limited resections resulting in decreased survival rates and poorer outcomes. With the ever aging population, this must be addressed and clinical modifications implemented to improve outcomes of elderly patients undergoing surgical interventions for colorectal malignancies. Elderly patients should have continued, aggressive screening for colorectal malignancy and strict adherence to accepted surgical and adjuvant treatment guidelines.

One of the most important aspects to delivering appropriate care to elderly patients with CRC is to consider the patient's wishes as well as expectations from the surgical intervention. In this respect, functional outcomes and quality of life take precedence in treating elderly patients, especially the aged elderly. Of patients >75 years old who underwent elective surgery, few demonstrated protracted decline in ADL and most experienced significant improvement in quality of life.³⁴ Approximately 10% of elderly patients >80 years old have protracted postoperative disability. Estimation of physical ability and surgical stress is useful for predicting decline in ADL and postoperative disability. It has been shown that, in patients <80 years of age, a complete resection for cure is most important, whereas in patients >80 years old, avoidance of a stoma becomes paramount. These are important considerations for the geriatric surgeon.³³

A prospective study was recently undertaken to specifically evaluate the epidemiology and risk of surgical intervention for CRC in elderly patients. A large cohort of 47,455 patients was divided based on age <75 years old and >75 years old.³³ It was determined that a significant portion of elderly CRC patients are female, with multiple comorbidities leading to advanced ASA levels of 3 and above. The study determined that elderly patients underwent surgical interventions less often than younger patients (81% vs. 88% respectively, $P < .001$), more frequently required urgent or emergency operations, and were more likely to have operative procedures in which the primary cancer was not resected. Obstructive tumors are significantly more common in patients >70 years old, and elderly patients are still presenting far too commonly with surgical emergencies resulting from obstruction and perforation in up to 40% of the cases.¹¹ In addition, elderly patients had higher postoperative mortality than younger patients (10.6% vs. 3.8%, respectively). Right-sided resections, Hartmann's procedures, transanal endoscopic microsurgery, and transanal resection of tumors were more common in elderly patients, whereas formal resections, including low anterior and abdominoperineal resections, were more common in younger patients.³³ Elderly patients are less likely to undergo CDS; with each half a decade increase in age >70 years old, the odds of receiving cancer-directed surgery were reduced by 44%. Interestingly, many of these patients presented with lower-stage Duke classification lesions. However, this was not secondary to earlier presentations as one might assume, but rather secondary to understaging from surgical treatment. Accurate staging may not be possible with local resections, limiting the number of lymph nodes available for proper staging.³⁵ Elderly patients also are less likely to undergo preoperative irradiation and neoadjuvant chemotherapy, reducing the likelihood of curative resection.³³

Liver resection for CRC liver metastases in properly selected elderly patients 70 years of age or greater is feasible with older patients having similar operative survival to younger patients. Palliative surgery remains a viable option for elderly patients with disseminated CRC and should be aimed at the reduction of symptoms such as pain, obstruction, or hemorrhage. Bowel obstruction can be relieved with intestinal bypass or a diverting colostomy. The most common site of disseminated disease is the liver, and uncontrolled liver metastases are responsible for pain, abdominal distention, jaundice, and inferior vena caval obstruction. Elderly patients with metastatic disease who are not candidates for curative resection may be considered for ablation of the lesions by local destruction, cryotherapy, or radiofrequency ablation. More traditional means such as chemotherapy, which can be administered via the hepatic artery or radiation, also may be used.³⁶

Similar to breast cancer, an upper age limit for CRC has not been clearly established. Screening for CRC may not lead to an observed survival benefit until 5 years or longer after

screening had occurred. This would limit the benefit of screening in aged populations with limited life expectancy. An interesting way of looking at this controversy is from a recent study that determined that the number of screening colonoscopies needed to prevent one CRC-related death (NNS) increased as with increasing age and comorbidities. For example, in healthy men and women aged 75 to 79 years old, the NNS was 50. The corresponding NNS in patients 90 years and older was 279 in women and 482 in men.³⁷ Consideration for continued screening in very elderly patients should take into account age and predicted life expectancy, comorbid burden, expected duration of the protective effect of screening, risk for cancer, results of previous screening colonoscopies, and patient preference.³⁷

Lung

Lung cancer is the leading cause of cancer-related deaths in the United States for patients >70 years old. National Cancer Institute statistics show that the peak incidence of lung cancer is between 75 and 79 years of age. Elderly lung cancer patients also have a higher mortality rate, and therefore, the peak mortality rate is between ages 75 and 84 years.³⁸ Non-small cell lung cancer accounts for roughly 80% of all lung cancer cases, and >50% of these patients are >65 years of age. Interestingly, approximately 30% of these patients are 70 years or older at diagnosis.³⁹ Lung cancer is highly prevalent among elderly patients, so much so that a 2-cm, asymptomatic, solitary pulmonary nodule in a 70-year-old male smoker has a >70% chance of being an occult lung cancer.² Squamous cell carcinomas are more common among elderly patients than among younger patients, and these tumors are associated with a higher incidence of local disease, tend to have lower recurrence rates, and have longer survival times than nonsquamous cancers.³⁸ In cases of resectable primary lung cancer, surgery remains the treatment of choice independent of age.¹¹

The estimated life expectancy of untreated lung cancer is approximately 9 months. This can increase to as high as 18 months with palliative chemotherapy and radiation. However, the life expectancy of an elderly patient who has undergone a successful operative resection is estimated to be as high as 31 months, making this the preferred option when feasible.¹³ However, despite this and the fact that more elderly patients present with stage I disease, elderly patients are offered curative surgery less frequently than younger counterparts. The same holds true for chemotherapy and radiation.

Advanced age is an independent risk factor for death after thoracotomy, with significantly increased mortality after age 65. These reasons are multifactorial partly due to the physiologic debilitation that occurs with division of the intrathoracic muscles that aid in respiratory function and the loss of lung volume after resections.¹³ One study demonstrated that patients 70 years of age or older who underwent thoracotomy for lung cancer had an operative mortality rate of 14%, which is directly related to the extent of the pulmonary resection. In one of the largest prospective, multi-institutional trials conducted, The Lung Cancer Study Group, increasing age led to a significant increase in 30-day mortality for patients undergoing thoracotomy and lung resection.¹³ They found overall mortality to be approximately 3.5% in patients <65 years old, which rose to 7.3% for patients 70 years or older and as high as 8.1% for octogenarians. However, with improved surgical options, including minimally invasive video-assisted thoracic surgery (VATS) in the past decade, the mortality rate has ranged from 3% to 5% in carefully selected patients.² In a recent study conducted to determine if VATS resulted in lower morbidity in the elderly population in comparison to open, rib-spreading thoracotomy, the overall morbidity for minimally invasive surgery was 28%; this increased to 45% with traditional open procedures.³⁹ Furthermore, elderly patients undergoing VATS tended to have less severe complications compared to patients undergoing thoracotomy.³⁹ Limited resections (segmentectomies) may be a consideration in elderly patients with limited life expectancy or poor cardiac and pulmonary reserve who may not tolerate a more extensive procedure. Some studies have shown that limited resections may provide a comparable survival rate to lobectomies in elderly patients as long as the resection includes all foci of tumors and provides a microscopically free margin. The most striking finding was that any survival difference between treatment modalities disappeared after 71 years of age. Interestingly, even smaller resections such as VATS and wedge resection may be a viable oncologic option in an elderly patient with resectable disease but limited life expectancy.¹³ This is limited to very small tumors <7 mm in diameter and not yet proven to be clinically efficacious. Of particular interest is that VATS procedures may result in lower rates of postoperative confusion in elderly patients and this may be secondary to the decreased physiologic stress of minimally invasive procedures, faster recovery rates, and decreased narcotic requirement for pain control.¹³ Careful preoperative selection and optimization combined with aggressive postoperative care and rehabilitation make surgical intervention for resectable disease feasible in aged populations.

Trauma

Patients >65 years of age currently account for approximately 23% of total hospital trauma admissions—many of which are multisystem and life threatening.⁴⁰ Geriatric trauma will

continue to challenge surgeons in understanding the physical and physiologic impact of various mechanisms of injury, the need for careful assessment of comorbid conditions with particular attention to medication regimens, the rehabilitative capacity of an elderly trauma patient, and the knowledge of specific interventions that help to minimize morbidity and mortality in this population following traumatic injury.

The current geriatric population has fewer disabilities and is considerably more active than previous generations, which predisposes them to traumatic injuries. The most common type of trauma is blunt injury resulting from falls and motor vehicle collisions or pedestrian accidents. Falls currently account for 20% of severe injuries in elderly patients. Many underlying chronic and acute diseases common to elderly patients place them at increased risk for falls. These diseases include postural hypotension, leading to syncopal "drop attacks"; dysrhythmias from sick sinus syndrome; autonomic dysfunction; polypharmacy with improper dosage of antihypertensives and oral hypoglycemic agents resulting in hypotension; and hypoglycemia, respectively.⁴¹

Elderly patients also can fall victim to penetrating trauma, especially in elderly patients who may have underlying depression and suicidal ideations or are victims of elder abuse. It is estimated that approximately 40% of all trauma patients by 2050 will be >65 years old.⁴² With the expanding elderly population, this will be an increasing source of morbidity and mortality; the risk of death after major trauma with multi-system and life-threatening injuries rises steeply after age 45 years old and doubles by age 75 years old. In contrast to what is observed for abdominal and thoracic surgery, even after controlling for injury severity and pre-existing medical conditions, patients aged 65 years and older sustaining traumatic injury were 4.6 times more likely to die than younger patients.⁴² Of note, there are several interesting aspects of care of the acutely injured elderly patient that must be kept in mind. First, physiologic reserve can be challenged by trauma. For example, previously unknown disease such as cardiac impairment may be acutely unmasked. Secondly, medications common to elderly patients, such as beta blockers and anticoagulation, can not only inhibit the physiologic response to stress but may even worsen injury. Finally, elderly patients with impaired functional status posttrauma are more likely to lose their ability to function independently without the support of a nursing home.

Elderly patients are particularly susceptible to trauma due to changes that occur with aging, specifically, gait instability, decreased hearing and visual acuity, presence of confusion or dementia, underlying comorbid conditions, and poor reserve to tolerate the physiologic stress of traumatic injuries. Pre-existing medical conditions increase the risk of death after trauma significantly (up to threefold).⁴⁰ This is worsened when combined with an elderly patient's decreased functional reserve for handling physiologic abnormalities accompanying major trauma, such as hypotension and hypoxia. It is important to consider a trauma patient's age, as patients aged 65 to 80 years old have a 6.6% overall mortality rate after traumatic injury, which rises to 10% in patients 80 years or older.⁴²

Despite the increased risk of morbidity and mortality after traumatic injury, it is interesting to note that there is currently an under-triaging of elderly patients to level 1 trauma centers despite high injury severity scores.⁴² In one study, elderly patients >65 years old were five times more likely to be under-triaged to nondesignated trauma hospitals than younger counterparts.⁴² However, a reduction in morbidity and mortality and posttraumatic complications as well as faster rehabilitation can result from better triaging practices. In one particular study involving acutely injured octogenarians with injury severity scores between 21 to 45, inhospital survival was as high as 56% in trauma centers, and this dramatically decreased to 8% in those treated at nontrauma hospitals.⁴²

It is important to determine the medication regimen of elderly trauma patients. Medications such as beta blockers, calcium channel blockers, diuretics, and afterload reduction agents may impair critical augmentation of myocardial function in trauma patients, especially if they are hypovolemic. Approximately 20% of the elderly population with coronary artery disease and 10% of those with hypertension are currently on beta blocker therapy.⁴² Therefore, tachycardia, one of the most valued signs of continued hypovolemia from either ongoing blood volume loss or underresuscitation, is lost in the elderly patient on beta blocker therapy. This makes interpretation of hemodynamic parameters in elderly patients inaccurate and, at times, misleading, which could lead to delays in appropriate interventions and resuscitation. However, it is important to keep in mind that, to date, evidence supporting early hemodynamic monitoring in elderly patients is lacking.

The other medication class that can be detrimental to an elderly, acutely injured patient is anticoagulation, ranging from aspirin and clopidogrel (Plavix) to warfarin, which may, at times, be supratherapeutic. Massive intracranial hemorrhages resulting from minor falls from standing in elderly patients are demonstrated in Fig. 46-7. Both patients subsequently had extremely poor prognosis. Warfarin therapy may be used in patients with atrial fibrillation, DVT, and prosthetic heart valves. The mortality rate of elderly patients on warfarin with a traumatic intracranial hemorrhage was 48% compared with 10% in an age-matched cohort not on anticoagulation therapy.⁴² One of the most important caveats to treating

elderly patients on anticoagulation with blunt head injury is the potential for significant, life-threatening intracranial hemorrhage despite initial normal head (computed tomography) CT scans. In one study, >70% of patients with minor mechanisms and negative CT scan, admitted for observation subsequently, clinically deteriorated within 12 hours of admission with a Glasgow Coma Scale of <10 and were subsequently found to have significant intracranial hemorrhages.⁴² Therefore, prompt reversal of anticoagulation, particularly if supratherapeutic, is warranted to reduce morbidity and mortality following blunt head injury. In addition to increased risk of mortality in elderly patients sustaining blunt head trauma, a significant portion fail to resume functional independence after traumatic injury. It is estimated that approximately 20 to 25% of elderly trauma patients require discharge to a skilled nursing facility for long-term care and rehabilitation.⁴⁰ Poor functional outcome has been attributed to several factors among which are age >75 years old, presence of shock on admission, severe head injury, and development of infectious complications.

Massive intracranial hemorrhage resulting from seemingly minor trauma. The importance of immediate reversal of anticoagulation in elderly patients cannot be overestimated.

A particular concern in elderly patients sustaining blunt trauma is pelvic and extremity fractures (Fig. 46-8). Elderly patients are particularly susceptible to these injuries secondary to underlying medical conditions such as osteoporosis. Furthermore, these injuries, in particular, can not only increase the mortality of elderly trauma patients but also can predispose them to complications resulting from immobility leading to pneumonia and atelectasis, DVT, and pulmonary embolism. These injuries also predispose to functional impairment. Pelvic fractures are the most serious skeletal injury in the elderly.⁴³ Timely surgical intervention for extremity fractures in elderly patients is crucial to prompt recovery and helps to minimize mortality and morbidity from such injuries. In one study, a delay in providing surgical treatment for hip fractures by more than 2 days was associated with greater than double the risk of death within the first postoperative year.⁴²

Elderly patients are extremely susceptible to long bone fractures due to underlying medical conditions such as osteoporosis, leading to death or debilitation. Interestingly, this patient who suffered a traumatic long bone fracture had previously undergone a hip replacement a few months prior following a simple fall.

MINIMALLY INVASIVE SURGERY

Laparoscopy

Open abdominal procedures may require more intensive postoperative care, longer hospital stays, and an increased need for postoperative rehabilitation and possible institutionalization for elderly patients with limited reserve. However, the increasing experience with laparoscopic techniques, combined with minimized pain, decreased length of hospital stay, and low morbidity and mortality rates, has led to the increased use of minimal access procedures among elderly patients. It has expanded from cholecystectomies to more complex procedures including colon resections, gastrectomies, and cardiac surgery.

Laparoscopic surgery reduces common postoperative complications such as atelectasis, GI ileus, and wound infections. In elderly surgical patients, these complications easily progress to pneumonia, DVT, and metabolic and electrolyte disturbances.⁴³ Decreased postoperative pain from smaller incisions leads to faster return to a preoperative level of functioning including early ambulation, which decreases complications from prolonged bed rest, such as DVT and pneumonia from compromised pulmonary mechanics. The latter is especially important for elderly patients because deconditioning occurs with long hospital stays, which depresses their ability to return to preoperative functional status. Laparoscopic surgery also provides the added benefit of reduction of the inflammatory, hormonal, and metabolic stress induced by major open surgical operations. However, these benefits must be balanced against the potential adverse effects of carbon dioxide (CO₂) insufflation and hemodynamic alterations induced by pneumoperitoneum and increased intra-abdominal pressure with concomitant decrease in venous return.⁴⁴ Therefore, decisions to perform minimal access procedures in the elderly must be individualized to the patient with careful

consideration of the impact of comorbid conditions and the potential for poor cardiopulmonary reserves. This helps to provide the optimal circumstance for intervention resulting in improved surgical outcomes.

The cardiopulmonary effects induced by pneumoperitoneum are secondary to CO₂ insufflation and increased intra-abdominal pressure.⁴⁴ CO₂ insufflation is associated with hypercarbia and acidosis, both of which are proven direct myocardial depressants.⁴⁴ Hypercarbia is reported to be problematic in patients with pre-existing pulmonary disease with chronic CO₂ retention, but this is rarely observed. In patients without pre-existing disease, these alterations can be minimized by increasing minute ventilation during the procedure. The increased intra-abdominal pressure during insufflation can lead to increased afterload, increased peripheral vascular resistance and mean systemic pressure, and decreased preload.⁴⁴ This can result in depressed myocardial function, which is of potentially serious consequence in an elderly patient with poor physiologic reserve.

It is important to maintain tight control over the intra-abdominal pressure applied during the laparoscopic procedure. For example, pressures up to 20 mmHg are associated with increased filling pressures and cardiac output. However, further increased elevations result in decreased central venous pressures and cardiac output, which can be life threatening in a patient with pre-existing cardiac dysfunction and poor functional reserve.

Although the occurrence of these serious consequences are rare, adequate preoperative knowledge of the physiologic changes induced by laparoscopic techniques, as well as the changes that occur with advancing age, leads to better control of the variables that lead to adverse outcomes. Maintenance of adequate preload (i.e., adequate IV fluid administration) and intraoperative volume control, and careful mechanical ventilation to control hypercarbia and acidosis are basic concepts that allow the safe application of minimally invasive techniques in the elderly. It also is important to remember that elderly patients undergoing laparoscopic procedures must be closely monitored for any evidence of respiratory or hemodynamic compromise resulting from the pneumoperitoneum. If such changes do occur, it is crucial to immediately decompress the abdomen and allow the patient time to recover.

Studies have demonstrated that both advanced age >70 years old and an ASA classification of 3 or 4 are associated with higher conversion rates for laparoscopic cholecystectomy to open cholecystectomy.⁴⁵ These additional challenges, however, are not a contraindication to attempting the less invasive approach because conversion to an open procedure does not adversely impact the overall morbidity and mortality of the patient.

A particularly useful application of minimally invasive techniques is to rule out a surgical abdomen in an elderly patient presenting with acute abdominal pain. Vague, poorly localized pain, further obscured by several underlying confounding comorbid conditions, as is the case with ischemic colitis and mesenteric ischemia, may subject an elderly patient with poor reserve to the risk of general anesthesia and a negative exploratory laparotomy. Analysis of several studies directed at the application of laparoscopic techniques for the patient with acute abdominal pain demonstrated that approximately 41% had pathology necessitating open laparotomy, 10% had pathology amendable to laparoscopic intervention (i.e., acute cholecystitis), and 48% had nonsurgical disease that was subsequently managed nonoperatively, avoiding a negative exploration.⁴⁵ Therefore, laparoscopic evaluation of abdominal pain in the critically ill elderly patient may prove to be a valuable tool.

ENDOVASCULAR SURGERY

Abdominal aortic aneurysm (AAA) is a disease that primarily affects the elderly male patient. With increasing use of screening abdominal CT scans and ultrasounds for evaluation of various abdominal complaints, AAAs are being identified with greater frequency, most of which are diagnosed in elderly patients, given the increased prevalence of AAA with increasing age. In fact, the percentage of AAA rises from about 1% at age 55 to 60 years to approximately 10% in patients 80 years of age or older.⁴⁶ Elderly patients, and octogenarians in particular, were deemed poor operative candidates for the traditional open repair given the frequent presence of comorbid conditions and limited cardiopulmonary reserve to tolerate a major operation or the many hours of required operative time and general anesthesia. Elderly patients had an increased perioperative morbidity and mortality following open aortic surgery in comparison to younger cohorts. However, the introduction of endovascular techniques for repair of AAA has shifted the risk-benefit ratio for operative intervention, allowing greater life expectancy for the elective repair of this potentially life-threatening condition with the benefits of minimally invasive techniques as described above.

Studies have demonstrated that endovascular aortic repair (EVAR) is feasible and efficacious in elderly patients, including those previously considered unfit for open repair. EVAR is a minimally invasive technique in which a prosthetic graft is introduced into the aortic lumen via the common femoral artery to exclude the aortic aneurysm sac. EVAR significantly

reduces operative and anesthesia times, blood loss, intensive care needs, length of stays, and major postoperative morbidity associated with open AAA repair. The most common complication following EVAR in elderly patients is renal impairment. Typically, patients are discharged 1 to 2 days following surgery and the graft is deployed via small bilateral groin incisions, obviating the need for a major laparotomy incision. Figure 46-9 demonstrates the endovascular repair of AAA and right iliac artery aneurysm via bilateral groin access in an 82-year-old man who was discharged from the hospital on postoperative day 2. This procedure also can be done using epidural anesthesia for high-risk candidates who may tolerate general anesthesia poorly. Endovascular repair has even been described under local anesthesia in patients at extreme high risk of rupture and death or after rupture and hemodynamic instability precluding the ability to tolerate general anesthesia.⁴⁷ This was a reportable circumstance and obviously not the current standard of care.

Endovascular repair of abdominal aortic aneurysms (AAAs) is gaining favor for suitable elderly patients to prevent rupture. Through minimal groin incisions, this 82-year-old patient underwent repair of an AAA and right iliac artery aneurysm and was discharged on postoperative day 2.

Careful consideration of the life expectancy and the risk of rupture dictate the necessity for intervention. EVAR remains a viable option in elderly patients. Nonoperative management is justified in frail elderly patients with multiple comorbidities and reduced life expectancy whose operative risks outweigh the risk of rupture and in those who are unlikely to survive long enough to benefit from the repair.

THYROID AND PARATHYROID SURGERY

The prevalence of thyroid disease increases with advancing age. The etiologies, risk factors, and presentations of thyroid disease are similar across all ages, and therefore, are not discussed in detail. Of note, however, is that elderly patients more often present with cardiac manifestations of hyperthyroidism, such as atrial fibrillation, than do their younger counterparts. A common finding requiring evaluation in elderly patients is the presence of a thyroid nodule, usually detected by physical examination. These nodules usually are single and four times more common in women, making them a particular concern for postmenopausal elderly women. Indications for surgical intervention for thyroid nodules are dependent on the characteristics of the nodule (i.e., whether it is benign or malignant, or whether the patient is euthyroid or thyrotoxic). In addition, surgical intervention becomes necessary if the nodule enlarges, producing compressive symptoms.

Papillary carcinoma in elderly patients tends to be sporadic with a bell-shaped distribution of age at presentation, occurring primarily in patients aged 30 to 59 years old. The incidence of papillary carcinoma decreases in patients >60 years of age.⁴⁸ However, patients >60 years of age have increased risk of local recurrence and for the development of distant metastases. Metastatic disease may be more common in this population secondary to delayed referral for surgical intervention because of the misconception that the surgeon

will be unwilling to operate on an elderly patient with thyroid disease. Age is also a prognostic indicator for patients with follicular carcinoma. There is a 2.2 times increased risk of mortality from follicular carcinoma per 20 years of increasing age.⁴⁹ Therefore, prognosis for elderly patients with differentiated thyroid carcinomas is worse when compared to younger counterparts. The higher prevalence of vascular invasion and extracapsular extension among older patients is, in part, responsible for the poorer prognosis in geriatric patients. Advancing age leads to increased mortality risk for patients with thyroid cancer and is demonstrated by the AMES (*age, metastases, extent of primary tumor, and size of tumor*) classification system developed by the Lahey Clinic.

Anaplastic carcinoma is a highly aggressive form of thyroid carcinoma with dismal prognosis. It accounts for approximately 1% of all thyroid malignancies; however, it occurs primarily in elderly patients.⁵⁰ This poorly differentiated tumor rapidly invades local structures, leading to clinical deterioration and eventually tracheal obstruction. These patients may present with a painful, rapidly enlarging neck mass accompanied by dysphagia and cervical tenderness. This leads to respiratory compromise and impingement of the airway. Unfortunately, because of the aggressive nature of the disease and the dismal prognosis, surgical resection of the tumor is not attempted for cure. Furthermore, radiation therapy and chemotherapy offer little benefit. Airway blockage, however, may necessitate surgical palliation or permanent tracheostomy to alleviate symptoms of respiratory distress.

PARATHYROID SURGERY

Approximately 2% of the geriatric population, including 3% of women 75 years of age or older, will develop primary hyperparathyroidism.⁵¹ Geriatric patients are usually referred to surgery only when advanced disease is present because of concerns regarding the risks of surgery, but low rates of morbidity and negligible mortality combined with high cure rates of approximately 95 to 98% make parathyroidectomy safe and effective. Convincing evidence of the benefit of surgery is the usual marked symptomatic improvement, which greatly improves the quality of life for most patients. The National Institutes of Health Consensus Development Statement recommends curative therapy after diagnosis of primary hyperthyroidism is established in a patient regardless of age. Specific indications for operative intervention regardless of age include a 30% decrease in creatinine clearance, 24-hour urinary calcium excretion >400 mg, and decreased bone density.^{52,53}

Elderly patients are especially prone to developing mental manifestations of hyperparathyroidism that may be severe enough to produce a dementia-like state. There often is a significant improvement in mental status after parathyroidectomy. Another specific symptom of hyperparathyroidism that may easily be mistaken for osteoporosis and can be present in postmenopausal, elderly women is orthopedic disease; specifically back pain, and possibly, the occurrence of vertebral fractures. This pain can be of moderate intensity, leading to impaired mobility and severely affecting the quality of life of elderly patients. The decreased bone density observed in elderly patients with hyperparathyroidism tends to improve during the first 2 years after successful parathyroid surgery.

Limited parathyroidectomies with minimal dissection in geriatric patients are an effective alternative. This is a viable option in patients with multiple comorbid conditions in whom the increased risk of surgical intervention or general anesthesia remains a concern. One study demonstrated that preoperative localization of the hyperfunctioning gland with the aid of ^{99m}Tc-sestamibi nuclear scanning, as well as intraoperative parathyroid hormone (PTH) assays to rapidly confirm that all hypersecreting glands have been removed, allows limited parathyroidectomy to be performed with accuracy in elderly patients (Fig. 46-10).⁵¹ This procedure is described as "limited" because bilateral neck dissection for identification and biopsy of the remaining glands to determine if they are hypersecreting becomes unnecessary. The half-life of intact PTH is approximately 3 to 4 minutes. Therefore, a drop in the intraoperative PTH level at approximately 10 minutes after resection of the suspect hypersecreting gland suggests a 98% probability that the patient will return to normocalcemic levels postoperatively.⁵¹

Parathyroid adenoma in an elderly patient with high calcium levels and elevated parathyroid hormone levels. **A.** Sestamibi scan showed right-upper-gland adenoma facilitating a directed incision. **B.** One-g pituitary adenoma was easily identified intraoperatively (white arrow). Black arrow points to the recurrent laryngeal nerve.

PALLIATIVE SURGERY

Palliative surgery is defined as surgical intervention targeted to alleviate a patient's symptoms, thus improving the patient's quality of life despite minimal impact on the patient's survival (see Chap. 48).⁵⁴ With an increasing number of aging surgical patients who often present with advanced disease, surgeons must be familiar with the concept of palliation to control disease. This concept focuses on providing the maximal benefit to the patient using the least-invasive intervention. Ultimately, this leads to symptom relief and preservation of the quality of life in terminal disease states. The uses of palliative surgery can range from extensive debulking operations aimed at aiding in the effectiveness of chemotherapy and radiation, to less complex operations to alleviate symptoms such as intractable vomiting, severe pain, cachexia, and anorexia that are common to terminal disease states. The success of palliative surgery is a careful balance between achieving symptom relief while ensuring that the development of new symptoms from the palliative intervention itself does not occur.

Palliative care in the treatment of advanced disease often is associated with age bias; older patients are more prone to be offered palliative care in comparison to younger patients. In a recent survey, two surgical scenarios were presented to a panel of surgeons.³⁵ The first patient was an 85-year-old woman with excellent functional status presenting for evaluation of back pain, jaundice, weight loss, and vomiting. Appropriate studies were completed with CT scan that demonstrated a mass in the head of the pancreas with invasion into the portal vein. The patient in the second scenario experienced identical symptoms, but was significantly younger. Most of the surgeons selected major surgical intervention for the younger patient, while only one third of the panel offered the same intervention for the older patient. The majority offered only palliative care for the older patient. It is important to note that those surgeons who offered operative intervention based their decision on the functional status of the patient preoperatively. When transitioning from curative therapy to palliation, the risks and benefits of the proposed surgical intervention should be examined, as well as the intended impact to the patient's quality of life.

There currently is no evidence to support that palliative surgery is less effective for elderly patients with surgically unresectable disease. Younger patients undergoing palliative interventions do not have a demonstrated improved outcome when compared to disease-matched older patients. Therefore, it is important to recognize that age is not a limitation to surgical intervention, and that all interventions should be individualized based on the severity of symptoms and the predicted benefit.

Surgical palliative care can range from nonoperative management of malignant obstructions by percutaneous methods (Fig. 46-11) to laparoscopic surgery for the treatment of life-threatening illness by minimally invasive technique (Fig. 46-12). An interesting challenge in palliative care is the determination of the actual cause of a patient's symptoms to offer the most beneficial, but least invasive, intervention. Treatment of malignant pleural effusions, for example, should be tailored to the source of the symptoms, not the effusion. Effusions should be treated only when they cause significant distress for patients with terminal disease.³⁵ Dyspnea in a terminal patient can be the result of chest wall restriction, pulmonary fibrosis from previous radiation treatment, infiltration of the primary cancer, or early airway obstruction from mediastinal spread of the primary tumor.³⁵ If it is determined that a patient's dyspnea is largely secondary to a malignant pleural effusion, the goal of palliative intervention is lung expansion, preferably with permanent pleurodesis. Permanent control can be achieved via thoracoscopy or by more invasive thoracotomy with chemical pleurodesis.³⁵ The latter intervention is highly effective for permanent resolution, and therefore, may be more invasive than necessary for patients with late-stage terminal disease. In these patients, medical pleurodesis with intrapleural injection of a sclerosant via thoracostomy tube placement is a better alternative.³⁵ For surgical therapy, minimally invasive procedures such as VATS may be an appropriate method to assess the apposition of pleural surfaces and may allow for talc pleurodesis or insertion of a pleuroperitoneal shunt.³⁵

Palliative intervention for symptom relief and prevention of complications can be demonstrated in the management of terminal pancreatic cancer and metastatic CRC. Two thirds of patients with pancreatic cancer present with advanced disease, which often is diagnosed after evaluation of obstructive jaundice. Despite advanced disease, surgical intervention improves quality of life through relief of biliary obstruction. Percutaneous transhepatic stenting has emerged as a viable alternative to surgical bypass, achieving similar results and lowering mortality rates with the occurrence of fewer early complications. Endoscopic stenting is yet another option. If a patient does not have multiple comorbidities with good functional status, surgical intervention then can provide a definitive diagnosis and permanent biliary decompression and gastric drainage. In addition, an important palliative intervention that can be provided to patients with the open procedure is chemical splanchnicectomy, which is infiltration of the celiac plexus with an agent such as alcohol for effective relief of intractable pain from tumor invasion of the celiac plexus.³⁵ A gastroenterostomy drainage procedure is effective protection against gastric outlet obstruction, which inevitably develops in 30% of patients.

Palliative surgery for disseminated CRC should be aimed at the reduction of symptoms such as pain, obstruction, or hemorrhage. Bowel obstruction can be relieved with intestinal bypass or a diverting colostomy. The most common site of disseminated disease is the liver. Uncontrolled liver metastasis is responsible for pain, abdominal distention, jaundice, and inferior vena caval obstruction. Many patients with liver metastasis are not candidates for resection, and therefore may be considered for ablation of the lesions by local destruction, cryotherapy, or radiofrequency ablation. More traditional means, such as chemotherapy, which can be administered via the hepatic artery or radiation, also may be used. Systemic corticosteroid therapy can be used in patients with advanced metastatic disease to reduce pain caused by swelling of the liver capsule. If bone metastases are present, pain may be controlled by irradiation, and prophylactic fixation of long bones may be considered to decrease pain as well as morbidity from pathologic fractures.³⁵ Similarly, cerebral irradiation and high-dose steroid therapy may help to decrease intracranial pressure from metastatic disease as well as delay the onset of neurologic symptoms and cognitive impairment, which are essential to maintain quality of life of the patient.³⁵

SPECIFIC SYMPTOM MANAGEMENT

Gastrointestinal Disturbances

The distressing symptoms often faced by terminally ill patients either result from the disease process or as a side effect of treatment. The causes of nausea and vomiting in terminally ill patients are multifactorial and can be attributed to various medications or chemotherapy treatments, gastric stasis, obstruction of the GI tract, mesenteric metastases, irritation of the GI tract, raised intracranial pressure from cerebral metastasis, or anxiety-induced emesis. Treatment should be focused on prevention of dehydration and malnutrition from poor oral intake. Antiemetics may be administered for control of nausea and vomiting. The oral route of administration is the best option for prophylaxis before chemotherapy treatments. However, other preparations such as suppositories or injections can be appropriate for patients who are unable to tolerate oral medications.

Diarrhea and constipation also are common GI disturbances in terminal patients. Constipation is particularly common in patients receiving chronic narcotic medications. Constipation also can be caused by such events as tumor invasion leading to intestinal obstruction, metabolic abnormalities such as hypercalcemia from metastatic disease, and dehydration. Because constipation may be worsened by dehydration, adequate fluid intake often helps to alleviate symptoms. Constipation can lead to fecal impaction, nausea, and colicky abdominal pain. If there is difficulty distinguishing between constipation and early bowel obstruction, diagnostic tests are useful, but should be kept to a minimum in terminal patients. Patients can be treated with stool softeners and stimulant agents. Laxatives with peristalsis-stimulating action, such as senna or bisacodyl, should be used with caution because of the potential for causing intestinal colic.

The occurrence of diarrhea also is multifactorial and can be caused by medications, overload incontinence with fecal impaction, from the disease process itself, malignant bowel obstruction, or improper laxative therapy. Radiation therapy can cause diarrhea by damage of the intestinal mucosa, which results in the release of prostaglandins and the malabsorption of bile salts that increases peristalsis. Once the underlying causes are identified and appropriately managed, patients can be given bulk-forming agents and opiate derivatives to aid in symptomatic improvement.

DEPRESSION AND ASTHENIA

Asthenia is a condition of reduced energy levels accompanied by fatigue and generalized weakness without the presence of physical or mental exertion.⁵⁵ In a study by Hinshaw and

associates, asthenia was present in approximately 90% of patients and was more prevalent than pain, leading to the potential for impaired quality of life.⁵⁵ Both of these symptoms commonly affect the terminally ill patient. However, if identified, appropriate interventions can be provided in an effort to improve quality of life and enhance the patient's functional status. In cancer patients, overactivity of the hypothalamic-pituitary-adrenal axis and elevation of interleukin-6 levels have been reported in patients suffering with depression. Natural killer cell activity has been demonstrated to decline in patients with depression, causing an immunosuppressive effect and weakening the patient's response to tumor.⁵⁵ Poorly controlled pain and complications from disease progression also can cause terminal patients to develop depression. These complications include somnolence and depression that can occur with hypercalcemia from bony metastases with lung and breast cancer. These must be controlled as much as possible before the consideration of pharmacologic therapy to alleviate symptoms of depression.

Appropriate therapy for depression and asthenia must be individualized. If a patient has good functional status with a predicted survival time of several months, the initiation of standard antidepressants is appropriate. However, if there is an expected short survival period with progression of depressive symptoms impairing quality of life, then a psychostimulant is more appropriate because of its immediate effect, better short-term efficacy, and the tendency for development of tolerance, usually within 3 months.⁵⁵ Psychostimulants such as amphetamine and methylphenidate also increase appetite at lower doses and help to reduce sedation that may result from treatment with narcotic medications for pain management.⁵⁵ Psychostimulants also are effective in the management of asthenia, which shares a common clinical presentation with depression. However, pharmacologic therapy for asthenia should be provided only after treatable causes of this symptom, such as medications (including narcotics), the presence of pain, anemia, dehydration, and infection, as well as metabolic abnormalities, such as hyponatremia, hypokalemia, and hypercalcemia, have been assessed and corrected.⁵⁵

Cachexia and Anorexia

Cachexia refers to catabolic changes associated with progressive wasting that is present in patients with advanced illness; prominent symptoms include anorexia, weight loss, and asthenia.⁵⁶ A subsequent loss of muscle and fat leading to anemia, hypoalbuminemia, and hypoproteinemia also is common. This is a chronic form of malnutrition and is not reversible with short-term nutritional support and hyperalimentation.⁵⁶ Malnourished cancer patients with cachexia have reduced response to antineoplastic medications, radiation, and chemotherapy, as well as decreased survival rates.³⁵ The mechanism of cachexia is poorly understood, but hypotheses include actions of interleukin-6, tumor necrosis factor, and interferon-mediating metabolic changes in chronic illness.⁵⁶

Management of cachexia begins with the identification of correctable causes. Patients may have underlying metabolic derangements, as well as dehydration, that must be appropriately treated. Poorly controlled pain, anemia, and sleep disturbances also may exacerbate symptoms of cachexia, leading to malnutrition and wasting. Patients with terminal disease additionally often suffer from GI disturbances, such as constipation and nausea, which may lead to anorexia. Malabsorption is common in patients with pancreatic cancer, and supplementation of pancreatic enzymes may improve absorption and help to improve nutritional status. Nausea and vomiting should be appropriately managed. It is important to rule out mechanical causes of malnutrition that can effectively be treated with nonoperative management such as bowel rest and nasogastric tube compression or operative intervention.

If no underlying correctable abnormalities are identified, patients may benefit from pharmacologic intervention with dexamethasone and prednisone, which increase appetites in patients with advanced cancer, leading to improved quality of life.⁵⁶ The onset of effect is rapid but short-lived, and thus should be reserved for patients at terminal stages of disease. Other agents, such as progestational drugs, namely megestrol acetate (Megace), also stimulate appetite and cause weight gain in cachexia patients.⁵⁶

Malignant Bowel Obstruction

Patients with malignant bowel obstruction typically present with cramping abdominal pain, nausea, and vomiting, which may be a common complication of advanced terminal disease secondary to GI malignancy or from extrinsic compression of bowel loops from progressive tumor burden. Conservative management can be effective and includes NPO, IV hydration, and nasogastric decompression. However, long-term management often is difficult. Medical management with pharmacologic agents such as somatostatin analogues to decrease GI output may also be considered for symptom alleviation, along with analgesics and antiemetics. Octreotide effectively decreases the volume of GI secretions via inhibition of intestinal hormones and growth hormone and is 70% effective in patients suffering with bowel obstruction with the added effect of decreasing colic and nausea.⁵⁶ However,

surgical palliation via bypass procedures, decompressing, or diverting ostomies may be required.

Surgical intervention may provide permanent alleviation of obstruction and eliminate the need for repeated nasogastric decompressions that can limit patient comfort. In one study, approximately 40 to 70% of patients reported relief of symptoms of obstruction after surgical intervention.⁵⁶ This must be balanced against the risk of perioperative mortality from surgical intervention, which ranges from approximately 12 to 20%, as well as the potential for mortality from wound infection, poor wound healing, and fistula formation.⁵⁶ Patients in whom the risk of surgical intervention outweighs the benefit of palliation include patients who have ascites or multiple sites of obstruction accompanied by poor functional status and poor nutrition with serum albumin levels <3 g/dL.⁵⁶ Should conservative management fail in a patient who is unfit to undergo surgical intervention, alternatives include a venting gastrostomy or jejunostomy, which can be inserted percutaneously.³⁵

Pain Management

Intractable pain is one of the most distressing symptoms affecting a terminally ill patient. Nociceptive pain can be categorized as somatic, visceral, or deafferentation pain.^{57,58} Visceral pain frequently is secondary to tumor involvement of sympathetically innervated organs by either direct invasion or compression that leads to stretching or distention of the affected viscera. Typical examples are metastatic invasion of organs such as with distention of the liver capsule by tumor or pain that occurs with pancreatic cancer from invasion of nerve roots or plexus. This pain typically is poorly localized and difficult to describe. Somatic pain results from the activation of somatic nociceptors and typically is well localized and constant. A common example is bone metastasis. Deafferentation pain, also known as *neuropathic pain*, results from injury to the nervous system from tumor compression or infiltration. This pain often is severe and leads to functional impairment such as that which occurs with invasion of the lumbosacral or brachial plexus.

Drugs that are commonly used in pain management are nonopioid compounds such as acetaminophen and nonsteroidal compounds.⁵⁶ These drugs often can be combined with opioids to improve analgesia. Opioids are the other class of familiar drugs useful in pain management and include codeine or stronger agents such as morphine, oxycodone, methadone, hydromorphone (Dilaudid), and fentanyl. Adjuvant agents such as corticosteroids, antidepressants, muscle relaxants, and certain anticonvulsants may be used in combination with opioid and nonopioid compounds for synergistic effects. The initial assessment of the patient should attempt to assess the pain in regard to severity, alleviating/aggravating factors, and other qualitative features often used to describe pain. The best therapy for the individual patient then should be determined. It is important to keep patient comfort in mind and to address comorbid conditions that will affect treatment. For example, dysphagia leads to difficulty in swallowing, making oral medications either painful or impossible; diaphoresis may alter the effect of transdermal patches because of an inability to stay in place; and muscle wasting and cachexia will make intramuscular and subcutaneous routes of administration extremely painful. If a patient is vomiting or has had profuse diarrhea, oral and rectal medications are inappropriate. The most common method to administer medications is the oral route, but buccal and sublingual approaches to medication administration are particularly useful in patients who suffer with dysphagia.⁵⁶ Liquid forms are easier as well. IV administration, as well as other more intrusive methods of drug administration, also can be used.

For most postoperative pain regimens, medications have been dosed on an as-needed basis. However, terminal patients with chronic, constant, debilitating pain require more regimental administration with around-the-clock dosing, sustained-release medications, or immediate-release medications used for breakthrough pain management. A useful method currently used for pain management is the use of long-acting narcotics with extended analgesic effect. Transdermal fentanyl (Duragesic) patches that reduce the requirement for frequent dosing with excellent control of pain are particularly helpful in chronic pain management. One patch may be applied every 72 hours, but frequency can be increased to every 48 hours for more severe, chronic pain.

Medication dosing should constantly be evaluated and adjusted according to the patient's pain scale. On the typical scale of one to 10 in increasing severity, if a patient rates pain between three and six despite the current regimen, then dosages should be increased by 25 to 50%; if a patient rates pain between seven and 10, dosages may be increased by 50 to 100%.⁵⁶

NSAIDs are effective in managing mild to moderate somatic pain and pain associated with inflammation. NSAIDs such as aspirin, ibuprofen, and naproxen, as well as acetaminophen, are particularly effective for managing pain from bony metastases. These medications do have a "ceiling effect," meaning the drug ceases to provide analgesia above a certain dosage.⁵⁹ These drugs also should be used with caution in elderly populations because of the potential to cause delirium as well as other toxic side effects, such as GI bleeding and renal failure. Opioids such as codeine can be added to NSAIDs for an increased analgesic effect. If pain remains poorly controlled, stronger opioids, such as morphine,

hydromorphone, and fentanyl, can be administered.

Short-acting medications, such as Demerol, which has a half-life of approximately 2.5 to 3 hours, should be avoided in the management of chronic pain.⁵⁶ Demerol, for example, does not have many administration options and is given only by injection because it is ineffective by oral administration. Furthermore, it has toxic intermediates that lead to central nervous system toxicity, resulting in tremors, confusion, or seizure activity. These intermediates may also lower the threshold for seizure activity.⁵⁶

Many side effects can occur with administration of pain medications on a chronic basis, the most common being GI symptoms. For example, the most common side effect of opioid administration is constipation, secondary to decreased peristaltic activity and increased absorption.⁵⁶ Consequently, all patients who are administered opioids also should be placed on a stool softener to avoid constipation. It is important to note that some patients may require an increase in their pain medication regimen at particular times, such as before aggressive wound care or during transport.

Respiratory depression is often a concern when prescribing high doses of opioids. This is far less common in patients who have been on a constant regimen of opioid compounds for >36 hours.⁵⁶ Tolerance to the respiratory-depressant effect of opioids develops within 36 hours of administration, leading to relatively safe administration in terminally ill patients.⁵⁶ Addiction to pain medication should not be a deterrent to providing adequate pain management. Addiction is defined as the preoccupation and seeking of medications, despite known harm, for a reason other than pain management. Terminally ill patients require pain medication for control of severe intractable pain to improve their quality of life but rarely demonstrate symptoms of addiction.

Ethical Considerations

Ethical considerations and end-of life care dilemmas have gained prominent focus in the care of elderly patients, especially in the terminal stages of illness. This is a particularly important issue given the increasing effectiveness of modern therapies and sophisticated intensive care available to patients with the technical ability to sustain life indefinitely. It is, therefore, critical to begin to address these issues early in the course of disease to properly interact with patients and family members regarding prognosis, treatment options, alternatives, and plan of care in terminal stages. Development of a definitive plan of care for a terminally ill patient eases the transition from curative therapy to palliation. Open discussions regarding end-of-life care, withholding or withdrawal of life support, and medical futility are critical issues for patients, family, and caregivers and should be held as soon as is appropriate.

Defining medical futility remains controversial in respect to both practical definitions and clinical determinants. The American Thoracic Society has stated that "a life-sustaining intervention is futile if reasoning and experience indicate that the intervention would be highly unlikely to result in meaningful survival for the patient," with attention paid to both the duration of the survival as well as quality of life.⁵⁵ Table 46-3 summarizes the goals for ethical decision making in the elderly surgical patient.

Table 46-3 Goals for Ethical Decision Making in Elderly Surgical Patient
1. Acknowledge medical futility; physicians are not required to provide life-sustaining treatment that is deemed medically futile.
2. Clarify patients' wishes regarding life-sustaining therapies in accordance with Patient Self-Determination Act (i.e., advance directives, living wills, do not intubate/resuscitate orders).
3. Respect patient autonomy: right to accept and refuse treatment despite consequences of decision.
• Ensure mental competency before establishing autonomy.
• May appoint surrogate decision maker in case of incapacitation.

In actual clinical practice, it is difficult to predict whether a particular therapy will, in fact, be futile. Prognostic scales have been developed to better define medical futility based on objective patient data. For example, the Acute Physiology and Chronic Health Evaluation score can be used as a quantitative prognosis tool. However, this is a general scoring system and, although predictive of gross mortality, it is difficult to individualize for patients. However, this system could help clarify a patient's wishes regarding life-sustaining treatment via advance directives, living wills, and do not resuscitate (DNR) orders to avoid unnecessary prolongation of futile treatment.

Physicians are not required to provide life-sustaining treatments that are deemed medically futile. This can override requests by patients or family members to continue aggressive therapy. It is important to realize that palliation is different from euthanasia and is protected by the law, even if it hastens the occurrence of death by the principle of double effect. Double effect is defined as an act with good intention that produces a secondary effect that is harmful.⁵⁶ Therefore, physicians should not fear legal retribution from families in disagreements regarding treatment plans.

The governing principle in end-of-life decision making is patient autonomy, which takes precedence over physicians' judgment of what is the most appropriate care. A patient has a right to refuse treatment, even if it delays appropriate treatment or results in the patient's death.⁵⁶ However, these preferences need to be documented during a time of mental competency. Surrogate decision making is tantamount to a patient's wishes, giving surrogates complete decision-making responsibilities. Physicians are not required to provide futile care. The Patient Self-Determination Act allows a patient to document preferences for life-sustaining interventions and resuscitation before undergoing treatments in the form of advance directives and living wills.⁵⁴ These documents define the patient's wishes regarding life-support measures. In addition, a surrogate for decision making can be appointed by the patient to make decisions regarding plan of care in the event the patient becomes mentally incapacitated.⁵⁴ Despite the availability of such documentation, few patients make necessary arrangements before clinical decompensation. Furthermore, this issue is rarely addressed by the physician with the patient and family until recovery is unlikely. Unfortunately, most DNR orders are written only within days of a patient's death. This issue should always be addressed with patients before operative intervention. It is important to also acknowledge that DNR orders can be temporarily suspended in the operating room, placing both the surgeon and patient at ease. This practice is appropriate because most adverse events that occur in the operating room are secondary to acute, reversible events and are immediately detectable with careful monitoring. Necessary interventions can be instituted immediately in a controlled setting with excellent results, unlike events that may occur outside the operating room.

To summarize, the four goals of surgical care of elderly patients are as follows:

1. Provide timely diagnosis of disease processes followed by appropriate intervention without the bias of ageism and the false assumption that elderly patients will suffer increased morbidity and mortality.
2. Provide a careful preoperative assessment, taking into consideration the physiologic changes that occur with aging, to optimize an elderly patient for surgical interventions, thereby improving outcomes.
3. Provide interventions that maximize a patient's life span without comprising quality of life and independent function.
4. Relieve suffering with palliation when surgical care is not achievable.

The challenge for a surgeon, therefore, is to improve perioperative care of the elderly surgical patient with careful patient selection, accurately assess risk factors to reduce postoperative morbidity and mortality, and deliver quality surgical interventions without compromising functional vitality.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 47. Anesthesia of the Surgical Patient >

KEY POINTS

1. The incremental interchange of ideas across the specialties of anesthesia and surgery demonstrates the collaborative nature of science in general, and medicine in particular. Many surgeons contributed to the growth in anesthesia; more comprehensive anesthesia, in turn, allowed more complex surgery to develop.
2. The role of the anesthesiologist has expanded to become the perioperative physician. The anesthesiologist evaluates the patient preoperatively, provides the anesthetic, and is involved in postoperative pain relief.
3. The specialties of critical care medicine and pain medicine have grown out of the expanded field of anesthesiology. The postanesthesia care unit gave rise to the intensive care unit; the treatment of acute and chronic pain syndromes by anesthesiologists contributed to the growth of pain medicine as a specialty.
4. New and improved airway and intubation devices, such as the laryngeal mask airway and the video laryngoscope, along with the American Society of Anesthesiologists' airway management algorithm, have led to improved management and control of routine and difficult airways.
5. The study of proteomics will lead to anesthetics tailored to individuals, maximizing effects and reducing side effects of various anesthetic drugs.

TRUE COLLABORATION

The discipline of anesthesia embodies control of three great concerns of humankind: consciousness, pain, and movement. The field of anesthesiology combines the administration of anesthesia with the perioperative management of the patient's concerns, pain management, and critical illness. The fields of surgery and anesthesiology are truly collaborative and continue to evolve together, enabling the care of sicker patients and rapid recovery from outpatient and minimally invasive procedures.

BRIEF HISTORY OF ANESTHESIA

The discovery of anesthesia is one of the seminal American contributions to the world. Along with infection control and blood transfusion, anesthesia has enabled surgery to occupy its fundamental place in medicine. Before the advent of modern anesthesia in the 1840s, many substances and methods were tried in the search for pain relief and better operating conditions. Opium, alcohol, exposure to cold, compression of peripheral nerves, constriction of the carotid arteries to produce unconsciousness, and hypnosis (mesmerism) all proved less than satisfactory and dictated rapid and crude surgical procedures. Patients had to be restrained by several attendants, and only the most stoic could tolerate the screams heard in the operating theater. Charles Darwin, who witnessed two such operations, "rushed away before they were completed. Nor did I ever attend again, for hardly any inducement would have been strong enough to make me do so; this being long before the blessed days of chloroform. The two cases fairly haunted me for many a long year."¹

Modern Beginnings

In 1842, Crawford Long (1815–1878), a physician in rural Georgia, used diethyl ether to induce surgical anesthesia for the removal of two small neck tumors. Diethyl ether had been known for over 800 years but was not used for analgesic purposes. It became an inexpensive and popular recreational drug in the mid-nineteenth century and was used by American medical students at "ether frolics." Although Long did experiments to verify the analgesic effects of ether, he did not publish his work until 1848, in the *Southern Medical*

Journal, too late to be the unquestioned discoverer of anesthesia.²

Although Humphrey Davy (1778–1829) suggested using nitrous oxide for the relief of pain in surgical procedures in 1800, this was not pursued until 1844 by dentist Horace Wells (1815–1848). Wells astutely observed that a man who was injured after inhaling nitrous oxide during an exhibition of the "laughing gas" displayed no awareness of pain. After experimenting on himself, Wells attempted to demonstrate the analgesic effects of nitrous oxide for a dental procedure at Harvard Medical School in 1845. The public demonstration was a failure because nitrous oxide has analgesic properties but does not suffice as the sole anesthetic agent in every patient. Wells never recovered from his humiliating experience and eventually committed suicide. But he does hold a place in history as the first person to recognize and use the only anesthetic from the 1800s that is still in use today—nitrous oxide.

Ether Day

William Morton (1819–1868) was a dentist and partner of Horace Wells. After taking a course in anesthesia from Wells, Morton left the partnership in Hartford, Conn, and established himself in Boston. He continued his interest in anesthesia, but with diethyl ether replacing nitrous oxide. Ether proved a good choice, as it supports respiration and the cardiovascular system at analgesic levels and is potent enough to administer in room air without hypoxia. He practiced the administration of ether on a dog and then used it when extracting teeth from patients in his office. On October 16, 1846, Morton gave the first public demonstration of ether as an anesthetic for Johns Collins Warren, distinguished surgeon and a founder of Massachusetts General Hospital. In attendance in the surgical amphitheater were several surgeons, medical students, and a newspaper reporter. After anesthesia was induced using a makeshift inhaler, Warren successfully removed a vascular mass from the patient's neck with no ill effects. Warren was an originator of the *Boston Medical and Surgical Journal* (now *The New England Journal of Medicine*), and by November 1846, the demonstration was published in an article by Henry J. Bigelow.³ The stature of Warren and Bigelow lent considerable credence to the advent of surgical anesthesia; as news spread rapidly, surgeons around the world were quick to adopt this "American invention." Massachusetts General Hospital has restored and preserved the original amphitheater where the demonstration took place, now called the *Ether Dome*. It is designated as a Registered National Historic Landmark commemorating the first public demonstration, rather than discovery, of the use of ether as an anesthetic.

The First Anesthesiologists

John Snow (1813–1858) made science out of the art of anesthesia. He was a respected London physician who applied a scholarly, scientific method to investigate the clinical properties and pharmacology of ether, chloroform, and other anesthetic agents. Snow was an astute observer and published a detailed account of the five degrees of etherization in 1847. He vastly improved the apparatus for administering ether and mastered the clinical techniques of anesthetizing patients. As the leading anesthetist of his day, he gave anesthetics to the royal family, including chloroform during labor to Queen Victoria for the birth of Prince Leopold. The Queen's endorsement of "that blessed chloroform" removed the moral and social stigma against relieving pain during childbirth and brought anesthesia into public awareness. Chloroform, popularized in England by James Simpson (1811–1870), had a narrow therapeutic index and placed great clinical demands on the anesthetist. Ether, with its ability to maintain the cardiovascular and respiratory systems, remained in common use in the United States and often was administered by house staff, medical students, or nurses. Snow encouraged the administration of anesthesia by a physician and felt that a physician dedicated specifically to that purpose was appropriate and necessary. Snow and other exceptional British physicians specializing in anesthesia [Joseph Clover (1825–1882) and Sir Frederick Hewitt (1857–1916)] created a standard of excellence in the latter half of the nineteenth century. This atmosphere of professionalism led to the formation of anesthesia societies and the publication of papers in the prestigious *British Medical Journal* and *Lancet* in England years before such organizations existed in America.⁴

Cocaine: The First Local Anesthetic

The ancient Incas chewed coca leaves as a stimulant and may have been aware of its local anesthetic properties, allegedly facilitating trephination of the skull by chewing a clump of coca leaves and dripping the resultant saliva into the wound. The active alkaloid of the coca leaf was synthesized in 1860 and called *cocaine* by German chemist Albert Niemann, who noted that it "benumbs the nerves of the

tongue, depriving it of feeling."⁵ Sigmund Freud (1856–1939) of Vienna received a supply of cocaine from Merck, studied its properties, and wrote the famous monograph "Über Coca" in 1884. Freud was primarily interested in the stimulant and euphoric effects of cocaine and attempted to use it to treat morphine addiction. Freud and Karl Koller (1857–1944), an ophthalmologic intern, began to perform physiologic experiments with cocaine, measuring its effects on muscle strength. Although they both noted that the drug caused numbness of the tongue when swallowed, it was Koller who first instilled it into his own cornea; report of its use as a local anesthetic galvanized the medical world. Soon after, young American surgeons William Halsted (1852–1922) and Richard Hall described intradermal injection of cocaine and were the first to use it for regional blocks of the facial nerves, brachial plexus, and the internal pudendal and posterior tibial nerves.⁶ Halstead later became the first professor of surgery and chief surgeon at Johns Hopkins University, where he remained for >30 years. One of the founding fathers of modern surgery, he pioneered radical mastectomy with lymphadenectomy and the use of rubber gloves. While experimenting on themselves, Halstead and other early researchers became addicted to cocaine.⁷ Its toxic effects were the stimulus to find other local anesthetics—procaine was synthesized in 1905 and lidocaine in 1943.

The New York neurologist Leonard Corning (1855–1923) observed the regional blocks of Halstead and Hall, analytically studied local anesthesia effects on dogs, applied his knowledge to humans, and published the first textbook on local anesthesia in 1886. After experimenting on the spinal nerves of a dog, he intradurally injected a solution of cocaine into a patient, called it *spinal anesthesia*, and commented that it might be useful in surgery. His suggestion went unheeded for >10 years, until August Bier (1861–1949), a prominent German surgeon, gave the first deliberate spinal anesthetic.⁸ This incremental interchange of ideas and advances across the Atlantic and across the specialties of anesthesia and surgery demonstrates the collaborative nature of science in general, and medicine in particular. The development of surgery and anesthesia exemplify the dichotomy of two fledgling specialties that are mutually dependent, yet increasingly autonomous.

Twentieth Century

Developments in anesthesia on both sides of the Atlantic progressed rapidly in the twentieth century. The convergence of technologies that produced the hollow needle and syringe, coupled with the synthesis of barbiturates, gave rise to IV anesthesia in the early 1900s. Barbitol, followed by hexobarbital and thiopental in 1934, produced rapid and more pleasant induction of anesthesia than the inhaled gases. The concept of "balanced anesthesia" began in 1925, when John Lundy (1894–1973) proposed the use of thiopentone for induction, followed by inhaled agents for maintenance of anesthesia. Lundy directed the department of anesthesiology at the Mayo Clinic for 28 years. He established the first recovery room and blood bank, authored the first textbook on modern anesthesia, and helped found the American Board of Anesthesiology.

Nitrous oxide, diethyl ether, and chloroform, all discovered fortuitously by observation, remained the dominant inhalation agents until the accidental discovery of cyclopropane's anesthetic properties in 1923. Although rapid acting and pleasant smelling, cyclopropane was limited by its flammability and cardiac irritability. Because it was known that fluorination would reduce or eliminate flammability of chemical compounds, British chemist Charles Suckling set out to synthesize an anesthetic that was stable, potent, volatile, and not flammable. He successfully produced halothane in 1953. Introduced into clinical practice in 1956 after extensive testing in Manchester, England, and paired with an accurate calibrated vaporizer, halothane quickly became the most widely used fluorinated anesthetic. Enflurane and isoflurane, synthesized in the United States by Ross Tyrell, were introduced into clinical practice in 1972 and 1981, respectively. The newest agents, desflurane and sevoflurane, were introduced into clinical practice in the early 1990s. They possess a low solubility and are characterized by rapid onset and recovery, making them particularly well suited to outpatient surgery.

The motto of the American Society of Anesthesiologists (ASA) is "vigilance," and to that end, there has been continued progress in objective mechanical measurement of patient well-being. The early anesthesiologists used clinical signs such as patient color, depth of respiration, and pulse rate to monitor depth of anesthesia and patient well-being. Harvey Cushing, who eventually became Moseley Professor of Surgery at the Peter Bent Brigham Hospital, began the first anesthesia records or "ether charts" in 1895 while a medical student. They recorded pulse, respiratory rates, pupillary diameter, and the amounts of ether and other drugs administered. He later introduced the use of the portable sphygmomanometer of Riva-Rocci to measure blood pressure, and the precordial stethoscope to

monitor breath and heart sounds. Monitoring has since progressed to its current state with incremental developments in electrocardiography, pulse oximetry, and mass spectrometry, all mandatory for the safe administration of any anesthetic.

The control of the patient's airway and respiration as the purview of the anesthesiologist evolved with techniques of endotracheal intubation as pioneered by Sir Ivan Magill (1888–1986), and the invention of the cuffed endotracheal tube by Arthur Guedel (1883–1965). This later merged with the invention of mechanical ventilation and its introduction to the operating room as the embodiment of today's anesthesia machine. It was this expertise at control of respiration that paved the way for the most revolutionary modern development in anesthesia—the use of muscle relaxants. Curare, a nondepolarizing muscle relaxant, was popularized by Harold Griffith of Montreal. His report of the successful use of curare was a galvanizing event that revolutionized the practice of anesthesia, as the relaxation of abdominal muscles could be controlled to facilitate surgery.⁹ The depolarizing relaxant succinylcholine was introduced in 1949, and research has continued to provide the newer nondepolarizing drugs mivacurium, pancuronium, rocuronium, atracurium, and cisatracurium.

Anesthesiology Today—the Perioperative Physician

The specialty of anesthesia is no longer limited to the operating room. It is natural that anesthesiology, born out of the quest to relieve pain, gave rise to the field of acute and chronic pain medicine. The anesthesiologist consulting on the acute pain service may recommend oral, IM, or IV analgesia with a variety of agents, or patient-controlled analgesia. Postsurgical patients also may be treated with nerve blocks: regional (e.g., brachial plexus, popliteal, and femoral) or neuraxial (epidural or intrathecal). The discipline of chronic pain addresses patients who suffer for months or years with cancer or other debilitating diseases. Treatment modalities escalate from orally administered drugs, to diagnostic and therapeutic nerve blocks, to more invasive measures like dorsal column nerve stimulators, and radiofrequency or cryosurgical nerve ablation.

Daily management of the airway, fluids and transfusions, ventilation, drug delivery, monitoring, and caring for the sickest patients in the postanesthesia care unit prepared anesthesiologists to become major contributors to the development of critical care medicine. Out of the 28 founding members of the Society of Critical Medicine, 10 were anesthesiologists.¹⁰

The American Board of Anesthesiology became an independent board in 1941, and since then, has granted board certification to >25,000 diplomates. Certificates in Anesthesia Pain Management and Anesthesia Critical Care Medicine are granted to those completing additional postgraduate training. The ASA has >35,000 members, and its official journal, *Anesthesiology*, has a monthly circulation of 40,000 worldwide.

BASIC PHARMACOLOGY

Pharmacokinetics

Pharmacokinetics or the *time dependency* of a drug describes the relationship between the dose of a drug and its plasma or tissue concentration. It is what the body does to the drug. It relates to absorption, distribution, metabolism, and elimination. The route of administration, metabolism, protein binding, and tissue distribution all affect the pharmacokinetics of a particular drug.

ADMINISTRATION, DISTRIBUTION, METABOLISM, AND ELIMINATION

Administration of a drug affects its pharmacokinetics, as there will be different rates of drug entry into the circulation. For example, the oral and IV routes are subject to first-pass effect of the portal circulation; this can be bypassed with the nasal or sublingual route. Other routes of drug administration include transdermal, intramuscular, subcutaneous, or inhalation.

Distribution is the delivery of a drug from the systemic circulation to the tissues. Once a drug has entered the systemic circulation, the rate at which it will enter the tissues depends on several factors:

Molecular size of the drug, capillary permeability, polarity, and lipid solubility. Small molecules will pass more freely and quickly across cell membranes than large ones, but capillary permeability is variable and results in different diffusion rates. Renal glomerular capillaries are permeable to almost all non–protein-bound drugs; capillaries in the brain are fused (i.e., they have tight

junctions) and are relatively impermeable to all but the tiniest molecules (the blood-brain barrier). Un-ionized molecules pass more easily across cell membranes than charged molecules; diffusibility also increases with increasing lipid solubility.

Plasma protein and tissue binding. Many drugs bind to circulating proteins like albumin, glycoproteins, and globulins. Disease, age, and the presence of other drugs will affect the amount of protein binding; drug distribution is affected because only the unbound free portion of the drug can pass across the cell membrane. Drugs also bind reversibly to body tissues; if they bind with high affinity, they are said to be sequestered in that tissue (e.g., heavy metals are sequestered in bone).¹¹

The fluid volume in which a drug distributes is termed the *volume of distribution* (Vd). This mathematically derived value gives a rough estimation of the overall physical distribution of a drug in the body. A general rule for volume distribution is that the greater the Vd, the greater the diffusibility of the drug. Because drugs have variable ionization rates and bind differently to plasma proteins and tissues, the Vd is not a good predictor of the actual concentration of the drug after administration. Determining the apparent Vd (dose/concentration) is an attempt to more accurately ascertain the drug dose administered and its final concentration.

Metabolism is the permanent breakdown of original compounds into smaller metabolites. Drug elimination varies widely; some drugs are excreted unchanged by the body, some decompose via plasma enzymes, and some are degraded by organ-based enzymes in the liver. Many drugs rely on multiple pathways for elimination (i.e., metabolized by liver enzymes then excreted by the kidney). When a drug is given orally, it reaches the liver via the portal circulation and is partially metabolized before reaching the systemic circulation. This is why an oral dose of a drug often must be much higher than an equally effective IV dose. Some drugs (e.g., nitroglycerine) are hydrolyzed presystemically in the gut wall and must be administered sublingually to achieve an effective concentration.

It is important to remember that the response to drugs varies widely. The disposition of drugs is affected by age; weight; sex; pregnancy; disease states; and the concomitant use of alcohol, tobacco, and other licit and illicit drugs. Genetic polymorphism, or variations in genes which cause differing drug effects, is another explanation of varying drug response. This will be discussed later in the Future Direction of Anesthesia section on proteomics. This as yet unpredictable response to drugs underscores the importance of the most important monitor in the operating room—the anesthesiologist, who continuously assesses the patient's vital signs and adjusts the doses of anesthetic agents to match the surgical stimulus.

Pharmacodynamics

Pharmacodynamics, or how the plasma concentration of a drug translates into its effect on the body, depends on biologic variability, receptor physiology, and clinical evaluations of the actual drug. It is what the drug does to the body. An *agonist* is a drug that causes a response. A *full agonist* produces the full tissue response, and a *partial agonist* provokes less than the maximum response induced by a full agonist. An antagonist is a drug that does not provoke a response itself, but blocks agonist-mediated responses. An *additive effect* means that a second drug acts with the first drug and will produce an effect that is equal to the algebraic summation of both drugs. A *synergistic effect* means that two drugs interact to produce an effect that is greater than expected from the two drugs' algebraic summation.¹²

Hyporeactivity means a larger than expected dose is required to produce a response, and this effect is termed *tolerance*, *desensitization*, or *tachyphylaxis*. Tolerance usually results from chronic drug exposure, either through enzyme induction (e.g., alcohol) or depletion of neurotransmitters (e.g., cocaine).

Potency, Efficacy, Lethal Dose, and Therapeutic Index

The *potency* of a drug is the dose required to produce a given effect, such as pain relief or a change in heart rate. The average sensitivity to a particular drug can be expressed through the calculation of the effective dose; ED₅₀ would have the desired effect in 50% of the general population. The *efficacy* of any therapeutic agent is its power to produce a desired effect. Two drugs may have the same efficacy but different potencies. The difference in potency of the two drugs is described by the ratio ED_{50b}/ED_{50a}, where *a* is the less potent drug. If the ED_{50b} equals 4 and the ED_{50a} equals 0.4, then drug *a* is 10 times as potent as drug *b*. For example, 10 mg of morphine produces analgesia equal to that of 1 mg of hydromorphone. They are equally effective, but hydromorphone is 10 times as potent as morphine.

Dose-response curves show the relationship between the dose of a drug administered (or the resulting plasma concentration) and the pharmacologic effect of the drug. The pharmacologic effect might be secretion of a hormone, a change in heart rate, or contraction of a muscle. Between 20 and 80% of the maximum effect, the logarithm of the dose and its response has a linear relationship. The term *dose* only applies to the amount administered and not the actual concentration. If the concentration of an antagonist is increased (in the presence of a fixed concentration of agonist), the dose-response curve will be shifted to the right, and a higher agonist concentration will be required to achieve the desired effect. A basic dose-response curve is shown in Fig. 47-1.

The *lethal dose* (LD₅₀) of a drug produces death in 50% of animals to which it is given. The ratio of the lethal dose and effective dose, LD₅₀/ED₅₀, is the *therapeutic index*. A drug with a high therapeutic index is safer than a drug with a low or narrow therapeutic index.

ANESTHETIC AGENTS

Anesthesia can be *local*, *regional*, or *general* (Table 47-1). Local anesthesia is accomplished using a local anesthetic drug that can be injected intradermally and is used for the removal of small lesions or to repair traumatic injuries. Local anesthesia is the most frequent anesthetic administered by surgeons and may be accompanied by IV sedation to improve patient comfort.

Table 47-1 Anesthetic Agents, Their Actions, and Their Clinical Uses						
Effect	Monitor	IV Drugs	Potent Gases	Weak Gases	Local Anesthetics	
Unconsciousness	Electroencephalogram	Benzodiazepines	Sevoflurane	Nitrous oxide	— ^c	
Amnesia	Clinical signs	Midazolam	Desflurane			
Anxiolysis		Diazepam Lorazepam	Isoflurane Enflurane			
		Barbiturates	Halothane			
		Propofol				
		Etomidate				
		Ketamine ^a				

Analgesia	Heart rate	Opioids	Sevoflurane	Nitrous oxide	Amides	Esters
	Blood pressure	Morphine	Desflurane		Lidocaine	Cocaine
	Respiratory rate	Meperidine	Isoflurane		Bupivacaine	Procaine
	Clinical signs	Hydromorphone	Enflurane		Mepivacaine	Chloroprocaine
		Fentanyl	Halothane		Prilocaine	Tetracaine
		NSAIDs			Ropivacaine	Benzocaine
		Ketorolac			Regional peripheral nerve blocks	
		Parecoxib				
Muscle relaxation	Nerve stimulator	Depolarizing agent	Sevoflurane	___ ^b	Brachial plexus	
Paralysis	Tidal volume	Succinylcholine	Desflurane		Sciatic	
	Hand grip	Nondepolarizing agents	Isoflurane		Femoral	
	5-second head lift		Enflurane		Cervical plexus	
	Clinical signs	Pancuronium	Halothane		Regional central nerve blocks	
		Vecuronium				
		Rocuronium			Spinal	
		Atracurium			Epidural	
		Cis-atracurium				
		Mivacurium				

^a Note that the IV agents are quite specific in their effects, except for ketamine, which has both amnestic and analgesic qualities.

^b The potent inhalational anesthetics contribute to all three components of anesthesia, but nitrous oxide has weak amnestic and analgesic properties and provides no muscle relaxation at all.

^c The local anesthetics produce excellent analgesia and muscle relaxation, but contribute nothing to amnesia or anxiolysis; these anesthetics must be supplemented with an IV sedative.

General anesthesia entails all three elements of anesthesia (amnesia, analgesic, and muscle relaxation).

Local Anesthetics

Local anesthetics are divided into two groups based on their chemical structure: the amides and the esters. In general, the amides are metabolized in the liver and the esters are metabolized by plasma cholinesterases, which yield metabolites with slightly higher allergic potential than the amides (Table 47-2).

Table 47-2 Biologic Properties of Commonly Used Local Anesthetics			
Agent	Equianesthetic Concentration (%)	Approximate Anesthetic Duration (min)	Site of Metabolism
Esters			
Procaine	2	50	Plasma
Chloroprocaine	2	45	Plasma
Tetracaine	0.25	175	Plasma
Amides			
Prilocaine	1	100	Liver/lung
Lidocaine	1	100	Liver
Mepivacaine	1	100	Liver
Bupivacaine	0.25	175	Liver

Ropivacaine	0.3	150	Liver
Etidocaine	0.25	200	Liver

AMIDES

Lidocaine, bupivacaine, mepivacaine, prilocaine, and ropivacaine have in common an amide linkage between a benzene ring and a hydrocarbon chain that, in turn, is attached to a tertiary amine. The benzene ring confers lipid solubility for penetration of nerve membranes, and the tertiary amine attached to the hydrocarbon chain makes these local anesthetics water soluble. Lidocaine has a more rapid onset and is shorter acting than bupivacaine; however, both are widely used for tissue infiltration, regional nerve blocks, and spinal and epidural anesthesia. Ropivacaine is the most recently introduced local anesthetic. It is clinically similar to bupivacaine in that it has a slow onset and a long duration, but is less cardiotoxic. All amides are 95% metabolized in the liver, with 5% excreted unchanged by the kidneys.

ESTERS

Cocaine, procaine, chloroprocaine, tetracaine, and benzocaine have an ester linkage in place of the amide linkage mentioned above in the Amides section. Unique among local anesthetics, cocaine occurs in nature, was the first used clinically, produces vasoconstriction [making it useful for topical application (e.g., for intranasal surgery)], releases norepinephrine from nerve terminals resulting in hypertension, and is highly addictive. Cocaine is a Schedule II drug. Procaine, synthesized in 1905 as a nontoxic substitute for cocaine, has a short duration and is used for infiltration. Tetracaine has a long duration and is useful as a spinal anesthetic for lengthy operations. Benzocaine is for topical use only. The esters are hydrolyzed in the blood by pseudocholinesterase. Some of the metabolites have a greater allergic potential than the metabolites of the amide anesthetics, but true allergies to local anesthetics are rare.

The common characteristic of all local anesthetics is a reversible block of the transmission of neural impulses when placed on or near a nerve membrane. Local anesthetics block nerve conduction by stabilizing sodium channels in their closed state, preventing action potentials from propagating along the nerve. The individual local anesthetic agents have different recovery times based on lipid solubility and tissue binding, but return of neural function is spontaneous as the drug is metabolized or removed from the nerve by the vascular system.

Toxicity of local anesthetics results from absorption into the bloodstream or from inadvertent direct intravascular injection. Toxicity manifests first in the more sensitive central nervous system (CNS), and then the cardiovascular system.

CENTRAL NERVOUS SYSTEM

As plasma concentration of local anesthetic rises, symptoms progress from restlessness to complaints of tinnitus. Slurred speech, seizures, and unconsciousness follow. Cessation of the seizure via administration of a benzodiazepine or thiopental and maintenance of the airway is the immediate treatment. If the seizure persists, the trachea must be intubated with a cuffed endotracheal tube to guard against pulmonary aspiration of stomach contents.

CARDIOVASCULAR SYSTEM

With increasingly elevated plasma levels of local anesthetics, progression to hypotension, increased P-R intervals, bradycardia, and cardiac arrest may occur. Bupivacaine is more cardiotoxic than other local anesthetics. It has a direct effect on ventricular muscle, and because it is more lipid soluble than lidocaine, it binds tightly to sodium channels (it is called the *fast-in, slow-out local anesthetic*). Patients who have received an inadvertent intravascular injection of bupivacaine have experienced profound hypotension, ventricular tachycardia and fibrillation, and complete atrioventricular heart block that is extremely refractory to treatment. The toxic dose of lidocaine is approximately 5 mg/kg; that of bupivacaine is approximately 3 mg/kg.

Calculation of the toxic dose before injection is imperative. It is helpful to remember that for any drug or solution, 1% = 10 mg/mL. For a 50-kg person, the toxic dose of bupivacaine would be approximately 3 mg/kg, or $3 \times 50 = 150$ mg. A 0.5% solution of bupivacaine is 5

mg/mL, so $150 \text{ mL} / 5 \text{ mg/mL} = 30 \text{ mL}$ as the upper limit for infiltration. For lidocaine in the same patient, the calculation is $50 \text{ kg} \times 5 \text{ mg/mL} = 250 \text{ mg}$ toxic dose. If a 1% solution is used, the allowed amount would be $250 \text{ mg} / 10 \text{ mg/mL} = 25 \text{ mL}$.

ADDITIVES

Epinephrine has one physiologic and several clinical effects when added to local anesthetics. Epinephrine is a vasoconstrictor, and by reducing local bleeding, molecules of the local anesthetic remain in proximity to the nerve for a longer time period. Onset of the nerve block is faster, the quality of the block is improved, the duration is longer, and less local anesthetic will be absorbed into the bloodstream, thereby reducing toxicity. Although epinephrine 1:200,000 (5 $\mu\text{g/mL}$) added to a local anesthetic for infiltration will greatly lengthen the time of analgesia, epinephrine-containing solutions should not be injected into body parts with end-arteries, such as toes or fingers, as vasoconstriction may lead to ischemia or loss of a digit. When added to the local anesthetic, sodium bicarbonate will raise the pH, favoring the non-ionized uncharged form of the molecule. This speeds the onset of the block, especially in local anesthetics that are mixed with epinephrine. The pH of such solutions is around 4.5; therefore, the addition of sodium bicarbonate results in a relatively large increase in pH.¹³

Regional Anesthesia

PERIPHERAL

Local anesthetic can be injected *peripherally*, near a large nerve or plexus, to provide anesthesia to a larger region of the body. Examples include the brachial plexus for surgery of the arm or hand, blockade of the femoral and sciatic nerves for surgery of the lower extremity, ankle block for surgery of the foot or toes, intercostal block for analgesia of the thorax postoperatively, or blockade of the cervical plexus, which is ideal for carotid endarterectomy. Risks of peripheral regional nerve blocks are dependent on their location. For example, nerve blocks injected into the neck risk puncture of the carotid or vertebral arteries, intercostal nerves are in close proximity to the vascular bundle and have a high rate of absorption of local anesthetic, and nerve blocks of the thorax run the risk of causing pneumothorax. All peripheral nerve blocks may be supplemented intraoperatively with IV sedation and/or analgesics.

CENTRAL

Local anesthetic injected *centrally* near the spinal cord—spinal or epidural anesthesia—provides anesthesia for the lower half of the body. This is especially useful for genitourinary, gynecologic, inguinal hernia, or lower-extremity procedures. Spinal and epidural anesthesia block the spinal nerves as they exit the spinal cord. Spinal nerves are mixed nerves; they contain motor, sensory, and sympathetic components. The subsequent block will cause sensory anesthesia, loss of motor function, and blockade of the sympathetic nerves from the level of the anesthetic distally to the lower extremities. Subsequent vasodilation of the vasculature from sympathetic block may result in hypotension, which is treatable with IV fluids and/or pressors.

SPINAL ANESTHESIA

Local anesthetic is injected directly into the dural sac surrounding the spinal cord. The level of injection is usually below L1 to L2, where the spinal cord ends in most adults. Because the local anesthetic is injected directly into the cerebrospinal fluid surrounding the spinal cord, only a small dose is needed, the onset of anesthesia is rapid, and the blockade thorough. Lidocaine, bupivacaine, and tetracaine are commonly used agents of differing durations; the block wears off naturally via drug uptake by the cerebrospinal fluid, bloodstream, or diffusion into fat. Epinephrine as an additive to the local anesthetic will significantly prolong the blockade.

Possible complications include hypotension, especially if the patient is not adequately prehydrated; high spinal block requires immediate airway management; and postdural puncture headache sometimes occurs. Spinal headache is related to the diameter and configuration of the spinal needle, and can be reduced to approximately 1% with the use of a small 25- or 27-gauge needle.

Cauda equina syndrome is injury to the nerves emanating distal to the spinal cord resulting in bowel and bladder dysfunction, and lower-extremity sensory and motor loss. It has mainly been seen in cases in which indwelling spinal microcatheters and high (5%) concentrations of lidocaine were used. Indwelling spinal catheters are no longer used.

EPIDURAL ANESTHESIA

Epidural anesthesia could also be called *extradural anesthesia*, because local anesthetics are injected into the epidural space surrounding the dural sac of the spinal cord. Much greater volumes of anesthetic are required than with spinal anesthesia, and the onset of the block is longer—10 to 15 minutes. As in spinal anesthesia, local anesthetic bathes the spinal nerves as they exit the dura; the patient achieves analgesia from the sensory block, muscle relaxation from blockade of the motor nerves, and hypotension from blockade of the sympathetic nerves as they exit the spinal cord. Note that regional anesthesia, whether peripheral or central, provides only two of the three major components of anesthesia—analgesia and muscle relaxation. Anxiolysis, amnesia, or sedation must be attained by supplemental IV administration of other drugs (e.g., the benzodiazepines or propofol infusion).

Complications are similar to those of spinal anesthesia. Inadvertent injection of local anesthetic into a dural tear will result in a high block, manifesting as unconsciousness, severe hypotension, and respiratory paralysis requiring immediate aggressive hemodynamic management and control of the airway. Indwelling catheters are often placed through introducers into the epidural space, allowing an intermittent or continuous technique, as opposed to the single-shot method of spinal anesthesia. By necessity, the epidural-introducing needles are of a much larger diameter (17- or 18-gauge) than spinal needles, and accidental dural puncture more often results in a severe headache that may last up to 10 days if left untreated.

General Anesthesia

General anesthesia describes a triad of three major and separate effects: unconsciousness (and amnesia), analgesia, and muscle relaxation (see Table 47-1). IV drugs usually produce a single, discrete effect, while most inhaled anesthetics produce elements of all three. General anesthesia is achieved with a combination of IV and inhaled drugs, each used to its maximum benefit. The science and art of anesthesia is a dynamic process. As the amount of stimulus to the patient changes during surgery, the patient's vital signs are used as a guide and the quantity of drugs is adjusted, maintaining an equilibrium between stimulus and dose. General anesthesia is what patients commonly think of when they are to be "put under," and can be a cause of considerable preoperative anxiety.¹⁴

INTRAVENOUS AGENTS

Unconsciousness and Amnesia

The IV agents that produce unconsciousness and amnesia are frequently used for the induction of general anesthesia. They include barbiturates, benzodiazepines, propofol, etomidate, and ketamine. Except for ketamine, the following agents have no analgesic properties, nor do they cause paralysis or muscle relaxation.

Barbiturates

The most common barbiturates are thiopental, thiamylal, and methohexital. The mechanism of action is at the γ -aminobutyric acid (GABA) receptor, where they inhibit excitatory synaptic transmission. They produce a rapid, smooth induction within 60 seconds, and wear off in about 5 minutes. In higher doses and in patients with intravascular depletion, they cause hypotension and myocardial depression. The barbiturates are anticonvulsants and protect the brain during neurosurgery by reducing cerebral metabolism.

Propofol

Propofol is an alkylated phenol that inhibits synaptic transmission through its effects at the GABA receptor. With a short duration, rapid recovery, and low incidence of nausea and vomiting, it has emerged as the agent of choice for ambulatory and minor general surgery. Additionally, propofol has bronchodilatory properties that make its use attractive in asthmatic patients and smokers. Propofol may cause hypotension, and should be used cautiously in patients with suspected hypovolemia and/or coronary artery disease (CAD), the latter of which may not tolerate a sudden drop in blood pressure. It can be used as a continuous infusion for sedation in the intensive care unit setting. Propofol is an irritant and frequently causes pain on injection.

Benzodiazepines

The most important uses of the benzodiazepines are for reduction of anxiety and to produce amnesia. Frequently used IV benzodiazepines are diazepam, lorazepam, and midazolam. They all inhibit synaptic transmission at the GABA receptor, but have differing durations of action. The benzodiazepines can produce peripheral vasodilatation and hypotension, but have minimal effects on respiration when used alone. They must be used with caution when given with opioids; a synergistic reaction causing respiratory depression is common. The benzodiazepines are excellent anticonvulsants and only rarely cause allergic reactions.

Etomidate

Etomidate is an imidazole derivative used for IV induction. Its rapid and almost complete hydrolysis to inactive metabolites results in rapid awakening. Like the above IV agents, etomidate acts on the GABA receptor. It has little effect on cardiac output and heart rate, and induction doses usually produce less reduction in blood pressure than that seen with thiopental or propofol. Etomidate is associated with pain on injection and more nausea and vomiting than thiopental or propofol.

Ketamine

Ketamine differs from the above IV agents in that it produces analgesia as well as amnesia. Its principal action is on the *N*-methyl-D-aspartate receptor; it has no action on the GABA receptor. It is a dissociative anesthetic, producing a cataleptic gaze with nystagmus. Patients may associate this with delirium and hallucinations while regaining consciousness. The addition of benzodiazepines has been shown to prevent these side effects. Ketamine can increase heart rate and blood pressure, which may cause myocardial ischemia in patients with CAD. Ketamine is useful in acutely hypovolemic patients to maintain blood pressure via sympathetic stimulation, but is a direct myocardial depressant in patients who are catecholamine depleted. Ketamine is a bronchodilator, making it useful for asthmatic patients, and rarely is associated with allergic reactions.

ANALGESIA

The IV analgesics most frequently used in anesthesia today have little effect on consciousness, amnesia, or muscle relaxation. The most important class is the *opioids*, so called because they were first isolated from opium, with morphine, codeine, meperidine, hydromorphone, and the fentanyl family being the most common. The most important *nonopioid* analgesics are ketamine (discussed above in the Ketamine section) and ketorolac, an IV NSAID.

Opioid Analgesics

The commonly used opioids—morphine, codeine, oxymorphone, meperidine, and the fentanyl-based compounds—act centrally on μ -receptors in the brain and spinal cord. The main side effects of opioids are euphoria, sedation, constipation, and respiratory depression, which also are mediated by the same μ -receptors in a dose-dependent fashion. Although opioids have differing potencies required for effective analgesia, *equianalgesic doses of opioids result in equal degrees of respiratory depression*. Thus, there is no completely safe opioid analgesic. The synthetic opioids fentanyl, and its analogues sufentanil, alfentanil, and remifentanil, are commonly used in the operating room. They differ pharmacokinetically in their lipid solubility, tissue binding, and elimination profiles, and therefore have differing potencies and durations of action. Remifentanil is remarkable in that it undergoes rapid hydrolysis that is unaffected by sex, age, weight, or renal or hepatic function, even after prolonged infusion. Recovery is within minutes, but there is little residual postoperative analgesia.

Naloxone and the longer-acting naltrexone are pure opioid *antagonists*. They can be used to reverse the side effects of opioid overdose (e.g., respiratory depression), but the analgesic effects of the opioid also will be reversed.

Nonopioid Analgesics

Ketamine, an *N*-methyl-D-aspartate receptor antagonist, is a potent analgesic, but is one of the few IV agents that also causes significant sedation and amnesia. Unlike the μ -receptor agonists, ketamine supports respiration. It can be used in combination with opioids, but the dysphoric effects must be masked with the simultaneous use of sedatives, usually a benzodiazepine like midazolam.

Ketorolac is a parenteral NSAID that produces analgesia by reducing prostaglandin formation via inhibition of the enzyme cyclooxygenase (COX). Intraoperative use of ketorolac reduces postoperative need for opioids. Two forms of COX have been identified: COX-1 is responsible for the synthesis of several prostaglandins as well as prostacyclin, which protects gastric mucosa, and thromboxane, which supports platelet function. COX-2 is induced by inflammatory reactions to produce more prostaglandins. Ketorolac (as well as many oral NSAIDs, aspirin, and indomethacin) inhibits both COX-1 and COX-2, which causes the major side effects of gastric bleeding, platelet dysfunction, and hepatic and renal damage. Parecoxib is a parenteral COX-2 NSAID now being tested that would presumably produce analgesia and reduce inflammation without causing GI bleeding or platelet dysfunction.

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents have no amnestic, hypnotic, or analgesic properties; patients must be properly anesthetized *before* and *in addition to* the administration of these agents. A paralyzed but unsedated patient will be aware, conscious, and in pain, yet be unable to communicate their predicament. Inappropriate administration of a neuromuscular blocking agent to an awake patient is one of the most traumatic experiences imaginable. Neuromuscular blockade is not a substitute for adequate anesthesia, but is rather an adjunct to the anesthetic. Depth of neuromuscular blockade is best monitored with a nerve stimulator to ensure patient immobility intraoperatively, and to confirm a lack of residual paralysis postoperatively.¹⁵

Unlike the local anesthetics, which affect the ability of nerves to conduct impulses, the neuromuscular blockers have no effect on either nerves or muscles, but act primarily on the *neuromuscular junction*.

There is one commonly used *depolarizing* neuromuscular blocker—succinylcholine. This agent binds to acetylcholine receptors on the postjunctional membrane in the neuromuscular junction and causes depolarization of muscle fibers.

Although the rapid onset (<60 seconds) and rapid offset (5 to 8 minutes) make succinylcholine ideal for management of the airway in certain situations, total body muscle fasciculations can cause postoperative aches and pains, an elevation in serum potassium levels, and an increase in intraocular and intragastric pressure. Its use in patients with burns or traumatic tissue injuries may result in a high enough rise in serum potassium levels to produce arrhythmias and cardiac arrest. Unlike other neuromuscular blocking agents, the effects of succinylcholine cannot be reversed. Succinylcholine is rapidly hydrolyzed by plasma cholinesterase, also referred to as *pseudocholinesterase*. There are many reasons for a patient to have low pseudocholinesterase levels, such as liver disease, concomitant use of other drugs, pregnancy, and cancer. These factors are usually not clinically problematic, delaying return of motor function only by several minutes. Some patients have a genetic disorder manifesting as atypical plasma cholinesterase; the atypical enzyme has less-than-normal activity, and/or the patient has extremely low levels of the enzyme. The incidence of the homozygous form is approximately one in 3000; the effects of a single dose of succinylcholine may last several hours instead of several minutes. Treatment is to keep the patient sedated and unaware he or she is paralyzed, continue mechanical ventilation, test the return of motor function with a peripheral nerve stimulator, and extubate the patient only after he or she has fully regained motor strength. Two separate blood tests must be drawn: *pseudocholinesterase level* to determine the amount of enzyme present, and *dibucaine number*, which indicates the quality of the enzyme. Patients with laboratory-confirmed abnormal pseudocholinesterase levels and/or dibucaine numbers should be counseled to avoid succinylcholine as well as mivacurium, which is also hydrolyzed by pseudocholinesterase. First-degree family members should also be tested. Succinylcholine is the only IV triggering agent of malignant hyperthermia (MH) (discussed below in the Malignant Hyperthermia section).

There are several competitive *nondepolarizing* agents available for clinical use. The longest acting is *pancuronium*, which is excreted almost completely unchanged by the kidney. Intermediate-duration neuromuscular blockers include *vecuronium* and *rocuronium*, which are metabolized by both the kidneys and liver, and *atracurium* and *cis-atracurium*, which undergo breakdown in plasma known as *Hofmann elimination*. The agent with shortest duration is *mivacurium*, the only nondepolarizer that is metabolized by plasma cholinesterase, and like succinylcholine, is subject to the same prolonged blockade in patients with plasma cholinesterase deficiency. All nondepolarizers reversibly bind to the postsynaptic terminal in the neuromuscular junction and prevent acetylcholine from depolarizing the muscle. Muscle blockade occurs without fasciculation and without the subsequent side effects seen with succinylcholine. The most

commonly used agents of this type and their advantages and disadvantages are listed in Table 47-3.

Table 47-3 Advantages and Disadvantages to Common Nondepolarizing Neuromuscular Blocking Agents			
Agent	Duration (h)	Advantages	Disadvantages
Pancuronium	>1	No histamine release	Tachycardia; slow onset; long duration
Vecuronium	<1	No cardiovascular effects	Intermediate onset
Rocuronium	<1	Fast onset; no cardiovascular effects	—
Mivacurium	<1	Fast onset; short duration & histamine release	—

Source: Adapted with permission from Rutter TW, Tremper KK: Anesthesiology and pain management, in Greenfield LJ (ed): *Greenfield's Surgery: Scientific Principles and Practice*, 4th ed. Philadelphia: Lippincott & Williams, 2006, p 452.

The reversal of neuromuscular blockade is not a true reversal of the drug, as with protamine reversal of heparinized patients. Neuromuscular blocking reversal agents, usually neostigmine, edrophonium, or pyridostigmine, increase acetylcholine levels by inhibiting acetylcholinesterase, the enzyme that breaks down acetylcholine. The subsequently increased circulating levels of acetylcholine prevail in the competition for the postsynaptic receptor, and motor function returns. Use of the peripheral nerve stimulator is required to follow depth and reversal of motor blockade, but it is essential to correlate data from the nerve stimulator with clinical signs that indicate return of motor function, including tidal volume, vital capacity, hand grip, and 5-second sustained head lift.

INHALATIONAL AGENTS

Unlike the IV agents, the inhalational agents provide all three characteristics of general anesthesia: unconsciousness, analgesia, and muscle relaxation. However, it would be impractical to use an inhalation-only technique in larger surgical procedures, because the doses required would cause unacceptable side effects, so IV adjuncts such as opioid analgesics and neuromuscular blockers are added to optimize the anesthetic. All inhaled anesthetics display a dose-dependent reduction in mean arterial blood pressure except for nitrous oxide, which maintains or slightly raises the blood pressure. Nitrous oxide, although not potent enough to use alone, provides partial anesthesia and allows a second agent to be used in smaller doses, reducing side effects.

Minimum alveolar concentration (MAC) is a measure of anesthetic potency. It is the ED₅₀ of an inhaled agent (i.e., the dose required to block a response to a painful stimulus in 50% of subjects). The higher the MAC, the less potent an agent is. The potency and speed of induction of inhaled agents correlates with their lipid solubility and is known as the *Meyer-Overton rule*. Nitrous oxide has a low solubility and is a weak anesthetic agent, but has the most rapid onset and offset. The "potent" gases (e.g., desflurane, sevoflurane, enflurane, and halothane) are more soluble in blood than nitrous oxide and can be given in lower concentrations, but have longer induction and emergence characteristics.

Sevoflurane and desflurane are the two most recently introduced inhalational agents in common use. Because of their relatively lower tissue and blood solubility, induction and recovery are more rapid than with isoflurane or enflurane.

All of the potent inhalational agents (e.g., halothane, isoflurane, enflurane, sevoflurane, and desflurane), as well as the depolarizing agent succinylcholine, are triggering agents for MH. Table 47-4 lists the advantages and disadvantages of each agent.

Table 47-4 Advantages and Disadvantages of Common Inhalational Agents			
Agent	MAC (%)	Advantages	Disadvantages
Nitrous oxide	105	Analgesia; minimal cardiac and respiratory depression	Sympathetic stimulation; expansion of closed air space
Halothane	0.75	Effective in low concentrations; minimal airway irritability; inexpensive	Cardiac depression and arrhythmia hepatic necrosis; slow elimination
Enflurane	1.68	Muscle relaxation	Strong smell; seizures
		No effect on cardiac rate or rhythm	

Isoflurane	1.15	Muscle relaxation; no effect on cardiac rate or rhythm	Strong smell
Desflurane	6	Rapid induction and emergence	Coughing; high cost
Sevoflurane	1.71	Rapid induction and emergence; pleasant smell; ideal for mask induction	High cost; metabolized by liver

MAC = minimum alveolar concentration.

ANESTHESIA MANAGEMENT

Preoperative Evaluation and Preparation

The ASA has adopted basic standards for the evaluation of patients before surgery. These standards require the anesthesiologist to determine the medical status of the patient by developing a plan of anesthetic care and to discuss this plan with the patient and/or legal guardian.

The preoperative visit results in a summary of all pertinent findings, including a detailed medical history, current drug therapy, complete physical examination, and laboratory and specific testing results. Based on these findings, the anesthesiologist may find that the patient is not in optimal medical condition to undergo elective surgery. These findings and opinions are then discussed with the patient's primary physician, and the surgery may be delayed or cancelled until the patient's medical condition is further tested and optimized.

The detailed medical history obtained at the preoperative visit should include the patient's previous exposure and experience with anesthesia, as well as any family history of problems with anesthesia. History of atopy (medication, foods, or environmental) is an important aspect of this evaluation in that it may predispose patients to form antibodies against antigens that may be represented by agents administered during the perioperative period. A careful review of major organ systems and their function also should be performed.

The physical examination is targeted primarily at the CNS, cardiovascular system, lungs, and upper airway. Specific areas to investigate are shown in Table 47-5.

Table 47-5 Preoperative Physical Examination			
Central Nervous System	Cardiovascular System	Respiratory System	Oral Airway
Consciousness; neurocognition; peripheral sensory	Blood pressure; standing and sitting, bilateral; peripheral pulses; heart auscultation; heart rate; murmur; rhythm	Auscultation of lungs; wheezes; rales	Cervical spine mobility; visualize uvula; artificial teeth; thyromental distance

Concurrent medications must be fully explored, and adverse interactions with agents administered during the perioperative period need to be considered. However, concurrent medications that produce desired effects (i.e., beta blockade, antihypertensive, and antiasthma medications) can and should be continued throughout the perioperative period; patients should be counseled to continue these medications up to and including the morning of surgery. Careful documentation will allow the anesthesiologist to make informed decisions about the perioperative selection of drugs and therapy as well as monitoring techniques.

Preoperative laboratory data and specific testing for elective surgery should be patient- and situation-specific. Examples include: serum potassium for a patient on diuretics, glucose in a diabetic patient, or hemoglobin concentration in any surgery with a high risk of blood loss. Coagulation tests are not necessary if the patient is not receiving anticoagulants or has no signs or symptoms of abnormal clotting. Otherwise healthy patients usually do not need preoperative laboratory testing, and tests performed within the previous 6 months are usually sufficient.¹⁶ Other tests that should be generated by history and physical examination include chest radiograph if there is

evidence of chest disease, and pulmonary function tests in patients who are morbidly obese, severe asthmatics, or patients undergoing pulmonary resection surgery. An electrocardiogram should be performed in all symptomatic patients, and in asymptomatic men age 45 years or older and asymptomatic women age 50 years or older. Urine pregnancy testing should be performed on the day of surgery in all women of childbearing age.

Risk Assessment

An integral part of the preoperative visit is for the anesthesiologist to assess patient risk. Risk assessment encompasses two major questions: (a) Is the patient in optimal medical condition for surgery? and (b) Are the anticipated benefits of surgery greater than the surgical and anesthetic risks associated with the procedure?

Research into quantifying preoperative factors that correlate with the development of postoperative morbidity and mortality has recently gained great interest. Originally designed as a simple classification of a patient's physical status immediately before surgery, the ASA physical status scale is one of the few prospective scales that correlate with the risk of anesthesia and surgery (Table 47-6).

Table 47-6 American Society of Anesthesiologists Physical Status Classification System	
P1	A normal healthy patient
P2	A patient with mild systemic disease
P3	A patient with severe systemic disease
P4	A patient with severe systemic disease that is a constant threat to life
P5	A moribund patient who is not expected to survive without the operation
P6	A declared brain-dead patient whose organs are being removed for donor purposes

Criticism of the ASA scale is primarily due to its exclusion of age and difficulty of intubation (discussed later in this chapter). Cullen and associates examined 1095 patients undergoing total hip replacement, prostatectomy, or cholecystectomy, and found that both age and ASA scale accurately predicts postoperative morbidity and mortality¹⁷ (Table 47-7). The ASA scale remains useful and should be applied to all patients during the preoperative visit.

Table 47-7 American Society of Anesthesiologists Physical Status and Mortality	
Score	Mortality (%)
P1	0.1
P2	0.2
P3	1.8
P4	7.8
P5	9.4

EVALUATION OF THE AIRWAY

The airway examination is an effort to identify those patients in whom management of the airway and conventional endotracheal intubation may be difficult. It is vitally important to recognize such patients before administering medications that induce apnea.

MALLAMPATI CLASSIFICATION

The amount of the posterior pharynx one can visualize preoperatively is important and correlates with the difficulty of intubation. A large tongue (relative to the size of the mouth) that also interferes with visualization of the larynx on laryngoscopy will obscure visualization of the pharynx. The Mallampati classification (Fig. 47-2, Table 47-8) is based on the structures visualized with maximal mouth opening and

tongue protrusion in the sitting position.

Fig. 47-2.

Table 47-8 Mallampati Classification
Class I: soft palate, fauces, uvula, pillars
Class II: soft palate, fauces, portion of uvula
Class III: soft palate, base of uvula
Class IV: hard palate only

Other predictors of difficult intubation include obesity, immobility of the neck, interincisor distance <4 cm in an adult, a large overbite, or the inability to shift the lower incisors in front of the upper incisors. The thyromental distance [i.e., the distance from the thyroid cartilage to the mentum (tip of the chin)] should be >6.5 to 7 cm.

CONSIDERATION OF PATIENTS WITH COMORBIDITIES

A thorough knowledge of the pathophysiology of concurrent medical conditions regardless of the reason for surgery is essential for optimal perioperative care. Optimal anesthesia extends beyond pharmacology and technical procedures. Specifically, ischemic heart disease, renal dysfunction, pulmonary disease, metabolic and endocrine disorders, CNS diseases, and diseases of the liver and biliary tract can have major impact on the management of anesthesia.

ISCHEMIC HEART DISEASE

Ischemic heart disease is the result of the heart demanding more oxygen (O₂) than its supply can provide. A supply problem may be due to many factors, including hypoxia, anemia, hypotension and coronary artery atherosclerosis, thrombosis, or spasm. Additionally, the problem may be an increase in myocardial O₂ demand (tachycardia). In the vast majority of cases, the most responsible lesion is a reduction in the luminal area of coronary arteries due to atherosclerosis.

An estimated 14 million people in the United States have ischemic heart disease. Of these, as many as 4 million have few or no symptoms and are unaware that they are at risk for angina pectoris, myocardial infarction, or sudden death.

An important goal of the preoperative visit is for the anesthesiologist to ascertain the patient's severity, progression, and functional

limitations induced by ischemic heart disease. Furthermore, this visit can elucidate the possibility of previously undiagnosed ischemic heart disease. A thorough investigation of risk factors for ischemic heart disease is essential during the preoperative visit. The risk of perioperative death due to myocardial infarction in patients without ischemic heart disease is approximately 1%.¹⁸ In contrast, the risk in patients with known or suspected ischemic heart disease is approximately 3%,¹⁸ and in patients undergoing surgery for peripheral vascular disease, the combined risk of death due to cardiac causes is 29%.¹⁹

MAJOR RISK FACTORS FOR CORONARY ARTERY DISEASE

The risk of *hypercholesterolemia* is proportional to the increased serum level of low-density lipoprotein cholesterol. Reduction achieved via decreased dietary fat or pharmacotherapy reduces risk.

Hyperlipidemia may be familial, and thus may account for the fact that a strong family history of premature CAD is a significant risk factor. High-density lipoprotein cholesterol is protective.

Although definitely a risk factor, hypertension alone probably does not cause plaques. Rather, it may act synergistically with hypercholesterolemia by first causing mechanical wall stress and damage.

Smoking causes endothelial damage, and therefore promotes plaque thrombosis. Cessation greatly reduces the risk of CAD.

Diabetes mellitus is a strong independent risk factor. A hypothesis is that glycosylation products cause release of growth factors that stimulate smooth muscle proliferation.

OTHER RISK FACTORS

Hyperhomocysteinemia is becoming an established independent risk factor, but is still under evaluation. Reduction of levels by folate therapy may be beneficial.

Advanced age, male sex, obesity, and a sedentary lifestyle can also put a person at risk for developing ischemic heart disease.²⁰

Drugs used for the medical management of patients with ischemic heart disease should be continued throughout the perioperative period. Withdrawal of an antihypertensive drug or suspension of beta blockade can induce unwanted increases in sympathetic nervous system activity.¹²

Induction of anesthesia in patients with ischemic heart disease can be safely accomplished with a number of IV drugs. As many as 45% of patients have been shown to have myocardial ischemia during the stress of tracheal intubation, and direct laryngoscopy should be used for the shortest time possible to minimize the magnitude of stimulation.²¹

The intraoperative anesthetic technique should allow for the prompt control of hemodynamic variables; the maintenance of the balance between myocardial O₂ delivery and myocardial O₂ demand is probably the single most important factor in managing patients with ischemic heart disease. In this regard, muscle relaxants with minimal to no effects on heart rate and blood pressure, such as vecuronium and rocuronium, are attractive choices for neuromuscular blockade. Additionally, controlled myocardial depression using a volatile anesthetic in patients with a normal left ventricular ejection fraction may help to minimize the stimulation of the sympathetic nervous system and subsequent increases in myocardial O₂ requirements. In patients with impaired left ventricular function, continued myocardial depression with volatile anesthetics may not be tolerated; the addition of short-acting opioids such as fentanyl is beneficial. In cardiac surgical patients, it is not uncommon for high-dose opioids to be used as the predominant anesthetic.

PULMONARY DISEASE

Chronic pulmonary disease has developed into a worldwide public health problem. Chronic obstructive pulmonary disease (COPD), distinguished from asthma that is characterized by reversible airway smooth muscle constriction, is a progressive disease that leads to the destruction of the lung parenchyma.

Infection, noxious particles, and gases can exacerbate COPD. Historically, certain lung function parameters (i.e., significantly abnormal spirometry or arterial blood gas analysis) were once considered contraindications for anesthesia. However, anesthetic techniques have

improved, and it has been shown that patients with severe lung disease can safely undergo anesthesia.²² Zollinger and Pasch found no specific parameters of lung function that were predictive of postoperative lung complications. The highest predictive parameter found was upper abdominal surgery and thoracic surgery.²³

General anesthesia can be performed safely in patients with pulmonary disease.²⁴ Inhaled anesthetics are often used due to their bronchodilating properties.²⁵ Some authors have advocated pretreatment with salbutamol, a long-acting beta agonist, which may prevent bronchoconstriction during anesthetic induction.^{26,27}

Regional and local anesthesia have the benefit of avoiding tracheal irritation and stimulating bronchospasm. However, patients with COPD may become hypoxic while lying strictly supine, and sensory levels of anesthetic above T10 are associated with the impairment of respiratory muscle activity necessary for patients with COPD to maintain adequate ventilation.¹²

Intraoperatively, mechanical ventilation using a slow breathing rate (at eight breaths per minute) should be used to allow for passive exhalation in the presence of increased airway resistance. This slow breathing, facilitated by high inspiratory flow rate, may allow for improved maintenance of normal partial pressure of arterial oxygen (PaO₂) and partial pressure of arterial carbon dioxide (CO₂) levels. Patients should also be well hydrated during the procedure with adequate crystalloid/colloid volume therapy, which may allow for less viscous pulmonary secretions following surgery.

RENAL DISEASE

Five percent of the adult population may have pre-existing renal disease that could contribute to perioperative morbidity.²⁸ In addition, the risk of acute renal failure is increased by certain events or patient characteristics independent of pre-existing renal disease, such as hypovolemia and obstructive vascular disease. Ischemic tubular damage (i.e., acute tubular necrosis) is the most likely cause of acute renal failure in the perioperative period, reflecting events that cause an imbalance of O₂ supply to O₂ demand in the medullary ascending tubular cells.

Virtually all anesthetic drugs and techniques are associated with decreases in renal blood flow, the glomerular filtration rate, and urine output, reflecting multiple mechanisms such as decreased cardiac output, altered autonomic nervous system activity, neuroendocrine changes, and positive pressure ventilation. Renal blood flow (15 to 25% of the cardiac output) far exceeds renal O₂ needs, but ensures optimal clearance of wastes and drugs. Prehydration and the depth of anesthesia may influence the renal response to anesthesia.

Management of anesthesia in patients with chronic renal disease requires attention to intraoperative fluid management and tight control of ventilation, as respiratory alkalosis will shift the oxyhemoglobin dissociation curve, and respiratory acidosis could raise serum potassium to dangerous levels. Because of decreased excretion by the kidney, doses of opioids and neuromuscular blocking agents must be attenuated.

HEPATOBIILIARY DISEASE

Management of anesthesia for the patient with liver disease requires an understanding of the many physiologic functions of the liver: synthesis of albumin and coagulation factors, metabolism of drugs, glucose homeostasis, and the production of bilirubin. Data from the 1970s suggested that approximately 1 in every 700 adult patients who are scheduled for elective surgical procedures has unknown liver disease or is in the prodromal phase of viral hepatitis. Severe hepatic necrosis following surgery and anesthesia is most often due to decreased hepatic O₂ delivery rather than the anesthetic.

Regional anesthesia may be useful in patients with advanced liver disease, assuming coagulation status is acceptable. When general anesthesia is selected, administration of modest doses of volatile anesthetics with or without nitrous oxide or fentanyl often is recommended. Selection of nondepolarizing muscle relaxants should consider clearance mechanisms for these drugs. For example, patients with hepatic cirrhosis may be hypersensitive to mivacurium because of the lowered plasma cholinesterase activity. Perfusion to the liver is maintained by administering fluids (guided by filling pressures) and maintaining adequate systemic pressure and cardiac output.

The coexisting presence of liver disease may influence the selection of volatile anesthetics. Halothane is the anesthetic most studied regarding possible hepatotoxicity. Halothane hepatitis occurs rarely (approximately 1:25,000 patients) and may have an immune-mediated mechanism stimulated by repeated exposures to halothane.²⁹ Halothane, enflurane, isoflurane, and desflurane all yield a reactive oxidative trifluoroacetyl halide and may be cross-reactive, but the magnitude of metabolism of the volatile anesthetics is a probable factor in the ability to cause hepatitis.³⁰ Halothane is metabolized 20%, enflurane 2%, isoflurane 0.2%, and desflurane 0.02%; desflurane probably has the least potential for liver injury. Sevoflurane does not yield any trifluoroacetylated metabolites and is unlikely to cause hepatitis.

An estimated 15 to 20 million adults in the United States have biliary tract disease. Treatment of gallbladder disease by open or laparoscopic cholecystectomy is most often performed with general anesthesia supplemented with muscle relaxants. Complete biliary tract obstruction could interfere with the clearance of some muscle relaxants dependent on liver metabolism, such as vecuronium and pancuronium. Anesthetic considerations for laparoscopic cholecystectomy are similar to those for other laparoscopic procedures. Insufflation of the abdominal cavity with CO₂ results in increased intra-abdominal pressure that may interfere with the ease of ventilation and venous return. During laparoscopic cholecystectomy, placement of the patient in the reverse Trendelenburg position favors movement of abdominal contents away from the operative site and may improve ventilation. However, this position may further interfere with venous return and reduce cardiac output, emphasizing the need to maintain intravascular fluid volume. Mechanical ventilation of the lungs is recommended to ensure adequate ventilation in the presence of increased intra-abdominal pressure and to offset the effects of systemic absorption of CO₂ used during insufflation of the abdominal cavity. High intra-abdominal pressure may increase the risk of passive reflux of gastric contents. Tracheal intubation with a cuffed tube is advised to minimize the risk of pulmonary aspiration.

METABOLIC AND ENDOCRINE DISEASE

Metabolic and endocrine disorders encompass a wide range of diseases. These diseases may be the primary reason for surgery or can exist in patients requiring surgery for other unrelated disorders. Preoperative evaluation of endocrine function consists of relevant medical history, glucose or protein in the urine, vital signs, history of fluctuations in body weight, survey of sexual function, and concomitant medications. The three metabolic and endocrine conditions that are most prevalent in patients undergoing surgery are diabetes mellitus, hypothyroidism, and obesity. The prevalence of all three conditions, either alone or in combination, in the general population has been steadily rising throughout the world for the past 20 to 30 years.^{12,31} The aging population and changes in the diagnostic criteria for diabetes mellitus are sure to continue this trend.^{12,32}

Patients with diabetes are at an increased risk for perioperative myocardial ischemia, stroke, renal dysfunction or failure, and increased mortality.³³ Increased wound infections and impairment of wound healing also is associated with the pre-existence of diabetes in patients undergoing surgery.³⁴

The stress response to surgery is associated with hyperglycemia in nondiabetic patients due to increased secretion of catabolic hormones, and a combination of reduced insulin secretion and increased insulin resistance.^{35,36} Improved glycemic control in diabetic patients undergoing major surgery has been shown to improve perioperative morbidity and mortality; avoidance of hypoglycemia and hyperglycemic events is the standard of care in these patients.^{32,37–39}

Anesthetic techniques in the diabetic patient can modulate the secretion of catabolic hormones.⁴⁰ However, regional anesthesia may carry greater risks to the diabetic patient with autonomic neuropathy, and the hypotension associated with regional anesthesia may be deleterious to the diabetic patient with co-existing CAD.³² There is no evidence that regional anesthesia or general anesthesia, either alone or in combination, offers any benefit to the diabetic surgical patient in terms of morbidity or mortality.³²

Hypothyroidism is a deficiency in the secretion of the thyroid hormones, thyroxine and 3,5',3-triiodothyronine, by the thyroid gland. More than 5 million Americans have this common medical condition, and as many as 10% of women may have some degree of thyroid hormone deficiency. Controlled clinical trials have not shown an increase in risk when patients with mild to moderate hypothyroidism undergo surgery.⁴¹ Nevertheless, close monitoring of these patients for adverse effects of anesthesia, including delayed gastric emptying, adrenal insufficiency, and hypovolemia, is warranted.⁴²

The prevalence of significant obesity continues to rise both in developed and developing countries and is associated with an increased incidence of a wide spectrum of medical and surgical pathologies⁴³ (Table 47-9). In the United States, one-third of people have a body weight more than 20% above their ideal weight.⁴⁴ Body mass index (BMI) is calculated by dividing the weight in kilograms by the square of the height in meters. In the United States, the prevalence of a BMI >25 kg/m² is 59.4% for men, 50.7% for women, and 54.9% for adults overall. Patients with a BMI >28 have increased perioperative morbidity over the general population.

Table 47-9 Disease Conditions Associated with Obesity	
Category	Examples
Cardiovascular disease	Sudden death, cardiomyopathy, hypertension, coronary artery disease, peripheral vascular disease
Respiratory disease	Restrictive lung disease, sleep apnea
Endocrine disease	Diabetes mellitus, hypothyroidism
GI disease	Hernia, gallstones
Malignancy	Breast, prostate, colorectal cancer
Musculoskeletal	Osteoarthritis, back pain

Source: Reproduced with permission from Adams JP, Murphy PG: Obesity in anaesthesia and intensive care. *Br J Anaesth* 85:91, 2000. By permission of Oxford University Press.

Anesthetic management of the obese patient is problematic, and tasks such as establishing IV access, applying monitoring equipment, managing the airway, and transporting the patient are more difficult. Ventilation may be a particular problem because of obstructive sleep apnea or because obesity itself imposes a restrictive ventilatory state with decreased expiratory reserve and vital capacity.¹² Induction of anesthesia is particularly challenging in the obese patient, as there is increased risk of pulmonary aspiration, and the increased mass of soft tissue about the head and neck make establishing and maintaining a patent airway difficult.

The impact of obesity on the pharmacokinetics of anesthetic drugs is variable. For example, blood volume is often increased in obese patients, which can decrease predicted concentrations of drugs, but adipose tissue has low blood flow, which could elevate blood concentrations of these agents. It is prudent to calculate the first dose of anesthetic based on ideal body weight, and base subsequent dosages on the patient's responsiveness.^{12,45}

CENTRAL NERVOUS SYSTEM DISEASE

Diseases of the CNS present unique situations for the anesthesiologist and require an understanding of the relationship between intracranial pressure (ICP), cerebral blood flow (CBF), and cerebral metabolic rate of O₂ consumption (CMRO₂). Preoperative assessment of ICP is difficult, as symptoms of headache, nausea, and vomiting are nonspecific, and signs of retinal changes do not occur acutely. A midline shift on computed tomography scanning or magnetic resonance imaging may indicate an expanding lesion in the brain.

Provision of anesthesia for intracranial procedures must balance hemodynamic factors such as fluid volume, mean arterial pressure, ICP, and CBF. For intracranial tumors, the mass effect of the tumor makes control of ICP and CBF critical. In intracranial aneurysm surgery, the goal of the anesthetic is to prevent sudden increases in systemic blood pressure that could rupture the aneurysm, especially during the stress of laryngoscopy and endotracheal intubation.

The relationship between mean arterial pressure, ICP, and CBF is affected by pharmacologic agents. Inhalational agents in high concentrations (>0.6 MAC) cause dilation of the cerebral vasculature, decreasing cerebral vascular resistance. CBF is therefore increased in a dose-dependent fashion, despite decreases in CMRO₂.¹²

Propofol decreases CBF, ICP, and CMRO₂.⁴⁶ Propofol may also decrease systemic blood pressure, resulting in a decrease in cerebral perfusion pressure; however, propofol does not alter the autoregulation of CBF.⁴⁷ Etomidate is a potent cerebral vasoconstrictor that reduces CBF and ICP and should be used with caution in patients with epilepsy due to its excitatory effects seen on electroencephalograms.⁴⁸

Opioids decrease CBF and may also decrease ICP under certain conditions. However, Sperry and associates have reported increases in ICP with the administration of fentanyl in head trauma patients.⁴⁹ Additionally, opioids have a depressant effect on consciousness and ventilation that may increase ICP if accompanied by an increase in partial pressure of arterial CO₂; opioids should be used with caution in head trauma patients.

Regardless of the drugs or technique selected, maintenance of stable hemodynamics is optimal. Recovery from anesthesia should be smooth, avoiding pain, coughing, and straining, all of which can increase blood pressure and ICP and cause bleeding at the surgical site.

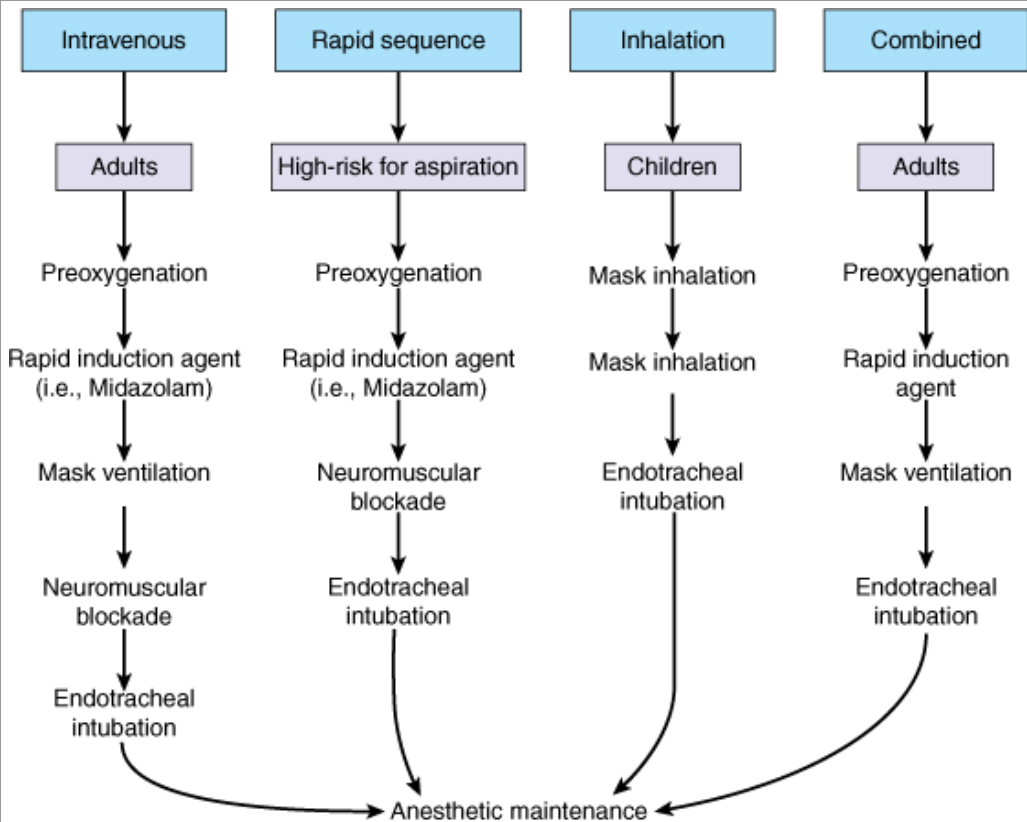

Fluid therapy can increase cerebral edema and ICP when administered in large quantities, resulting in hypervolemia. Euvolemia should be the goal in head trauma patients, while hypervolemia may be beneficial for patients with intracranial aneurysms, to reduce vasospasm.

INTRAOPERATIVE MANAGEMENT

Induction of General Anesthesia

During induction of anesthesia, the patient becomes unconscious and rapidly apneic, myocardial function is usually depressed, and vascular tone abruptly changes. The induction of general anesthesia is the most critical component of practicing anesthesia, as the majority of catastrophic anesthetic complications occur during this phase. There are several different techniques used for the induction of general anesthesia, each with significant advantages and disadvantages (Fig. 47-3). Each patient must be carefully evaluated during the preoperative period to ensure that the most efficacious and safe technique is used.

Fig. 47-3.

Techniques for the induction of general anesthesia.

IV induction, used primarily in adults, is smooth and is associated with a high level of patient satisfaction. The addition of opioids will blunt the response of laryngoscopy and intubation to avoid hypertension and tachycardia.

In a patient with a full stomach, the standard induction technique may result in vomiting and pulmonary aspiration of stomach contents. The goal of *rapid sequence induction* is to achieve secure protection of the airway with a cuffed endotracheal tube while preventing vomiting and aspiration.

Rapid sequence induction is performed as follows:

Proceed only after evaluation of the airway predicts an uncomplicated intubation.

Preoxygenate the patient.

Rapidly introduce an IV induction agent (e.g., propofol).

An assistant to the anesthesiologist presses firmly down on the cricoid cartilage to block any gastric contents from being regurgitated into the trachea, and

A muscle relaxant is injected, and the trachea is quickly intubated. The assistant is instructed not to release pressure on the cricoid cartilage until the cuff of the endotracheal tube is inflated and the position of the tube is confirmed.

Patients undergoing *inhalation induction* progress through three stages: (a) awake, (b) excitement, and (c) surgical level of anesthesia. Adult patients are not good candidates for this type of induction, as the smell of the inhalation agent is unpleasant and the excitement stage can last for several minutes, which may cause hypertension, tachycardia, laryngospasm, vomiting, and aspiration. Children, however, progress through stage 2 quickly and are highly motivated for inhalation induction as an alternative to the IV route. The benefit of postinduction IV cannulation is the avoidance of many presurgical anxieties, and inhalation induction is the most common technique for pediatric surgery.

Management of the Airway

After induction of anesthesia, the airway may be managed in several ways, including by face mask, with a laryngeal mask airway (LMA), or, most definitively, by endotracheal intubation with a cuffed endotracheal tube. Nasal and oral airways can help establish a patent airway in a patient being ventilated with a mask by creating an air passage behind the tongue (Fig. 47-4).

Fig. 47-4.

NASAL AIRWAYS

ORAL AIRWAYS

From left to right: two nasal airways and three oral airways.

The LMA is a cuffed oral airway that sits in the oropharynx. It is passed blindly, and the cuff is inflated to push the soft tissues away from the laryngeal inlet. Because it does not pass through the vocal cords, it does not fully protect against aspiration. It should not be used in patients with a full stomach (Fig. 47-5; lower left).

(Top) Laryngoscopes with curved straight blades; (Bottom) laryngomask airway, intubating laryngomask airway, and Bullard rigid fiberoptic laryngoscope.

The accurate placement of an endotracheal tube requires skill and proper equipment and conditions. Usually, the patient is unconscious and immobile (including paralysis of the muscles of respiration). Intubation is typically performed under direct visualization by looking through the mouth with a laryngoscope directly at the vocal cords (direct laryngoscopy), and watching the endotracheal tube pass through the cords into the trachea. To obtain a direct line of sight, the patient is placed in the sniffing position. The neck is flexed at the lower cervical spine and extended at the atlanto-occipital joint. This flexion and extension are amplified during laryngoscopy.

Laryngoscope handles contain batteries and can be fitted with curved (Macintosh) or straight (Miller) blades (see Fig. 47-5, top row).

Some patients have physical characteristics or a history suggesting difficulty in placing an endotracheal tube. A short neck, limited neck mobility, small interincisor distance, short thyromental distance, and Mallampati class IV may all represent a challenge to endotracheal intubation. Several devices have been developed to assist in management of the difficult airway. The Bullard rigid fiberoptic laryngoscope is a self-contained device that can be passed through a mouth with a narrow opening (Fig. 47-6). The head and neck also can be kept in a neutral position, as a direct line of sight needed with a standard laryngoscope is not necessary. Another new intubating device is the Glide scope, which allows visualization of the vocal cords on a screen (Fig. 47-7).

Video laryngoscope.

The intubating laryngeal mask airway (ILMA) is an advanced form of LMA designed to maintain a patent airway as well as facilitate tracheal intubation with an endotracheal tube. The ILMA can be placed in anticipated or unexpectedly difficult airways as an airway rescue device and as a guide for intubating the trachea. An endotracheal tube can be passed blindly through the ILMA into the larynx, or

the ILMA can be used as a conduit for a flexible fiberoptic scope (Fig. 47-8).

Intubating laryngeal mask airway with endotracheal tube.

The flexible fiberoptic intubation scope is the gold standard for difficult intubation. It is indicated in difficult or compromised airways where neck extension is not desirable, or in cases with risk of dental damage. The scope is constructed of fiberoptic bundles and cables encased in a sheath. The cables permit manipulation of the tip of the scope by adjustments made at the operating end of the device. There is a port for suction and/or insufflation of O₂. The scope gives excellent visualization of the airway with minimal hemodynamic stress when used properly. It can be used nasally or orally in an awake, spontaneously ventilating patient, whose airway has been treated with topical anesthetic. It requires skill for proper use, is expensive, and requires careful maintenance (Fig. 47-9).

Fluid Therapy

Numerous preparations of IV fluid are available for the replacement of perioperative fluid losses in patients undergoing surgery. Different fluid preparations may influence clinical parameters (e.g., platelet function) and may also affect postoperative outcome.

Traditionally, IV fluids have been classified according to whether they are crystalloid or colloid in nature. *Crystalloid fluids* comprise electrolyte solutions with or without a bicarbonate precursor such as acetate or lactate. The *colloids* contain a complex sugar or protein suspended in an electrolyte solution. A further distinction between IV fluid types may be based on the nature of the solution. Normal saline-based (0.9% sodium chloride) preparations (crystalloid or colloid) contain no electrolytes other than sodium and chloride. In contrast, balanced salt-based fluids such as lactated Ringer's solution contain other electrolytes, with or without a bicarbonate precursor.

Several types of colloids are available, but three are most commonly used—hydroxyethyl starch (HES), gelatin, and albumin. The HES preparations differ from one another according to their concentration, molecular weight, and extent of hydroxyethylation or substitution, with resultant varying physiochemical properties. HES solutions most often are described according to their weight-averaged mean molecular weight in kilodaltons (kDa): high-molecular-weight (450 kDa), middle-molecular-weight (200 kDa, 270 kDa), and low-molecular-weight (130 kDa, 70 kDa). HES 450 kDa solutions are available in a normal saline solution (HES 450/NS) and in a lactated, balanced salt solution (HES 450/BS). Although all of these colloids are used in Europe, gelatins are not available in the United States, and the only HES preparations approved by the U.S. Food and Drug Administration are the 6% high-molecular-weight (450 kDa) formulations.

The administration of a large volume of any type of IV fluid will cause dilution of platelets and coagulation factors and may lead to coagulopathy (i.e., dilutional coagulopathy). In addition, fluids can have a direct impact on blood clotting through effects on circulating

components of the coagulation cascade or by altering platelet function.

Recent evidence suggests that the nature of the solution itself may influence coagulation and bleeding. HES 450/NS may be associated with more bleeding than other fluids. HES 450 in a balanced salt solution appears to be equivalent to 5% albumin with respect to bleeding outcomes.^{51–53} Waters and colleagues reported that patients undergoing abdominal aortic aneurysm repair who received lactated Ringer's solution received smaller volumes of platelets and had less blood product exposure than those treated with normal saline.⁵⁴

It is possible that certain fluids may induce hypercoagulability that may be reflected not only by less bleeding, but also by an increased incidence of postoperative thrombotic complications (e.g., deep vein thrombosis and cerebrovascular accident). There are laboratory data⁵⁵ to suggest that IV fluid administration may induce a hypercoagulable state, but the clinical significance of this remains unclear.

The type of fluid administered intraoperatively to a patient can have a significant impact on renal function. The administration of HES/NS or normal saline to critically ill patients or elderly patients undergoing major surgery was associated with the development of renal dysfunction.^{56–58}

The administration of adequate IV fluids during the perioperative period results in a lower incidence of nausea, vomiting, and antiemetic use after minor or day case surgery.⁵⁹ In major noncardiac surgical patients, the administration of HES 450 (in a BS or NS solution, or a combination of balanced crystalloid and colloid) has been associated with less postoperative nausea, vomiting, and antiemetic use, and earlier return of postoperative bowel function as reflected by first consumption of solid food, than the administration of 5% albumin, lactated Ringer's solution, or normal saline alone.⁶⁰

Studies of patients undergoing ambulatory surgery have shown that perioperative IV fluid administration decreases the incidence of dizziness, drowsiness, thirst, and headache.⁶¹ In a randomized crossover study of healthy volunteers, subjective deterioration in mental status (lassitude and difficulty in abstract thinking) was reported only by individuals who received 0.9% sodium chloride, and not by those who received lactated Ringer's solution.⁶² The possible effect of different IV fluid preparations on CNS function has not yet been fully explored.

The relative impact of crystalloids and/or colloids on pulmonary function has been the subject of long-standing debate. No difference in postoperative pulmonary function was seen in cardiac surgery patients, orthopedic patients, or urologic surgery patients treated intraoperatively with different colloids.^{56,63,64} In a number of studies in major surgical patients that compared crystalloid (lactated Ringer's solution) with colloid (HES 130/NS, HES 450/NS, 5% albumin/BS),^{65–67} no difference was seen in the incidence or duration of mechanical ventilation or other indices of respiratory function. These findings suggest that the intraoperative administration of crystalloids does not have a detrimental effect on pulmonary function compared with the administration of colloids.

Transfusion of Red Blood Cells

ABO BLOOD GROUPS

There are four different ABO groups, which are determined by whether or not an individual's red blood cells (RBCs) carry the A antigen, the B antigen, both A and B, or neither. From early in childhood, normal healthy individuals make antibodies against A or B antigens that are not expressed on their own cells. People who are group A have anti-B antibodies in their plasma, people who are group B have anti-A antibodies, people who are group O have anti-A and anti-B antibodies, and people who are group AB have neither of these antibodies. These naturally occurring antibodies are mainly immunoglobulin M that attack and rapidly destroy RBCs. Anti-A antibodies attack RBCs of group A (or AB), and anti-B antibodies attack RBCs of group B (or AB).

ABO-INCOMPATIBLE RED CELL TRANSFUSION

If RBCs of the wrong group are transfused, in particular if group A RBCs are infused into a recipient who is group O, the recipient's anti-A antibodies bind to the transfused cells. This activates the complement pathways, which damages the red cell membranes and lyses the RBCs. Hb released from the damaged RBCs is toxic to the kidneys, while the fragments of ruptured cell membranes activate the blood-

clotting pathways. The patient suffers acute renal failure and disseminated intravascular coagulation.

BASICS OF RED BLOOD CELL COMPATIBILITY

Ensuring that the right blood group is transfused is imperative. It is essential to ensure that no ABO-incompatible RBC transfusion is ever given. This avoidable accident is likely to kill or harm the patient.

Procedures in which compatibility is determined by establishing both transfusion recipient and donor blood ABO types via crossmatch analysis have evolved over years of clinical and laboratory experience to minimize the risk of this disastrous error. These procedures will continue to evolve as improved computerized systems are introduced to help staff avoid errors in blood administration.

Rhesus D Antigen and Antibody

In a white population, about 15% will lack the Rhesus D (Rh D) antigen, and are termed *Rh D negative*. Antibodies to Rh D antigen occur only in individuals who are Rh D negative, and as a consequence of transfusion or pregnancy. Even small amounts of Rh D positive cells entering the circulation of an Rh D negative person can stimulate the production of antibodies to Rh D, usually immunoglobulin G.

PHYSIOLOGIC RESPONSE AND TOLERANCE OF ANEMIA

O₂ is carried in blood in two distinct forms: bound to Hb within the RBC and dissolved in the plasma. The actual oxygen content of arterial blood (CaO₂) is determined by the concentration of Hb in the blood, the arterial oxygen saturation of Hb (SaO₂), the O₂-binding capacity of Hb, the PaO₂, and the O₂ solubility of plasma. These variables are interrelated and can be expressed in the following equation:

$$\text{CaO}_2 = (\text{Hb} \times \text{SaO}_2 \times \text{Hb O}_2 \text{ binding capacity}) + (\text{PaO}_2 \times \text{plasma O}_2 \text{ solubility}).$$

Adult Hb consists of four protein chains, each carrying one heme group. One mole of Hb is able to bind to a maximum of 4 moles of O₂. O₂-binding capacity per gram of Hb is 1.39 g/mL. The relationship between PaO₂ and Hb O₂ saturation is shown in Fig. 47-12. The steep part of this curve [partial pressure of oxygen (PO₂) 20 to 40 mmHg] facilitates O₂ release from Hb. Tissue PO₂ values of different organs are also shown in Fig. 47-12 and lie on this steep part of the curve, facilitating O₂ release from Hb.

Fig. 47-12.

Oxygen hemoglobin dissociation curve. O₂ = oxygen; PO₂ = partial pressure of oxygen.

Mild anemia is compensated by a shift in the Hb-O₂ dissociation curve. The impact of more severe anemia may be physiologically modulated by an increase in cardiac output, which will increase tissue perfusion and cause a decrease in peripheral vascular resistance and decreases in whole blood viscosity.^{68,69}

Anemia not only decreases the O₂ content of blood but also decreases blood viscosity, promoting an increase in regional blood flow. Moreover, this increase in blood flow augments the perfused capillary area by an increase in filling pressures and microvasculature vasodilation that results in an increase in O₂ uptake by the tissue beds.⁷⁰ The effects of blood transfusion on O₂ uptake are not as optimal as increasing blood flow, because the rise in hematocrit increases blood viscosity, which alters regional microvascular blood flow (i.e., perfusion).⁵⁵

In normal animals undergoing acute hemodilution, cardiovascular function is maintained until the Hb level reaches between 3 and 5 g/dL, at which point ischemic changes then begin to appear on endocardial electrocardiogram leads (i.e., ST-segment changes).^{71,72}

HEMODILUTION AND CRITICAL HEMATOCRIT

The intentional dilution of blood volume often is referred to as *acute normovolemic hemodilution (ANH) anemia*. ANH is a technique in which whole blood is removed from a patient, while the circulating blood volume is maintained with acellular fluid. Blood is collected via central lines with simultaneous infusion of crystalloid or colloid solutions. Collected blood is reinfused after major blood loss has ceased, or sooner, if indicated. Blood units are reinfused in the reverse order of collection.

Under conditions of ANH, the increased plasma compartment becomes an important source of O₂, which is delivered to the tissues. Oxygenation is maintained by increased cardiac output and increased O₂ extraction by the tissues, and when these compensatory mechanisms fail to match the O₂ needs of the tissues, the "critical hematocrit" is said to have been reached. The critical hematocrit has been a source of debate for many years. A theoretical model was developed that describes the relation between hematocrit, myocardial O₂ demand, and the required coronary blood flow during progressive hemodilution.⁷³ Using this model, the determinants of critical hematocrit and the limits of ANH can be calculated based on the limits of coronary reserve. Because the critical hematocrit varies with

O₂ consumption and degree of CAD, a fixed critical hematocrit as a transfusion trigger is not appropriate in most patients. Rather, the indication for blood transfusions must individually take into account the specific circumstances of the patient, such as expected blood loss and required O₂ transport capacity reserves, hemodynamic stability, CAD, and systemic O₂ consumption.

RECOVERY FROM ANESTHESIA

Reversal of Neuromuscular Blockade

The elimination of neuromuscular blocking agents from the body and subsequent resumption of neuromuscular transmission takes a considerable amount of time, even with drugs such as vecuronium that have relatively short half-lives. Additionally, it is time consuming to wait for complete spontaneous recovery at the end of a surgical procedure. Therefore, it has become routine to antagonize the neuromuscular block pharmacologically with the use of reversal agents. Reversal agents raise the concentration of the neurotransmitter acetylcholine to a higher level than that of the neuromuscular blocking agent. This is accomplished by the use of anticholinesterase agents, which reduce the breakdown of acetylcholine. The most commonly used agents are neostigmine, pyridostigmine, and edrophonium.

The common side effects of these three anticholinesterase agents are bradycardia, bronchial and intestinal smooth muscle contractions, and excessive secretions from salivary and bronchial glands. These effects are primarily mediated by effects on muscarinic receptors, which are effectively blocked by the concomitant use of antimuscarinic drugs such as atropine or glycopyrrolate. To ensure adequate ventilation postoperatively, it is important that the neuromuscular blocking agents are fully reversed, as assessed by monitoring twitch strength with a nerve stimulator and clinically correlating this with signs such as grip strength or 5-second head lift.

The Postanesthesia Care Unit

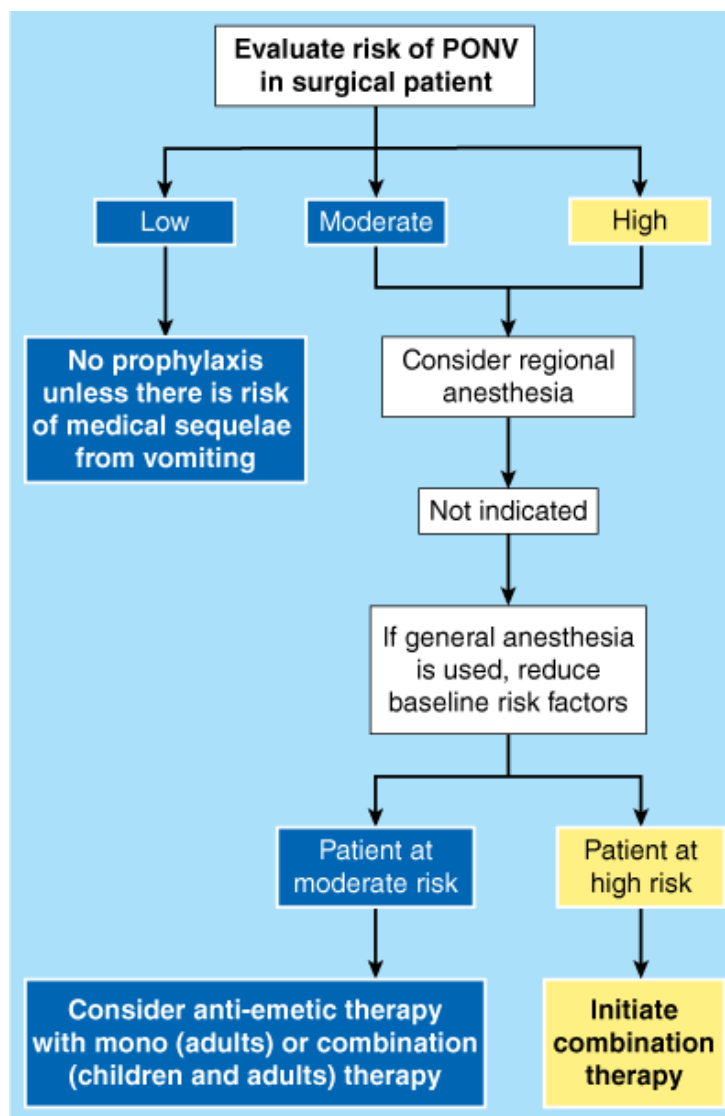

It is of primary importance that all patients awakening from anesthesia are followed in a recovery room, as approximately 10% of all anesthetic accidents occur in the recovery period. As more serious surgeries are performed on older and sicker patients, the number of patients requiring postoperative ventilation and medications to support their circulation increases with age. The new trend for postoperative pain control with continuous epidural administration of local anesthetics and narcotics demands close observation, because respiratory depression can occur. In most hospitals, the number of intensive care beds is too small to accommodate the increasing number of these patients. What originally began as the recovery room now must function as an intensive care unit setting for short stays. The name "recovery room" has been changed to postanesthetic care unit (PACU).

A variety of physiologic disorders that can affect different organ systems need to be diagnosed and treated in the PACU during emergence from anesthesia and surgery. Postoperative nausea and vomiting (PONV), airway support, and hypotension requiring pharmacologic support have been observed to be the most frequent complications in the PACU.⁷⁴ However, abnormal bleeding, hypertension, dysrhythmia, myocardial infarction, and altered mental status are not uncommon.⁷⁴

Postoperative Nausea and Vomiting

PONV typically occurs in 20 to 30% of surgical cases,⁷⁵ with considerable variation in frequency reported between studies (range 8 to 92%).⁷⁶ PONV is generally considered a transient, unpleasant event carrying little long-term morbidity; however, aspiration of emesis, gastric bleeding, and wound hematomas may occur with protracted or vigorous retching or vomiting. Troublesome PONV can prolong recovery room stay and hospitalization, and is one of the most common causes of hospital admission following ambulatory surgery. Published evidence suggests that prophylactic administration of antiemetics is not cost-effective in the surgical setting.⁷⁷ Recent consensus guidelines using data from systematic reviews, randomized trials and studies, and data from logistic regression models have been published.⁷⁷ An algorithm showing these guidelines is shown in Fig. 47-13.

Algorithm for the management of postoperative nausea and vomiting (PONV).

(Reproduced with permission from Gan TJ, Meyer T, Apfel CC, et al: Consensus guidelines for managing postoperative nausea and vomiting. *Anesth Analg* 97:62, 2003.)

Agents usually administered for PONV are the serotonin receptor antagonists ondansetron, dolasetron, granisetron, and tropisetron. The safety and efficacy of the compounds, when given at the end of surgery, are virtually identical.^{77,78} Metoclopramide, when used in the standard dose of 10 mg, is ineffective for PONV.⁷⁹ Although some studies have shown higher doses (20 mg) to have some effect on PONV, most evidence suggests that the serotonin receptor antagonists are the most efficacious choice.

Pain: The Fifth Vital Sign

Analgesic research methodology has been enhanced since the 1960s through the use of graduated and visual analog scales, tools that permit the standardization of pain scores. One frequently used graduated scale is a four-point measure of pain intensity (0 = no pain, 1 = mild pain, 2 = moderate pain, and 3 = severe pain) and a five-point measure of relief (0 = no relief, 1 = a little relief, 2 = some relief, 3 = a lot of relief, and 4 = complete relief).

Acute postoperative pain and its treatment (or prophylaxis) are significant challenges for the health care professional. Despite the recent development of new nonnarcotic analgesics and a better understanding of the side effects associated with pain medication of all types, acute postoperative pain remains a significant concern for patients and represents an extremely negative experience for patients

undergoing surgery. Many patients experience pain in the postoperative period despite the use of potent techniques such as patient-controlled analgesia, epidural analgesia, and regional anesthesia. The culture of acceptance of postoperative pain is changing. The American Pain Society has advocated the assessment of pain as the fifth vital sign, along with temperature, pulse, blood pressure, and respiratory rate. The four vital signs provide a quick snapshot of a patient's general condition, but pain management advocates claim the picture is not complete without including pain as the fifth vital sign. This approach may improve the efficacy of pain treatment. Many departments of anesthesiology support an active pain service and provide consultation for postoperative pain relief, including the administration of nerve blocks (Fig. 47-14).

Popliteal ultrasound.

MALIGNANT HYPERTHERMIA

MH is a life-threatening, acute disorder, developing during or after general anesthesia. The clinical incidence of MH is about 1:12,000 in children and 1:40,000 in adults. A genetic predisposition and one or more triggering agents are necessary to evoke MH. Triggering agents include all volatile anesthetics (e.g., halothane, enflurane, isoflurane, sevoflurane, and desflurane), and the depolarizing muscle relaxant succinylcholine. Volatile anesthetics and/or succinylcholine cause a rise in the myoplasmic calcium concentration in susceptible patients, resulting in persistent muscle contraction. The classic MH crisis entails a hypermetabolic state, tachycardia, and the elevation of end-tidal CO₂ in the face of constant minute ventilation. Respiratory and metabolic acidosis and muscle rigidity follow, as well as rhabdomyolysis, arrhythmias, hyperkalemia, and sudden cardiac arrest. A rise in temperature is often a late sign of MH.

Treatment must be aggressive and begin as soon as a case of MH is suspected:

- Call for help.

- Stop all volatile anesthetics and give 100% O₂.

- Hyperventilate the patient up to three times the calculated minute volume.

- Begin infusion of dantrolene sodium, 2.5 mg/kg IV. Repeat as necessary, titrating to clinical signs of MH. Continue dantrolene for at least 24 hours after the episode begins.

Give bicarbonate to treat acidosis if dantrolene is ineffective.

Treat hyperkalemia with insulin, glucose, and calcium.

Avoid calcium channel blockers

Continue to monitor core temperature.

Call the MH hotline to report the case and get advice: 1-888-274-7899.

FUTURE DIRECTION OF ANESTHESIA

The general mantra of "gene therapy is the future of medicine" must be more specifically related to how those genes create, shape, and regulate proteins. The study of how proteins manifest their activity and/or concentration, is called *proteomics* (from proteome—a fusion of "protein" and "genome").

As the technology advances to biologically identify individual proteins, studies of individual levels of proteomes will allow the study of disease processes on the molecular level, directly aiding diagnosis and therapeutics.⁸¹

Specifically to the field of anesthesiology, the technology of proteomics will be used to elucidate the actual mechanism of action of our anesthetic drugs and how these drugs have differing effects on different individuals. There will be a day when a buccal swab in the preoperative clinic will become routine; the results telling us which opioids carry the fewest side effects for that particular patient, for example, or which antiemetics are most effective, or which postoperative analgesics to use—a tailored anesthetic. Recent studies in mice have examined the $\alpha 5$ subunit of the GABA receptor, which appears to regulate memory. The human genome is polymorphic for the $\alpha 5$ gene; because each variant may manifest in different amounts of memory/amnesia, proteomics may someday lead to tests that determine the propensity of a particular patient to experience awareness and allow us to tailor the anesthetic even further.⁸²

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 48. Ethics, Palliative Care, and Care at the End of Life >

KEY POINTS

1. The physician should document that the patient or surrogate has the capacity to make a medical decision.
2. The physician discloses to the patient details regarding the diagnosis and treatment options sufficient for the patient to make an informed consent.
3. Living wills are written to anticipate treatment options and choices in the event that a patient is rendered incompetent by a terminal illness.
4. The durable power of attorney for health care identifies surrogate decision makers and invests them with the authority to make health care decisions on a patient's behalf in the event that patients are unable to speak for themselves.
5. Surgeons should encourage their patients to clearly identify their surrogates early in the course of treatment.
6. Seven requirements for the ethical conduct of clinical trials have been articulated: value, scientific validity, fair subject selection, favorable risk-benefit ratio, independent review, informed consent, and respect for enrolled subjects.
7. The Association of American Medical Colleges stresses three key points regarding potential conflict of interest: full disclosure, aggressive monitoring, and misconduct management.
8. Disclosure of error is consistent with recent ethical advances in medicine toward more openness with patients and the involvement of patients in their care.

WHY ETHICS MATTER

Dedicated to the advancement of surgery along its scientific and moral side.

June 10, 1926, dedication on the Murphy Auditorium, the first home of the American College of Surgeons

Ethical concerns involve not only the interests of patients, but also the interests of surgeons and society. Surgeons choose among the options available to them because they have particular opinions regarding what would be good (or bad) for their patients. Aristotle described practical wisdom (Greek: *phronesis*) as the capacity to choose the best option from among several imperfect alternatives (Fig. 48-1).¹ Frequently, surgeons are confronted with clinical or interpersonal situations in which there is incomplete information, uncertain outcomes, and/or complex personal and familial relationships. The capacity to choose wisely in such circumstances is the challenge of surgical practice.

Fig. 48-1.

DEFINITIONS

Biomedical ethics is the system of analysis and deliberation dedicated to guiding surgeons toward the "good" in the practice of surgery. One of the most influential ethical "systems" in the field of biomedical ethics is the principlist approach as articulated by Beauchamp and Childress.² In this approach to ethical issues, moral dilemmas are deliberated by using four guiding principles: autonomy, beneficence, nonmaleficence, and justice.²

The principle of autonomy respects the capacity of individuals to choose their own destiny, and it implies a right for individuals to make those choices. It also implies an obligation for physicians to permit patients to make autonomous choices about their medical care. Beneficence requires that proposed actions aim at and achieve something good whereas nonmaleficence aims at avoiding concrete harm: *primum non nocere*.^{*} Justice requires a fairness where both the benefits and burdens of a particular action are distributed equitably.

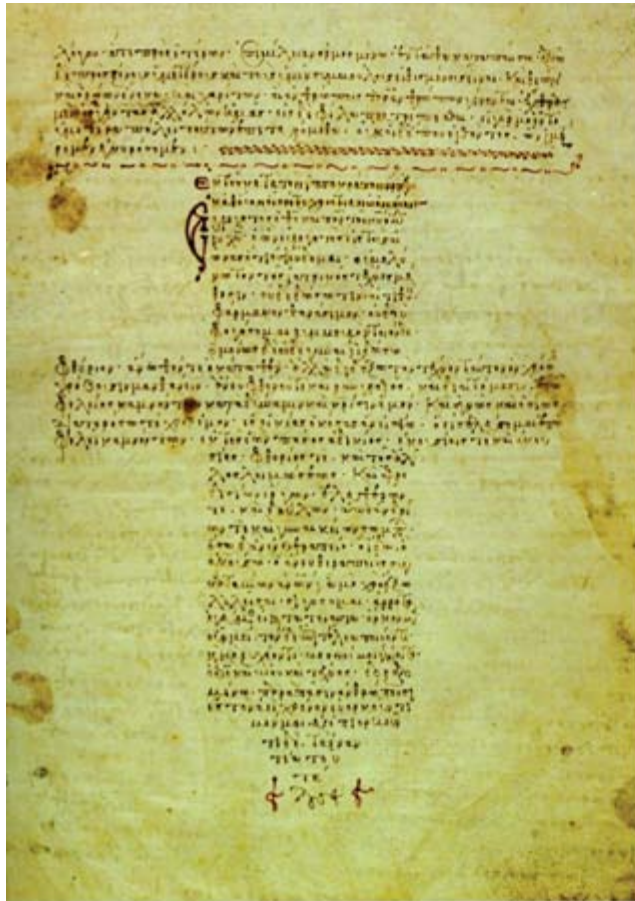

^{*}"First do no harm."

BIOMEDICAL ETHICS: AN OVERVIEW

The history of medical ethics has its origins in antiquity. The Hippocratic Oath along with other professional codes has guided

the actions of physicians for thousands of years (Fig. 48-2). The modern practice of medicine is therefore rooted in the Hippocratic tradition, but the growing technical powers of modern medicine raise new questions that were inconceivable in previous generations. Life support, dialysis, and modern drugs, as well as organ and cellular transplantation, have engendered new moral and ethical dilemmas. As such, the ethical challenges faced by the surgeon have become more complex and require greater attention.

Twelfth-century Byzantine manuscript. The Hippocratic oath was written out in the form of a cross from the Folio Biblioteca Vaticana.

[From <http://en.wikipedia.org/wiki/File:HippocraticOath.jpg>: Rutkow IM: *Surgery: An Illustrated History* 1993, p 27, from Wikipedia (accessed March 8, 2009).]

The case-based paradigm for bioethics is used when a difficult clinical situation confronts the clinical team and questions with apparently conflicting values or principles are raised (Fig. 48-3). The first step is to clarify the relevant principles (e.g., autonomy, beneficence, nonmaleficence, and justice) and values (e.g., self-determination, quality of life, etc.) at stake. After identifying the principles and values that are affecting the situation, a proposed course of action is considered given the circumstances.

The four principles of the care-based paradigm.

Much of the discourse in bioethics adopts this "principlist" approach in which the relevant principles are identified, weighted and balanced, and then applied to formulate a course of action. This approach to bioethics is a powerful technique for thinking through moral problems, as the four principles define the dimensions of the ethical dilemma and provide a means for assessing the impact or extent of each value and principle at stake.

The concept of *virtue ethics* was born with Socrates (Fig. 48-4) and raised in Plato's *Republic* where the four cardinal virtues of courage, justice, temperance, and practical wisdom are discussed.³⁻⁵ Practical wisdom is developed and acquired through experience. As such, the apprenticeship model of surgical residency teaches much more than technical mastery but moral training as well. In fact, the sociologist Charles Bosk argues that the "postgraduate training of surgeons is above all things an ethical training."⁶

SPECIFIC ISSUES IN SURGICAL ETHICS

Informed Consent

Although a relatively recent development, the doctrine of informed consent is one of the most widely established tenets of modern biomedical ethics. During the nineteenth and early twentieth centuries, most physicians practiced a form of benign paternalism whereby patients were rarely involved in the decision-making process regarding their medical care, relying instead on the beneficence of the physician. Consensus among the wider public eventually changed such that surgeons are now expected to have an open discussion about diagnosis and treatment with the patient to obtain informed consent. In the United States, the legal doctrine of *simple* consent dates from the 1914 decision in *Schloendorff v The Society of New York Hospital* regarding a case in which a surgeon removed a diseased uterus after the patient had consented to an examination under anesthesia, but with the express stipulation that no operative excision should be performed. The physician argued that his decision was justified by the beneficent obligation to avoid the risks of a second anesthetic. However, Justice Benjamin Cardozo stated:

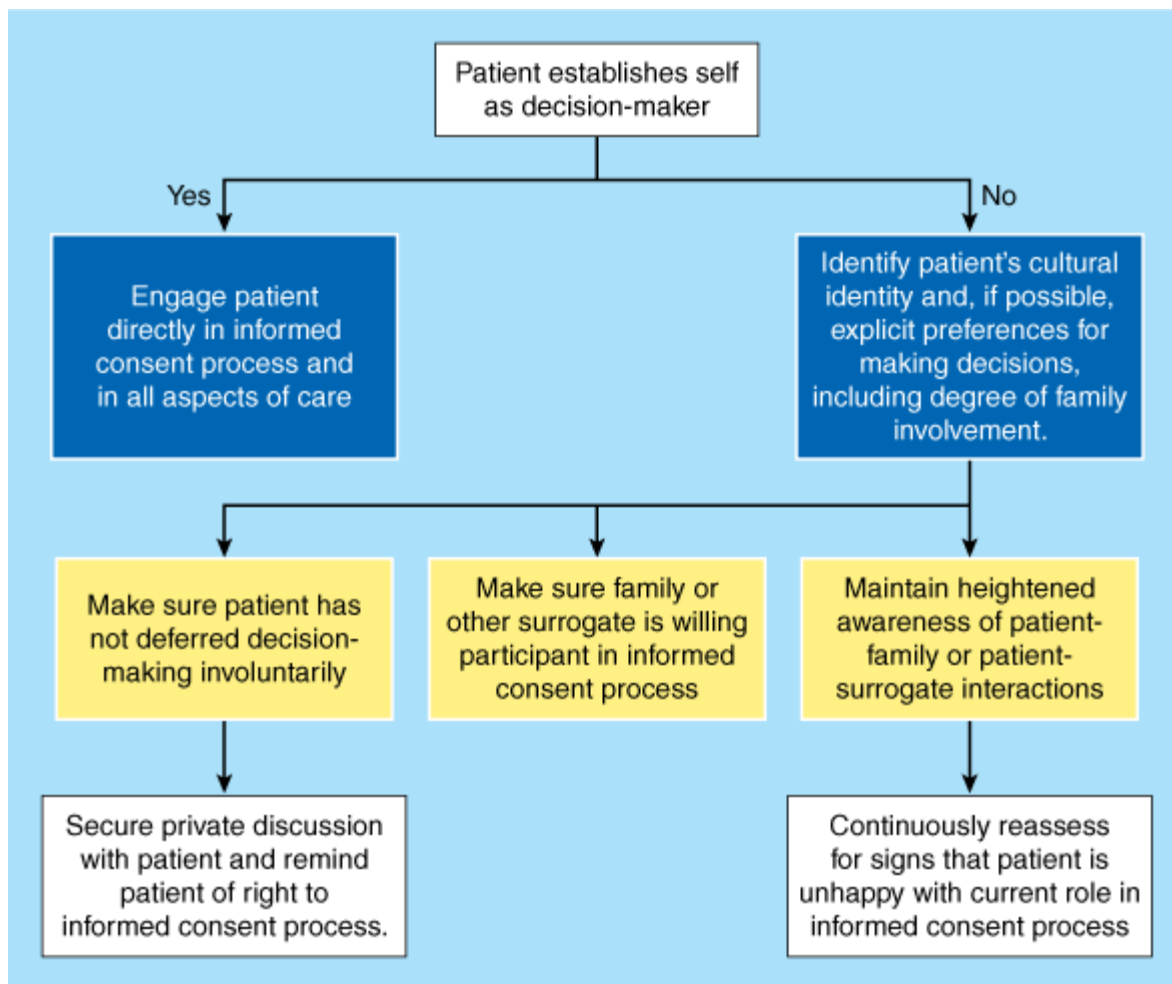

*Every human being of adult years and sound mind has a right to determine what shall be done with his body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages . . . except in cases of emergency, where the patient is unconscious, and where it is necessary to operate before consent can be obtained.*⁷

Having established that patients have the right to determine what happens to their bodies, it took some time for the modern concept of *informed* consent to emerge from the initial doctrine of *simple* consent. The initial approach appealed to a *professional practice standard* whereby physicians were obligated to disclose to patients the kind of information that experienced surgeons customarily disclosed.⁸ However, this disclosure was not always adequate for patient needs. In another landmark case, *Canterbury v Spence*, the court rejected the professional practice standard in favor of the *reasonable person standard* whereby physicians are obliged to disclose to patients all information regarding diagnosis, treatment options, and risks that a "reasonable patient" would want to know in a similar situation. Rather than relying on the practices or consensus of the medical community, the reasonable person standard empowers the public (reasonable persons) to determine how much information should be disclosed by physicians to ensure that consent is truly informed. The court did recognize, however, that there are practical limits on the amount of information that can be communicated or assimilated.⁸ Subsequent litigation has revolved around what reasonable people expect to be disclosed in the consent process to include the nature and frequency of potential complications, the prognostic life expectancy,⁹ and the surgeon-specific success rates.⁷ Despite the litigious environment of medical practice, it is difficult to prosecute a case of inadequate informed consent so long as the clinician has made a concerted and documented effort to involve the patient in the decision-making process.

Adequate informed consent entails at least four basic elements: (a) The physician documents that the patient or surrogate has the capacity to make a medical decision; (b) The surgeon discloses to the patient details regarding the diagnosis and treatment options sufficiently for the patient to make an informed choice; (c) The patient demonstrates understanding of the disclosed information before (d) authorizing freely a specific treatment plan without undue influence (Fig. 48-5). These goals are aimed at respecting each patient's prerogative for autonomous self-determination. To accomplish these goals, the surgeon needs to engage in a discussion about the causes and nature of the patient's disease, the risks and benefits of available treatment options, as well as details regarding what patients can expect after an operative intervention.^{10–17}

Algorithm for navigating the process of informed consent.

(From Childers R, Lipsett A, Pawlik T: Informed consent and the surgeon. *J Am Coll Surg* E-pub Jan. 21, 2009. Copyright 2009, with permission from Elsevier.)

Informed consent can be challenging in certain clinical settings. For example, obtaining consent for emergency surgery, where decisions are often made with incomplete information, can be difficult. Emergency consent requires the surgeon to consider if and how possible interventions might save a patient's life, and if successful, what kind of disability might be anticipated. Surgical emergencies are one of the few instances where the limits of patient autonomy are freely acknowledged, and surgeons are empowered by law and ethics to act promptly in the best interests of their patients according to the surgeon's judgment. Most applicable medical laws require physicians to provide the standard of care to incapacitated patients, even if it entails invasive procedures without the explicit consent of the patient or surrogate. If at all possible, surgeons should seek the permission of their patients to provide treatment, but when emergency medical conditions render patients unable to grant that permission, and when delay is likely to have grave consequences, surgeons are legally and ethically justified in providing whatever surgical treatment the surgeon judges necessary to preserve life and restore health.⁷ This justification is based on the social consensus that most people would want their lives and health protected in this way, and this consensus is manifest in the medical profession's general orientation to preserve life. It may be that subsequent care may be withdrawn or withheld when the clinical prognosis is clearer, but in the context of initial resuscitation of injured patients, incomplete information makes clear judgments about the patient's ultimate prognosis or outcome

impossible.

The process of consent can also be challenging in the pediatric population. For many reasons, children and adolescents cannot participate in the process of giving informed consent in the same way as adults. Depending on their age, children may lack the cognitive and emotional maturity to participate fully in the process. In addition, depending on the child's age, their specific circumstances, as well as the local jurisdiction, children may not have legal standing to fully participate on their own independent of their parents. The use of parents or guardians as surrogate decision makers only partially addresses the ethical responsibility of the surgeon to involve the child in the informed consent process. The surgeon should strive to augment the role of the decision makers by involving the child in the process. Specifically, children should receive age-appropriate information about their clinical situation and therapeutic options so that the surgeon can solicit the child's "assent" for treatment. In this manner, while the parents or surrogate decision makers formally give the informed consent, the child remains an integral part of the process.

Certain religious practices can present difficulties in treating minor children in need of life-saving blood transfusions; however, case law has made clear the precedent that parents, regardless of their held beliefs, may not place their minor children at mortal risk. In such a circumstance, the physician should seek counsel from the hospital medicolegal team, as well as from the institutional ethics team. Legal precedent has, in general, established that the hospital or physician can proceed with providing all necessary care for the child.

Obtaining "consent" for organ donation deserves specific mention.¹⁸ Historically, discussion of organ donation with families of potential donors was performed by transplant professionals, who were introduced to families by intensivists after brain death had been confirmed and the family had been informed of the fact of death. In other instances, consent might be obtained by intensivists caring for the donor, as they were assumed to know the patient's family and could facilitate the process. However, issues of moral "neutrality" as part of end-of-life care in the intensive care unit have caused a shift in how obtaining "consent" for organ donation is handled. Responsibility for obtaining consent from the donor family is now vested in trained "designated requestors" (or "organ procurement coordinators")¹⁹ or by "independent" intensivists who do not have a therapeutic clinical relationship with the potential donor.²⁰ In this way, the donor family can be allowed to make the decision regarding donation in a "neutral" environment without erosion of the therapeutic relationship with the treating physician.

The process of informed consent also can be limited by the capacity of patients to assimilate information in the context of their illness. For example, despite the best efforts of surgeons, evidence suggests that patients rarely retain much of what is disclosed in the consent conversation, and they may not remember discussing details of the procedure that become relevant when postoperative complications arise.²¹ It is important to recognize that the doctrine of informed consent places the most emphasis on the principle of autonomy precisely in those clinical situations when, because of their severe illness or impending death, patients are often divested of their autonomy.

The Boundaries of Autonomy: Advanced Directives and Powers of Attorney

Severe illness and impending death can often render patients incapable of exercising their autonomy regarding medical decisions. One approach to these difficult situations is to make decisions in the "best interests" of patients, but because such decisions require value judgments about which thoughtful people frequently disagree, ethicists, lawyers, and legislators have sought a more reliable solution. Advanced directives of various forms have been developed to carry forward into the future the autonomous choices of competent adults regarding health care decisions. Furthermore, the courts often accept "informal"

advanced directives in the form of sworn testimony about statements the patient made at some time previous to their illness. When a formal document expressing the patient's advanced directives fails to exist, surgeons should consider the comments patients and families make when asked about their wishes in the setting of debilitating illness.

Living wills are written to anticipate treatment options and choices in the event that a patient is rendered incompetent by a terminal illness. In the living will, the patient indicates which treatments she wishes to permit or prohibit in the setting of terminal illness. The possible treatments addressed often include mechanical ventilation, cardiopulmonary resuscitation, artificial nutrition, dialysis, antibiotics, or transfusion of blood products. Unfortunately, living wills are often too vague to offer concrete guidance in complex clinical situations, and the language ("terminal illness," "artificial nutrition") can be interpreted in many ways. Furthermore, by limiting the directive only to "terminal" conditions, it does not provide guidance for common clinical scenarios like advanced dementia, delirium, or persistent vegetative states where the patient is unable to make decisions, but is not "terminally" ill. Perhaps even more problematic is the evidence that demonstrates that healthy patients cannot reliably predict their preferences when they are actually sick. For example, the general public estimates the health-related quality of life (HRQoL) score of patients on dialysis at 0.39, although dialysis patients themselves rate their HRQoL at 0.56.²² Similarly, patients with colostomies rated their HRQoL at 0.92, compared to a score of 0.80 given by the general public for patients with colostomies.²² For these and other reasons, living wills are often unable to provide the extent of assistance they promise.²³

An alternative to living wills is the durable power of attorney for health care in which patients identify surrogate decision makers and invest them with the authority to make health care decisions on their behalf in the event that they are unable to speak for themselves. Proponents of this approach hope that the surrogate will be able to make decisions that reflect the choices that the patients themselves would make if they were able. Unfortunately, several studies demonstrate that surrogates are not much better than chance at predicting the choices patients make when the patient is able to state a preference.^{7,23,24} These data reveal a flaw in the guiding principle of surrogate decision making: Surrogates do not necessarily have privileged insight into the autonomous preferences of patients. However, the durable power of attorney at least allows patients to choose the person who will eventually make prudential decisions on their behalf and in their best interests; therefore, respecting the judgment of the surrogate is a way of respecting the self-determination of the incapacitated patient.²⁵

There is continuing enthusiasm for a wider use of advanced directives. In fact, the 1991 Patient Self Determination Act requires all U.S. health care facilities to (a) inform patients of their rights to have advanced directives, and (b) to document those advanced directives in the chart at the time any patient is admitted to the health care facility.⁷ However, only a minority of patients in U.S. hospitals have advanced directives despite concerted efforts to teach the public of their benefits. For example, the ambitious SUPPORT trial used specially trained nurses to promote communication between physicians, patients, and their surrogates to improve the care and decision making of critically ill patients. Despite this concerted effort, the intervention demonstrated "no significant change in the timing of do not resuscitate (DNR) orders, in physician-patient agreement about DNR orders, in the number of undesirable days (patients experiences), in the prevalence of pain, or in the resources consumed."²⁶

Some of the reluctance around physician-patient agreement about DNR orders may reflect patient and family anxiety that DNR orders equate to "do not treat." Patients and families should be assured, when appropriate, that declarations of DNR/do not intubate will not necessarily result in a change in ongoing routine clinical care. The issue of temporarily rescinding DNR/do not intubate orders around the time of an operative procedure may also need to be addressed with the family.

Patients should be encouraged to clearly identify their surrogates, both formally and informally, early in the course of treatment, and before any major elective operation. Often, around the time of surgery or at the end of life, there are limits to patient autonomy in medical decision making. Seeking an advanced directive or surrogate decision maker requires time that is not always available when the clinical situation deteriorates. As such, these issues should be clarified as early as possible in the patient-physician relationship.

Withdrawing and Withholding Life-Sustaining Therapies

The implementation of various forms of life support technology raise a number of legal and ethical concerns about when it is permissible to withdraw or withhold available therapeutic technology. There is general consensus among ethicists that there are no philosophic differences between withdrawing (stopping) or withholding (not starting) treatments that are no longer beneficial.²⁷ However, the right to refuse, withdraw, and withhold beneficial treatments was not established before the landmark case of Karen Ann Quinlan. In 1975, Ms. Quinlan lapsed into a persistent vegetative state requiring ventilator support. After several months without clinical improvement, Ms. Quinlan's parents asked the hospital to withdraw ventilator support. The hospital refused, fearing prosecution for euthanasia. The case was appealed to the New Jersey Supreme Court where the justices ruled that it was permissible to withdraw ventilator support.²⁸ This case established a now commonly recognized right to withdraw "extraordinary" life-saving technology if it is no longer desired by the patient or the patient's surrogate.

The difference between "ordinary" and "extraordinary" care, and whether there is an ethical difference in withholding or withdrawing "ordinary" vs. "extraordinary" care, has been an area of much contention. The 1983 Nancy Cruzan case highlighted this issue. In this case, Ms. Cruzan had suffered severe injuries in an automobile crash that rendered her in a persistent vegetative state. Ms. Cruzan's family asked that her tube feeds be withheld, but the hospital refused. The case was appealed to the U.S. Supreme Court, which ruled that the tube feeding could be withheld if her parents demonstrated "clear and convincing evidence" that the incapacitated patient would have rejected the treatment.²⁹ In this ruling, the court essentially ruled that there was no legal distinction between "ordinary" vs. "extraordinary" life-sustaining therapies.³⁰ In allowing the feeding tube to be removed, the court accepted the principle that a competent person (even through a surrogate decision maker) has the right to decline treatment under the Fourteenth Amendment of the U.S. Constitution. The court noted, however, that there has to be clear and convincing evidence of the patient's wishes (principle of autonomy) and that the burdens of the medical intervention should outweigh its benefits (consistent with the principles of beneficence and nonmaleficence).

In deliberating the issue of withdrawing vs. withholding life-sustaining therapies, the principle of "double effect" is often mentioned. According to the principle of "double effect," a treatment (e.g., opioid administration in the terminally ill) that is intended to help and not harm the patient (i.e., relieve pain) is ethically acceptable even if an unintended consequence (side effect) of its administration is to shorten the life of the patient (e.g., by respiratory depression). Under the principle of double effect, a physician may withhold or withdraw a life-sustaining therapy if the surgeon's *intent* is to relieve suffering, not to hasten death. The classic formulation of double effect has four elements (Fig. 48-6).

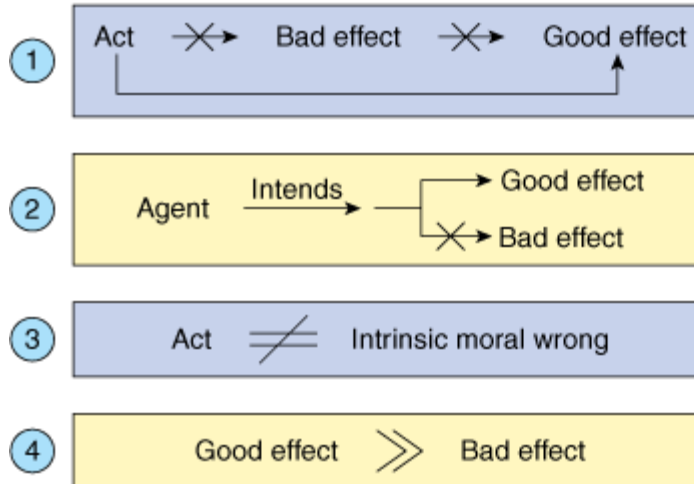

Fig. 48-6.

Double effect

Conditions

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

The four elements of the double effect principle: 1) The good effect is produced directly by the action and not by the bad effect. 2) The person must intend only the good effect, even though the bad effect may be foreseen. 3) The act itself must not be intrinsically wrong, or needs to be at least neutral. 4) The good effect is sufficiently desirable to compensate for allowing the bad effect.

Withholding or withdrawing of life-sustaining therapy is ethically justified under the principle of double effect if the physician's intent is to relieve suffering, not to kill the patient. Thus, in managing the distress of the dying, there is a fundamental ethical difference between titrating medications rapidly to achieve relief of distress and administering a very large bolus with the intent of causing apnea. It is important to note, however, that although the use of opioids for pain relief in advanced illness is frequently cited as the classic example of the double effect rule, opioids can be used safely without significant risk. In fact, if administered appropriately, in the vast majority of instances the rule of double effect need not be invoked when administering opioids for symptom relief in advanced illness.³¹

In accepting the ethical equivalence of withholding and withdrawing of life-sustaining therapy, surgeons can make difficult treatment decisions in the face of prognostic uncertainty.²⁷ In light of this, some important principles to consider when considering withdrawal of life-sustaining therapy include: (a) Any and all treatments can be withdrawn. If circumstances justify withdrawal of one therapy (e.g., IV pressors, antibiotics), they may also justify withdrawal of others. (b) Be aware of the symbolic value of continuing some therapies (e.g., nutrition, hydration) even though their role in palliation is questionable. (c) Before withdrawing life-sustaining therapy, ask the patient and family if a spiritual advisor (e.g., pastor, imam, rabbi, or priest) should be called. (d) Consider requesting an ethics consult.

Although the clinical setting may seem limited, a range of options usually exists with respect to withdrawing or withholding treatment, allowing for an incremental approach, for example (a) continuing the current regimen without adding new interventions or tests; (b) continuing the current regimen but withdrawing elements when they are no longer beneficial; and

(c) withdrawing and withholding all treatments that are not targeted to relieve symptoms and maximize patient comfort.

The surgeon might consider discussing the clinical situation with the patient or proxy decision maker, identify the various therapeutic options, and delineate the reasons why withholding or withdrawing life-sustaining therapy would be in the patient's best interest. If the patient (or designated proxy decision maker) does not agree with withholding or withdrawing life-sustaining therapy, the surgeon should consider or recommend a second medical opinion. If the second opinion corroborates that life-sustaining therapy should be withheld or withdrawn but the patient/family continues to disagree, the surgeon should consider assistance from institutional resources such as the ethics committee and hospital administration. Although the surgeon is not ethically obligated to provide treatment that he or she believes is futile, the surgeon is responsible for continued care of the patient, which may involve transferring the patient to a surgeon who is willing to provide the requested intervention.²⁷

PALLIATIVE CARE

General Principles of Palliative Care

Palliative care is a coordinated, interdisciplinary effort that aims to relieve suffering and improve quality of life for patients and their families in the context of serious illness.³³ It is offered simultaneously with all other appropriate medical treatment, and its indication is not limited to situations associated with a poor prognosis for survival. Palliative care strives to achieve more than symptom control, but it should not be confused with noncurative treatment.

The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."³⁴ Palliative care is both a philosophy of care and an organized, highly structured system for delivering care.

Palliative care includes the entire spectrum of intervention for the relief of symptoms and the promotion of quality of life. No specific therapy, including surgical intervention, is excluded from consideration. Therefore, surgeons have valuable contributions to make to palliative care. Furthermore, *surgical palliative care* can be defined as the treatment of suffering and the promotion of quality of life for seriously or terminally ill patients under the care of surgeons.³⁵ The standard of palliative treatment lies in the agreement between patient and physician that the expected outcome is relief from distressing symptoms, lessening of pain, and improvement of quality of life. The decision to intervene is based on the treatment's ability to meet the stated goals, rather than its impact on the underlying disease.

The fundamental elements of palliative care consist of pain and nonpain symptom management, communication among patients, their families, and care providers, and continuity of care across health systems and through the trajectory of illness. Additional features of system-based palliative care are team-based planning that includes patient and family; close attention to spiritual matters; and psychosocial support for patients, their families, and care providers, including bereavement support.

Indications for palliative care consultation in surgical practice include: (a) patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits; (b) assistance in clarification or reorientation of patient/family goals of care; (c) assistance in resolution of ethical dilemmas; (d) situations in which a patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only; (e) patients who are expected to die imminently or shortly after hospital discharge; and (f) provision of bereavement support for patient care staff, particularly after loss of a colleague under care³⁵ (Table 48-1).

Table 48-1 Indications for Palliative Care Consultation
Patients with conditions that are progressive and life-limiting, especially if characterized by burdensome symptoms, functional decline, and progressive cognitive deficits
Assistance in clarification or reorientation of patient/family goals of care
Assistance in resolution of ethical dilemmas
Situations in which patient/surrogate declines further invasive or curative treatments with stated preference for comfort measures only
Patients who are expected to die imminently or shortly after hospital discharge
Provision of bereavement support for patient care staff, particularly after loss of a colleague under care

Palliative Care: History and Philosophy

Palliative care, by virtue of its diverse goals, practices, and practitioners, has many origins, but it would not have emerged as a comprehensive philosophy of care without the seminal contributions of Dame Cicely Saunders (Fig. 48-7). Her life's work began at the bedside of an individual patient, but it ultimately led to the modern hospice movement, spawned a new medical specialty, initiated extensive scientific and social research, and has changed the perception of death and dying for millions of patients and families.

Dame Cicely Mary Strode Saunders.
(Courtesy of St. Christopher's Hospice.)

Saunders was a registered nurse, a medical social worker, and ultimately, a physician who was inspired by the needs of suffering soldiers in World War II. Her mentor, thoracic surgeon Howard Barrett, ultimately convinced her to become a physician to increase the credibility of her ideas in the physician-dominated health care system of that time. Saunders made three seminal contributions to the emerging field of palliative care: (a) She observed that the quality of life for patients with pain from advanced cancer is improved with scheduled dosing of opioids; (b) she developed the concept of Total Pain⁴¹ to include physiologic, spiritual, and existential dimensions of pain; and (c) she founded St. Christopher's Hospice in 1967. Each of these contributions illustrates principles that have become the salient themes of all palliative care: the emphasis on symptom control that correlates with enhanced quality of life, the recognition of the spiritual and existential dimensions of health and illness, and the insistence on teamwork as the operational model for delivery of care. Nathan Cherny (Fig. 48-8), another pioneer of palliative care, echoes these themes in his definition of palliative care: "[it] is concerned with three things: the quality of life, the value of life, and the meaning of life."³³ Therefore, it is *existence*, not death, that is the focus of palliative care.

Nathan Cherny, a pioneer for palliative care.

Surgeons have had an integral role in palliative care as it has evolved, and surgical procedures have been part of the armamentarium for symptom relief. For example, although mastectomy, gastrectomy, pancreaticoduodenectomy, and the Blalock-Taussig shunt are thought of as curative, or at least definitive, operations, the initial rationale for developing these procedures was their efficacy as palliative treatment.^{37,38} The official report from Massachusetts General Hospital of its experience treating victims of the Coconut Grove fire presciently identified psychologic and social care as major components for the total care the burn victims received.³⁹

In addition to developing procedures with palliative utility, surgeons have also made important contributions to the philosophy of palliative care. For example, in 1975, shortly after the hospice concept was established, the distinguished surgeon-educator J. Englebert Dunphey addressed the concept of nonabandonment of terminally ill patients in a landmark lecture that deeply shaped the developing specialty of palliative care.⁴⁰

The term *palliative care* was coined by a Canadian surgeon, Balfour Mount (Fig. 48-9), in 1975 on the opening of the first hospital-based palliative care program in North America. Surgeons were active in the establishment of many community hospice programs in the United States and have contributed popular professional and lay books on the subject.^{41–43}

Balfour Mount.

[Reproduced with permission from Canadian Broadcasting Company (Tracking number 22910).]

Over the past decade, the American College of Surgeons has issued several statements of principles outlining standards of palliative and end-of-life care in addition to its support of programs disseminating information to surgeons about the principles and practices of palliative care.^{44–46} The Royal College of Surgeons has acknowledged palliative care as a domain of expected competence for Fellowship for over a decade, and since 2002, the American Board of Surgery has included

palliative care as a domain of expected knowledge for its qualifying exam.

Over the last 40 years, hospice and palliative care have become established components of health care systems in varying degrees in most countries of the world. Table 48-2 shows a comparison of palliative care and hospice. Both have received repeated endorsements by the World Health Organization,⁴⁷ medical societies,⁴⁴ and medical specialty boards.⁴⁸ More than just a philosophy of care, hospice and palliative care have emerged as a medical specialty that provides a standard medical practice to patients in institutional settings and in patient homes. Palliative medicine was recognized as a medical subspecialty by the Royal College of Medicine in 1987 and by the American Board of Medical Specialties in 2006. Many insurers now reimburse these services as a standard benefit, and in the United States, the Medicare hospice benefit provides a per diem in support of nursing, social services, nurse aides, physician oversight, volunteers, chaplain support, durable medical equipment, and the cost of medications for symptom control.

Although all patients, regardless of prognosis, may benefit from the services of a palliative care physician with expertise in relieving intractable symptoms, hospice care⁴⁹ is a specific form of palliative care intended for patients who have an estimated prognosis of 6 months or less to live, usually certified by two physicians (the attending physician and hospice medical director). Initially, there are two certification periods of 3 months each, followed by recertification every 60 days thereafter. Continued services may continue well beyond the original 6 months of estimated survival, and they are based on ongoing disease progression, further functional decline, and persistent symptom burden. The goal of hospice is to provide holistic care at the end of life focused on relief of the patient's suffering. Most Americans indicate a preference to die at home, but nearly 75% die in an institutional setting (half in acute hospitals and another one fourth in nursing homes). Of the one fourth that do die at home, hospice services can help make that experience better for both patient and surviving loved ones. Earlier referral and wider use of the hospice benefit may help more patients achieve their goal of dying at home.

Concepts of Suffering, Pain, Health, and Healing

Palliative care addresses specifically the individual patient's experience of suffering due to illness. Indeed, the philosophical origins of palliative care began with attention to suffering and the existential questions suffering engenders. More than mere technologic evolution in the management of symptoms, the early proponents of palliative care sought a revolution in the moral foundations of medicine that challenged the assumptions that so often seemed to result in futile invasive intervention, and identified many of the problems that were subsequently taken up by medical ethicists. This reorientation of the goals of medical care from a focus on disease and its management to the patient's experience of illness focuses attention on the purpose of medicine and the meaning of health and healing.

Over the past half century, several concepts and theories about the nature of pain, suffering, and health have been proposed in service of the evolving conceptual framework of palliative care. For example, while considering the differences between disease-oriented and illness-oriented approaches to the care of seriously ill patients, psychiatrist Arthur Kleinman wrote, "There is a moral core to healing in all societies. [Healing] is the central purpose of medicine . . . the purpose of medicine is both control of disease processes and care for the illness experience. Nowhere is this clearer than in the relationship of the chronically ill to their medical system: For them, the control of disease is by definition limited; care for the life problems created by the disorder is the chief issue."⁵⁰

The relief of pain has been the clinical foundation for hospice and palliative care. It has been defined by the International Association for the Study of Pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."⁵¹ For purposes of interdisciplinary palliative care, Saunders's concept of "Total Pain"³⁶ is a more useful definition and is frequently used as the basis for palliative assessments. Total Pain is the sum total of four principal domains of pain: physical, psychologic, social or socioeconomic, and spiritual. Each of these contributes to, but is not synonymous with, suffering.

Persons suffer when their individual integrity or personhood is threatened: "Bodies do not suffer, only persons do."⁵² Personhood entails a transcendent dimension that often can frame the existential threat of death in some broader sense of

meaning. As such, issues related to a person's past history and future legacy become compellingly more central as physical decline becomes increasingly pronounced. As argued by Cassell, if physicians understand suffering in only its physical dimension (attention to laboratory values, x-rays, etc.), they may ignore the psychologic and spiritual pain that accompanies dying; such neglect may not only fail to relieve suffering, but actually compound it.⁵² Saunders's taxonomy of pain and Cassell's portrayal of the mechanism of suffering collectively represent the structure and function of the human psyche in the context of life-threatening illness.

Frankl⁵³ contributed to the philosophy of palliative care the notion that the willingness to survive is related to the capacity to make sense out of suffering, giving suffering a sense of meaning. Brody described suffering as the sense of anguish that besets an individual near the end of his life when his personal narrative is fragmented to the point of incoherence. This fragmentation prevents the individual from transforming his personal narrative into a legacy that will endure after death. Brody challenges physicians caring for severely ill patients to consider how their participation in the care of patients might best assist those patients in transforming a "broken story" into a "transcendent legacy."⁵⁴

Finally, the developmental framework for the end of life proposed by Byock⁵⁵ views the last phases of life not so much as an arena for suffering, but as a natural phase of life with its own developmental tasks, which, when achieved, result in deeply satisfying personal growth that reciprocates with the growth of those sharing this experience. Byock's four developmental tasks of the dying include: (a) renewal of a sense of personhood and meaning, (b) bringing closure to personal and community relationships, (c) bringing closure to worldly affairs, and (d) acceptance of the finality of life.

Effective Communication and Negotiating the Goals of Care

Changing the goals of care from cure to palliation near the end of life is both emotionally and clinically challenging, and it depends on a clear prognosis and effective communication. Unfortunately, prognostication can be notoriously difficult and inaccurate in advanced illness, and Christakis has argued that, to a large degree, physicians have abdicated their traditional responsibility to provide clear prognosis regarding incurable disease and approaching death.⁵⁶ However, there are validated tools for prognosis in critical illness (APACHE, MODS, etc.), and with most advanced diseases, functional status is the most powerful predictor of survival. For example, patients with advanced metastatic cancer who are resting/sleeping for 50% or more of normal waking hours and require some assistance with activities of daily living (ADL) have a projected survival of weeks, and patients who are essentially bedfast and dependent for ADL have a projected survival of days to a week or two at best. Table 48-3 shows a simple prognostic tool to aid clinicians in recognizing patients nearing the end of life.

Table 48-3 Simple Prognostication Tool in Advanced Illness (Especially Cancer)		
Functional Level	Performance Status (ECOG)	Prognosis
Able to perform all basic ADLs independently and some IADLs	2	Months
Resting/sleeping up to 50% or more of waking hours and requiring some assistance with basic ADLs	3	Weeks to a few months
Dependent for basic ADLs and bed to chair existence	4	Days to a few weeks at most

These observations apply to patients with advanced, progressive, incurable illnesses (e.g., metastatic cancer refractory to treatment).

Basic ADL = activities of daily living (e.g., transferring, toileting, bathing, dressing, and feeding oneself); IADL = instrumental activities of daily living (e.g., more complex activities such as meal preparation, performing household chores,

balancing a checkbook, shopping, etc.); ECOG = Eastern Cooperative Oncology Group functional (performance) status.

Alternatively, the Karnofsky Performance Scale is a scale of functional status ranging from 100 (high level of function) to 0 (death). It is commonly used in palliative care to roughly assess patient anticipated needs as well as prognosis. The Palliative Performance Scale⁵⁷ is a validated⁵⁸ expansion of the Karnofsky Performance Scale that includes five palliative-focused domains, including ambulation, activity level, self-care, intake, and level of consciousness, in addition to evidence of disease. The Missoula-Vitas Quality of Life Index is a 25-question scale specifically for palliative care and hospice patients that scores symptoms, function, interpersonal relationships, well being, and spirituality. Updates and Spanish versions are available.⁵⁵

Regardless of the prognostic tool used, the prognosis should be conveyed to the patient and family. If done well, communication and negotiation with patients and families about advanced terminal illnesses can potentially avoid great psychologic harm and help make a difficult transition easier. To communicate effectively and compassionately, it is helpful to pursue an organized process similar to the structured history and physical central to the evaluation of any patient. One such structured approach to delivering unfavorable news proposes six steps that can be easily learned by clinicians: (a) getting started by selection of the appropriate setting, introductions, and seating; (b) determining what the patient or family knows; (c) determining what the patient or family wants to know; (d) giving the information; (e) expressing empathy; and (f) establishing expectations, planning, and aftercare (Table 48-4).⁵⁹ Success with this approach to breaking bad news is critically dependent upon the clinician's ability to empathically respond to the patient's (and family's) reaction to the news.⁶⁰ The empathic response does not require the surgeon to share the same emotions of the patient, but it does require the surgeon to identify the patient's emotion and accurately reflect that awareness back to the patient. Patient assessment in these conversations should give the highest priority to identifying and responding to the most immediate source of distress. Relieving a pressing symptom is prerequisite for a more thorough search for other potential sources of suffering, and the assessment process, itself, can be therapeutic if conducted in a respectful and gentle manner.

Table 48-4 Communicating Unfavorable News: Important Principles
• Setting: Find a quiet, private place to meet. Sit down close to the patient.
• Listen: Clarify the patient's and/or the family's understanding of the situation.
• "Warning shot": Prepare patient and family and obtain their permission to communicate bad news (e.g., "I'm afraid I have bad news.").
• Silence: Pause after giving bad news. Allow patient/family to absorb/react to the news.
• Encourage: Convey hope that is realistic and appropriate to the circumstances (e.g., patient will not be abandoned; symptoms will be controlled).

CARE AT THE END OF LIFE

The process of dying and the care of a patient at the time of death is a distinct clinical entity that demands specific skills from physicians. The issues specific to dying and the available tools for compassionate care at the end of life are addressed in this section.

The Syndrome of Imminent Demise^{32,61}

In a patient who has progressed to the terminal stage of an advanced illness (e.g., cancer), a number of signs provide evidence of imminent death. As terminally ill patients progress toward death, they become increasingly bedbound, requiring assistance for all basic ADL. There is a steady decrease in desire and requests for food and fluids. More distressing to the

dying patient is a progressively dry mouth that may be confused by the treating team as thirst. It is often exacerbated by anticholinergic medications, mouth breathing, and supplemental oxygen (O₂) administered without humidification.

With progressive debility, fatigue, and weight loss, it is common for terminally ill patients to experience increasing difficulty swallowing. This may result in aspiration episodes and an inability to swallow tablets, requiring alternative routes for medication administration (e.g., IV, SC, PR, sublingual, buccal, or transdermal). In addition to the increased risk of aspiration, patients near death develop great difficulty clearing oropharyngeal and upper airway secretions, leading to noisy breathing or the so-called "death rattle." As death approaches, the respiratory pattern may change to increasingly frequent periods of apnea often following a Cheyne-Stokes pattern of rapid, progressively longer breaths leading up to an apneic period. As circulatory instability develops near death, patients may exhibit cool and mottled extremities. Periods of confusion are often accompanied by decreasing urine output and episodes of fecal and urinary incontinence.

A number of cognitive changes occur as death approaches. Patients who are in the last days of life may demonstrate some signs of confusion or delirium. Agitated delirium is a prominent feature of a difficult death. Other cognitive changes that may be seen include a decreased interest in social interactions, increased somnolence, reduced attention span, disorientation to time (often with altered sleep-wake cycles), and an altered dream life, including vivid "waking dreams" or visual hallucinations. Reduced hearing and visual acuity may be an issue for some patients; however, patients who appear comatose may still be aware of their surroundings. Severely cachectic patients may lose the ability to keep their eyes closed during sleep because of loss of the retro-orbital fat pad.

Common Symptoms at the End of Life and Their Management^{32,61,62}

The three most common, major symptoms that threaten the comfort of dying patients in their last days are respiratory distress, pain, and cognitive failure. General principles that are applicable to symptom management in the last days of life include: (a) anticipating symptoms before they develop; (b) minimizing technologic interventions (usually manage symptoms with medications); and (c) planning alternative routes for medications in case the oral route fails. It may be possible to cautiously reduce the dose of opioids and other medications as renal clearance decreases near the end of life, but it is important to remember that increased somnolence and decreasing respirations are prominent features of the dying process independent of medication side effects. Sudden cessation of opioid analgesics near the end of life could precipitate withdrawal symptoms, and therefore, medications should not be stopped for increasing somnolence or slowed respirations.

The principles of pharmacotherapy for pain and nonpain symptoms in the palliative care setting are outlined in Table 48-5. The World Health Organization,³⁴ the United States Agency for Health Care Policy and Research,⁶³ the Academy of Hospice and Palliative Medicine,⁶⁴ and many other agencies have endorsed a "step ladder" approach to cancer pain management that can predictably result in satisfactory pain control in most patients (Table 48-6). More refractory pain problems require additional expertise, and occasionally, more invasive approaches (Tables 48-7 and 48-8).

Table 48-5 Principles of Pharmacotherapy in Palliative Care
• Believe patient report of symptoms.
• Modify pathologic process when possible and appropriate.
• In terminally ill, avoid medications not directly linked to symptom control.
• Use a multidisciplinary approach.
• Consider nonpharmacologic approaches whenever possible.

• Engage participation of clinical pharmacist in treatment plan.
• Select drugs that can multitask (i.e., use haloperidol for agitated delirium and nausea).
• For pain, use adjuvant medications when possible (see Table 48-8).
• When using opioids, spare when possible (adjuvant medication, local or regional anesthetics, surgical interventions, etc.).
• Avoid fixed combination drugs.
• Avoid excessive cost.
• Select agents with minimum side effects.
• Anticipate and prophylax against side effects.
• For the elderly, the hypoproteinemic, the azotemic: "Start low and go slow."
• Oral route whenever possible and practical.
• No IM injections.
• Scheduled dosing, not prn, for persistent symptoms.
• Stepwise approach. (See the World Health Organization Analgesic Ladder for pain. See Table 48-6.)
• Reassess continuously and titrate to effect.
• Use equianalgesic doses when changing opioids (see Table 48-6).
• Assess patient/family's comprehension of management plan.

Table 48-6 The World Health Organization Three-Step Ladder for Control of Cancer Pain³⁴

Step 1 mild pain (visual analogue scale, 1–3)
Nonopioid ± adjuvant medication
Step 2 moderate pain (visual analogue scale, 4–6)
Opioid for mild to moderate pain and nonopioid ± an adjuvant
Step 3 severe pain (visual analogue scale, 7–10)
Opioid for moderate to severe pain ± nonopioid ± an adjuvant

Table 48-7 Analgesics for Persistent Pain

Drug	Initial Dosing (Adult, >60 kg)	Comments
Mild persistent pain, visual analogue scale (VAS) 1–3		
Acetaminophen (Tylenol)	Maximum = 3200 mg/24 h	Use <2400 mg if other potentially hepatotoxic drugs taken. Acetaminophen contained in concurrent nonprescription medications can easily exceed maximum daily allowable dose.
Aspirin	600–1500 mg PO qid	Gastric bleeding, platelet dysfunction
Choline magnesium trisilicylate (Trilisate)	750–1500 mg PO bid	Useful for avoiding platelet dysfunction
Ibuprofen (Advil, Motrin)	Maximum = 3200 mg/24 h	Gastropathy, nephropathy, decreased platelet aggregation
Naproxen (Naprosyn)	250 mg PO bidMaximum = 1300 mg/24 h	Available as a transcutaneous gel
Moderate persistent pain, VAS 4–6		

Hydrocodone (Vicodin, Lortab)	5–7.5 mg PO q4h	Most prescribed drug in the United States
		Acetaminophen in compounded drug limits use to moderate pain.
Oxycodone	5 mg PO q4h	Sold as single agent or compounded with aspirin or acetaminophen.
		Slow release form available (Oxycontin)
Severe persistent pain, VAS 7–10		
Morphine	10 mg PO q2–4h 2–4 mg IV q4h	Standard drug for comparison to alternative opioids. Avoid or caution when giving to the elderly, patients with diminished glomerular filtration rate, or liver disease. Slow release PO form available (MS Contin).
Hydromorphone	1–3 mg PO, PR q4h 1 mg IV, SC q4h	Suppository form available
		Oral dose forms limited to 4 mg maximum
Fentanyl, transdermal	12 µg/h patch q72h	Not for acute pain management. Do not use on opioid-naïve patients. Absorption unpredictable in cachectic patients.
Methadone	Consultation with pain management, clinical pharmacists, or palliative care/ hospice services skilled in methadone use is recommended for those inexperienced in prescribing methadone.	Not a first-line agent, although very effective, especially for pain with a neuropathic component
		Very inexpensive
		Can be given PO, IV, SC, PR, sublingually, and vaginally
		Its long half-life makes dosing more difficult than alternative opioids and close monitoring is required when initiating
		Numerous medications, alcohol, and cigarette smoking can alter its serum levels
		Physicians who write methadone prescriptions for pain should specify this indication. Methadone use for drug withdrawal treatment requires special licensure.

Risk factors for NSAID-induced nephropathy include: advanced age, decreased glomerular filtration rate, congestive heart failure, hypovolemia, pressors, hepatic dysfunction, concomitant nephrotoxic agents. Dose reduction and hydration reduce risk.

Opioids compounded with aspirin or acetaminophen are limited to treatment of moderate persistent pain because of dose-limiting toxicities of acetaminophen and aspirin.

Slow-release preparations of morphine and oxycodone may be given rectally.

Timed-release tablets or patches should never be crushed or cut.

Opioid analgesics are the agents of choice for severe cancer-related pain. Sedation is a common side effect when initiating opioid therapy. Tolerance to this usually develops within a few days. If sedation persists beyond a few days, a stimulant (methylphenidate 2.5–5 mg PO bid) can be given.

Initiate bowel stimulant prophylaxis for constipation when prescribing opioids unless contraindicated.

Adjuvant or coanalgesic agents are drugs that enhance analgesic efficacy of opioids, treat concurrent symptoms that exacerbate pain, or provide independent analgesia for specific types of pain (e.g., a tricyclic antidepressant for treatment of neuropathic pain). Coanalgesics can be initiated for persistent pain at any visual analogue scale level. Gabapentin is

commonly used as an initial agent for neuropathic pain.

No place for meperidine (Demerol), propoxyphene [Darvon, Darvocet, or mixed agonist-antagonist agents (Stadol, Talwin)] in management of persistent pain.

Always consider alternative approaches (axial analgesia, operative approaches, etc.) when managing severe persistent pain.

NOTE: These are not recommendations for specific patients. The inter- and intraindividual variability to opioids requires individualizing dosing and titration to effect.

Table 48-8 Examples of Adjuvant Medications for Treatment of Neuropathic, Visceral, and Bone Pain ^a				
Drug Class	Initial Dosing (Adult, >60 kg)	Comments		
Tricyclic antidepressants	Amitriptyline 10–25 mg PO qhs	Sedating properties may be useful for relief of other concurrent symptoms. Side effects may precede benefit. Avoid in the elderly due to anticholinergic side effects.		
Best for continuous burning or tingling pain and allodynia				
Efficacy for pain not due to antidepressant effect				
Dose generally less than that required for antidepressant effect	Nortriptyline 10–25 mg PO qd	Less anticholinergic effect		
Dose titrated up every few days until effect. Pain may respond to alternative antidepressants if no response to initial agent.	Doxepin 10–25 mg PO qhs			
	Imipramine 10–25 mg PO qd			
Anticonvulsants		.		
For shooting, stabbing pain	Gabapentin 100–300 mg PO qd. Titrate up rapidly as needed. Max: 1800 mg qd	Commonly used first-line agent. Generally well tolerated. Does not require blood level monitoring.		
	Carbamazepine 200 mg PO q12h	Effective. Well studied. Requires blood monitoring.		
	Valproic acid 250 mg PO tid			
Local anesthetics	Lidocaine transdermal patch 5%. Apply to painful areas. Max: 3 simultaneous patches	Systemic toxicity can result from applying more than recommended number per unit time and		
Systemic use requires monitoring.			Lidocaine/prilocaine topical. Apply to	

Nebulized local anesthetics (lidocaine, bupivacaine) can be used for severe, refractory cough.	over 12 h (each patch contains 700 mg lidocaine).	in patients with liver failure. Effective for postherpetic neuralgia.		painful areas.	
			Miscellaneous	Bisphosphonates (pamidronate, zoledronic acid)	For bone pain and reduced incidence of skeletal complications secondary to malignancy—best results in myeloma and breast cancer. Contraindicated in renal failure.
				Calcitonin nasal spray	Refractory bone pain
	Dexamethasone	For bone pain, acute nerve compression, visceral pain secondary to tumor infiltration or luminal obstruction by reducing inflammatory component of tumor			
	Radionuclides (Sr-89)	For malignant bone pain secondary to osteoclastic activity. 4–6 wk delay in benefit. Requires adequate bone marrow reserve. For prognosis of more than 3 mo.			
	Octreotide	Reduces GI secretions that contribute to visceral pain			

^a Recommendations are based on experience of practitioners of hospice and palliative medicine and in some instances do not reflect current clinical trials.

Source: Adapted, with permission from Dunn GP: Surgical palliative care, in Cameron JL (ed): *Current Surgical Therapy*, 9th ed. Philadelphia: Elsevier, 2008. Copyright Elsevier.

The primary treatment of dyspnea (air hunger) in the dying is opioids, which should be cautiously titrated to increase comfort and reduce tachypnea to a range of 15 to 20 breaths/min. Air movement across the face generated by a fan can sometimes be quite helpful. If this is not effective, empiric use of supplemental O₂ by nasal cannula (2 to 3 L/min) may bring some subjective relief, independent of observable changes in pulse oximetry. Supplemental O₂ should be humidified to avoid exacerbation of dry mouth. Typical starting doses of an immediate release opioid for breathlessness should be one half to two thirds of a starting dose of the same agent for cancer pain. For patients already on opioids for pain, a 25 to 50% increment in the dose of the current immediate release agent for breakthrough pain often will be effective in relieving breathlessness in addition to breakthrough pain.

The availability and variety of drugs should not prevent consideration of nonpharmacologic therapy. Massage therapy, music therapy, art therapy, guided imagery, hypnosis, physical therapy, pet therapy, and others play a constructive role not only for the relief of symptoms, but for promoting a sense of hope through improving function, aesthetic pleasure, and social

connectedness. Talents and capacities neglected during the treatment and progression of disease can be recovered even in the most advanced stages of illness.

Pain is often less of a problem in the last days of life because the reduced activity level is associated with lower incident pain. This, combined with lower renal clearance of opioids, may result in greater potency of the prescribed agents. Severe pain crises are fortunately rare, but when they are inadequately addressed, can cause great and lasting distress (complicated grief) for loved ones who witness the final hours or days of agony. Such situations may require continuous administration of parenteral opioids. As death approaches and patients become less verbal, it is important to assess pain frequently, including the use of close observation for nonverbal signs of distress (e.g., grimacing, increased respiratory rate). Adequate dosing of opioid analgesics may require alternate route(s) of administration as patients become more somnolent or develop swallowing difficulties. Opioids should not be stopped abruptly, even if the patient becomes nonresponsive because sudden withdrawal can cause severe distress.^{65,66}

Cognitive failure at the end of life is manifested in most patients by increasing somnolence and delirium. Gradually increasing somnolence can be accompanied by periods of disorientation and mild confusion, and it may respond to the reassuring presence of loved ones and caregivers with minimal need for medications. A more distressing form of delirium also can develop, manifested by increasing agitation that may require the use of neuroleptic medications. Increasing amounts of opioids and/or benzodiazepines may exacerbate the delirium (especially in the elderly).

Pronouncing Death⁶⁷

If the body is hypothermic or has been hypothermic, such as a drowning victim pulled from the water in the winter, the physician should not declare death until warming attempts have been made. In the hospital, hospice, or home setting, the declaration of death becomes part of the medical or legal record of the event. There are a number of physical signs of death a physician should look for in confirming the patient's demise: complete lack of responsiveness to verbal or tactile stimuli, absence of heart beat and respirations, fixed pupils, skin color change to a waxen hue as blood settles, gradual poikilothermia, and sphincter relaxation with loss of urine and feces. For deaths in the home with patients who have been enrolled in hospice, the hospice nurse on call should be contacted immediately. In some states, deaths at home may require a brief police investigation and report. For deaths in the hospital, the family must be notified (in person, if possible). A coroner or medical examiner may need to be contacted under specific circumstances (e.g., deaths in the operating room), but most deaths do not require their services. However, the pronouncing physician will need to complete a death certificate according to local regulations. Survivors may also be approached, if appropriate, regarding potential autopsy and organ donation. Finally, it is important to accommodate religious rituals that may be important to the dying patient or the family. *Bereavement* is the experience of loss by death of a person to whom one is attached. *Mourning* is the process of adapting to such a loss in the thoughts, feelings, and behaviors that one experiences after the loss.⁶⁸ Although grief and mourning are accentuated in the immediate period around death, it is important to note that patients and families may begin the process of bereavement well before the time of death as patients and families grieve incremental losses of independence, vitality, and control. In addition to the surviving loved ones, it is important to acknowledge that caregivers also experience grief for the loss of their patients.^{69,70}

PROFESSIONAL ETHICS: CONFLICT OF INTEREST, RESEARCH, AND CLINICAL ETHICS

Conflict of Interest

Conflicts of interest for surgeons can arise in many situations in which the potential benefits or gains to be realized by the surgeon are, or are perceived to be, in conflict with the responsibility to put the patient's interests before the surgeon's own. Conflicts of interest for the surgeon can involve actual or perceived situations in which the individual stands to gain monetarily by his or her role as a physician or investigator. In the academic community, monetary gain may not be the primary factor. Instead, motivators such as power, tenure, or authorship on a publication may serve as potential sources of conflict of interest. For example, the accrual of subjects in research studies or patients in surgical series may ensure surgeons better authorship or more financial gains. The dual-role of the surgeon-scientist therefore needs to be considered because the duty as surgeon can conflict with the role of scientist or clinical researcher.

Research Ethics

Over the last three decades in the United States, the ethical requirements for the conduct of human subject research have been formalized and widely accepted. Although detailed informed consent is a necessary condition for the conduct of ethically good human subject research, other factors also determine whether research is designed and conducted ethically. Emanuel and colleagues⁷¹ described seven requirements for all clinical research studies to be ethically sound: (a) value—enhancement(s) of health or knowledge must be derived from the research; (b) scientific validity—the research must be methodologically rigorous; (c) fair subject selection—scientific objectives, not vulnerability or privilege, and the potential for and distribution of risks and benefits, should determine communities selected as study sites and the inclusion criteria for individual subjects; (d) favorable risk-benefit ratio—within the context of standard clinical practice and the research protocol, risks must be minimized, potential benefits enhanced, and the potential benefits to individuals and knowledge gained for society must outweigh the risks; (e) independent review—unaffiliated individuals must review the research and approve, amend, or terminate it; (f) informed consent—individuals should be informed about the research and provide their voluntary consent; and (g) respect for enrolled subjects—subjects should have their privacy protected, the opportunity to withdraw, and their well-being monitored.⁷¹

Special Concerns in Surgical Research

A significant issue for clinical surgical research is that it is often analyzed in a retrospective manner and not commonly undertaken in a prospective double-blind, randomized fashion. For a randomized trial to be undertaken, the researchers should be in a state of equipoise—that is, there must be a state of genuine uncertainty on the part of the clinical investigator or the expert medical community regarding the comparative therapeutic merits of each arm in a trial.⁷² To randomize subjects to receive two different treatments, a researcher must believe that the existing data are not sufficient to conclude that one treatment strategy is better than another. In designing surgical trials, surgeons usually have biases that one treatment is better than another and often have difficulty maintaining the state of equipoise. As such, it is frequently difficult to demonstrate that a randomized trial is necessary or feasible, and treatment options that question the validity of clinical tenets are difficult to accept. Meakins has suggested that a slightly different hierarchy of evidence applies to evidence-based surgery.⁷³

A second major issue for surgical trials is whether it is ethically acceptable to have a placebo-controlled surgical trial. Some commentators have argued that sham surgery is always wrong because, unlike a placebo medication that is harmless, every surgical procedure carries some risk.⁷⁴ Others have argued that sham operations are essential to the design of a valid randomized clinical trial because, without a sham operation, it is not possible to know if the surgical intervention is the cause of improvement in patient symptoms or whether the improvement is due to the effect of having surgery.^{75,76} Most surgeons

readily agree that designing an appropriately low-risk sham surgical procedure would create problems for the surgeon-patient relationship in that the surgeon would need to keep the sham a secret.⁷⁷ In this sense, a sham surgical arm of a trial is very different from a placebo medication in that there cannot be blinding of the surgeon as to which procedure was undertaken. As a result, to have a sham surgery arm in a clinical trial, the interactions between the surgeon and the subject must be limited and the surgeon performing the procedure should not be the researcher who follows the subject during the trial. Despite difficulties with designing a surgical trial in which the surgeon could ethically perform a sham operation, there are specific circumstances that allow for placebo operations to be conducted, so long as certain criteria are met and are analyzed on a case by case basis.^{78,79}

Surgical Innovation and Surgical Research

An important issue is whether surgical innovation should be treated as research or as standard of care. Many of the advances in surgical technique and surgical technology have resulted from the innovations that individual surgeons have discovered or created during the course of challenging operations. As every patient is different and the surgeon is always trying to determine the best way to complete an operation, innovations have developed that have often moved the field of surgery forward.⁸⁰ In the Korean and Vietnam wars, the military guidelines for the treatment of vascular injuries recommended ligation and amputation rather than interposition grafting of vascular injuries. Individual surgeons chose to ignore those guidelines and subsequently demonstrated the value of reconstructive techniques that ultimately became the standard of care. It is debated whether modifications in an accepted surgical technique based on the circumstances of an individual patient and the skill and judgment of an individual surgeon should require the same type of prior approval that enrollment in a clinical trial would warrant.⁸¹ However, if a surgeon decides to use a new technique on several occasions and to study the outcomes, Institutional Review Board approval and all other ethical requirements for research are necessary. These situations require strict oversight as well as explicit consent by the patient.⁸² In particular, when developing new and innovative techniques, the surgeon should work in close consultation with his or her senior colleagues, including the chairperson of the department. Frequently, more senior individuals can provide sage ethical advice regarding what constitutes minor innovative changes in a technique vs. true novel research.

When compared to the formalized process for new drug approval by the Food and Drug Administration, the process for a surgeon developing an innovative operation is relatively unregulated and unsupervised.

Clinical Ethics: Disclosure of Errors

Disclosure of error—either in medical or research matters—is important, but often difficult (see Chap. 12). Errors of judgment, errors in technique, and system errors are responsible for most errors that result in complications and deaths. Hospitals are evaluated based on the number of complications and deaths that occur in surgical patients, and surgeons traditionally review their complications and deaths in a formal exercise known as the *mortality and morbidity conference*, or *M&M*. The exercise places importance on the attending surgeon's responsibility for errors made, whether he or she made them themselves, and the value of the exercise is related to the effect of "peer pressure"—the entire department knows about the case—on reducing repeated occurrences of such an error. Although a time-honored ritual in surgery, the M&M conference is nonetheless a poor method for analyzing causes of error and for developing methods to prevent them. Moreover, the proceedings of the M&M conference are protected from disclosure by the privilege of "peer review," and the details are rarely shared with patients or those outside of the department.

A report from the United States Institute of Medicine titled "To Err Is Human" highlighted the large number of medical errors

that occur and encouraged efforts to prevent patient harm.⁸³ Medical errors are generally considered to be "preventable adverse medical events."⁸⁴ Given that medical errors clearly occur with some frequency, the question becomes what and how should patients be told of medical errors and what is the surgeon's ethical responsibility for this disclosure.⁸⁵

Disclosure of error is consistent with the ethical tenets of openness with patients and the involvement of patients in their care. In contrast, failing to disclose errors to patients undermines public trust in medicine and potentially compromises the treatment of the consequences of errors. In addition, failure to self-disclose medical errors can be construed as a breach of professional ethics, as it is a failure to act solely for the patient's best interests. Patients require information regarding medical errors so that additional harm can be avoided. In addition, information regarding a medical error may be needed so that patients can make independent and well-informed decisions about future aspects of their care. The principles of autonomy and justice dictate that surgeons need to respect individuals by being fair in providing accurate information about all aspects of their care—even the medical errors.

Disclosing one's own errors is therefore part of the ethical standard of honesty and putting the patient's interests above one's own. Disclosing the errors of others is more complicated and may require careful consideration and consultation. Surgeons sometimes discover that a prior operation has included an apparent error; an injured bile duct or a stenotic anastomosis may lead to the condition for which the surgeon is now treating the patient. Declaring a finding as an "error" may be inaccurate, however, and a nonjudgmental assessment of the situation is usually advisable. When clear evidence of a mistake is at hand, the surgeon's responsibility is defined by his or her obligation to act as the patient's agent.
