Multiple etiologies for inflammatory bowel disease have been proposed, but none are proven. The consistent geographic differences in incidence suggest an environmental factor such as diet or infection. Smoking, alcohol, and oral contraceptive use also have been implicated. Family history may play a role because 10 to 30% of patients with inflammatory bowel disease report a family member with the same disease.³³ Other theories focus on an autoimmune mechanism and/or a defect in the intestinal immune system. Although there is general agreement that interaction among the immune system, the mucosal barrier of the gut, and a variety of infectious agents is involved in the pathogenesis of inflammatory bowel disease, the mechanism(s) by which these interactions produce disease is poorly understood.³⁴ Bacteria such as *Mycobacterium paratuberculosis* and *Listeria monocytogenes*, and viruses such as paramyxovirus and measles virus, have been suggested as etiologic agents in Crohn's disease. A defect in the gut mucosal barrier, which increases exposure to intraluminal bacteria, toxins, or proinflammatory substances, also has been suggested. Finally, an autoimmune mechanism has been postulated. Although there is no clear evidence linking an immunologic disorder to inflammatory bowel disease, the similarity of many of the extraintestinal manifestations to rheumatologic disorders has made this theory attractive. Regardless of the underlying cause of either ulcerative colitis or Crohn's disease, both disorders are characterized by intestinal inflammation and medical therapy is largely based upon reducing inflammation.

PATHOLOGY AND DIFFERENTIAL DIAGNOSIS

Although ulcerative colitis and Crohn's colitis share many pathologic and clinical similarities, these conditions may be differentiated in 85% of patients. Ulcerative colitis is a mucosal process in which the colonic mucosa and submucosa are infiltrated with inflammatory cells. The mucosa may be atrophic and crypt abscesses are common. Endoscopically, the mucosa is frequently friable and may possess multiple inflammatory pseudopolyps. In long-standing ulcerative colitis, the colon may be foreshortened and the mucosa replaced by scar. In quiescent ulcerative colitis, the colonic mucosa may appear normal endoscopically and microscopically. Ulcerative

colitis may affect the rectum (proctitis), rectum and sigmoid colon (proctosigmoiditis), rectum and left colon (left-sided colitis), or the rectum and entire colon (pancolitis). Ulcerative colitis does not involve the small intestine, but the terminal ileum may demonstrate inflammatory changes ("backwash ileitis"). A key feature of ulcerative colitis is the continuous involvement of the rectum and colon; rectal sparing or skip lesions suggest a diagnosis of Crohn's disease. Symptoms are related to the degree of mucosal inflammation and the extent of colitis. Patients typically complain of bloody diarrhea and crampy abdominal pain. Proctitis may produce tenesmus. Severe abdominal pain and fever raises the concern of *fulminant colitis* or *toxic megacolon*. Physical findings are nonspecific and range from minimal abdominal tenderness and distention to frank peritonitis. In the nonemergent setting, the diagnosis typically is made by colonoscopy and mucosal biopsy.

In contrast to ulcerative colitis, Crohn's disease is a transmural inflammatory process that can affect any part of the GI tract from mouth to anus. Mucosal ulcerations, an inflammatory cell infiltrate, and noncaseating granulomas are characteristic pathologic findings. Chronic inflammation may ultimately result in fibrosis, strictures, and fistulas in either the colon or small intestine. The endoscopic appearance of Crohn's colitis is characterized by deep serpiginous ulcers and a "cobblestone" appearance. Skip lesions and rectal sparing are common. Symptoms of Crohn's disease depend upon the severity of inflammation and/or fibrosis and the location of inflammation in the GI tract. Acute inflammation may produce diarrhea, crampy abdominal pain, and fever. Strictures may produce symptoms of obstruction. Weight loss is common, both because of obstruction and from protein loss. Perianal Crohn's disease may present with pain, swelling, and drainage from fistulas or abscesses. Physical findings are also related to the site and severity of disease.

In 15% of patients with colitis from inflammatory bowel disease, differentiation of ulcerative colitis from Crohn's colitis proves impossible either grossly or microscopically (indeterminate colitis). These patients typically present with symptoms similar to ulcerative colitis. Endoscopic and pathologic findings usually include features common to both diseases.

Further differential diagnoses include infectious colitides, especially *Campylobacter jejuni*, *Entamoeba histolytica*, *C. difficile*, *Neisseria gonococcus*, *Salmonella*, and *Shigella* species.

EXTRAINTESTINAL MANIFESTATIONS

The liver is a common site of extracolonic disease in inflammatory bowel disease. Fatty infiltration of the liver is present in 40 to 50% of patients and cirrhosis is found in 2 to 5%. Fatty infiltration may be reversed by medical or surgical treatment of colonic disease, but cirrhosis is irreversible. Primary sclerosing cholangitis is a progressive disease characterized by intra- and extrahepatic bile duct strictures. Forty to 60% of patients with primary sclerosing cholangitis have ulcerative colitis. Colectomy will not reverse this disease, and the only effective therapy is liver transplantation. Pericholangitis also is associated with inflammatory bowel disease and may be diagnosed with a liver biopsy. Bile duct carcinoma is a rare complication of long-standing inflammatory bowel disease. Patients who develop bile duct carcinoma in the presence of inflammatory bowel disease are, on average, 20 years younger than other patients with bile duct carcinoma.

Arthritis is also a common extracolonic manifestation of inflammatory bowel disease, and the incidence is 20 times greater than in the general population. Arthritis usually improves with treatment of the colonic disease. Sacroiliitis and ankylosing spondylitis are associated with inflammatory bowel disease, although the relationship is poorly understood. Medical and surgical treatment of the colonic disease does not impact symptoms.

Erythema nodosum is seen in 5 to 15% of patients with inflammatory bowel disease and usually coincides with clinical disease activity. Women are affected three to four times more frequently than men. The characteristic lesions are raised, red, and predominantly on the lower legs. Pyoderma gangrenosum is an uncommon but serious condition that occurs almost exclusively in patients with inflammatory bowel disease. The lesion begins as an erythematous plaque, papule, or bleb, usually located on the pretibial region of the leg and occasionally near a stoma. The lesions progress and ulcerate, leading to a painful, necrotic wound. Pyoderma gangrenosum may respond to resection of the affected bowel in some patients. In others, this disorder is unaffected by treatment of the underlying bowel disease.

Up to 10% of patients with inflammatory bowel disease will develop ocular lesions. These include uveitis, iritis, episcleritis, and conjunctivitis. They usually develop during an acute exacerbation of the inflammatory bowel disease. The etiology is unknown.

PRINCIPLES OF NONOPERATIVE MANAGEMENT

Medical therapy for inflammatory bowel disease focuses on decreasing inflammation and alleviating symptoms, and many of the agents used are the same for both ulcerative colitis and Crohn's disease. In general, mild to moderate flares may be treated in the outpatient setting. More severe signs and symptoms mandate hospitalization. Pancolitis generally requires more aggressive therapy than limited disease. Because ulcerative proctitis and proctosigmoiditis are limited to the distal large intestine, topical therapy with salicylate and/or corticosteroid suppositories and enemas can be extremely effective. Systemic therapy rarely is required in these patients.

Salicylates

Sulfasalazine (Azulfidine), 5-ASA, and related compounds are first-line agents in the medical treatment of mild to moderate inflammatory bowel disease. These compounds decrease inflammation by inhibition of cyclooxygenase and 5-lipoxygenase in the gut mucosa. They require direct contact with affected mucosa for efficacy. Multiple preparations are available for administration to different sites in the small intestine and colon [sulfasalazine, mesalamine (Pentasa), Asacol, Rowasa, Canasa].

Antibiotics

Antibiotics often are used to decrease the intraluminal bacterial load in Crohn's disease. Metronidazole has been reported to improve Crohn's colitis and perianal

disease, but the evidence is weak. Fluoroquinolones also may be effective in some cases. In the absence of fulminant colitis or toxic megacolon, antibiotics are not used to treat ulcerative colitis.

Corticosteroids

Corticosteroids (either oral or parenteral) are a key component of treatment for an acute exacerbation of either ulcerative colitis or Crohn's disease. Corticosteroids are nonspecific inhibitors of the immune system and 75 to 90% of patients will improve with the administration of these drugs. However, corticosteroids have a number of serious side effects and use of these agents should be limited to the shortest course possible. In addition, corticosteroids should be used judiciously in children because of the potential adverse effect on growth. Failure to wean corticosteroids is a relative indication for surgery.

Because of the systemic effects of corticosteroids, an effort has been made to develop drugs that act locally and have limited systemic absorption. Newer agents such as budesonide, beclomethasone dipropionate, and tixocortol pivalate undergo rapid hepatic degradation that significantly decreases systemic toxicity. Budesonide is available as an oral preparation. Corticosteroid enemas provide effective local therapy for proctitis and proctosigmoiditis and have fewer side effects than systemic corticosteroids.

Immunosuppressive Agents

Azathioprine and 6-mercaptopurine are antimetabolite drugs that interfere with nucleic acid synthesis and thus decrease proliferation of inflammatory cells. These agents are useful for treating ulcerative colitis and Crohn's disease in patients who have failed salicylate therapy or who are dependent upon or refractory to corticosteroids. It is important to note, however, that the onset of action of these drugs takes 6 to 12 weeks, and concomitant use of corticosteroids almost always is required.³⁴

Cyclosporine is an immunosuppressive agent that interferes with T-cell function. Although cyclosporine is not routinely used to treat inflammatory bowel disease, up to 80% of patients with an acute flare of ulcerative colitis will improve with its use. However, the majority of these patients will ultimately require colectomy. Cyclosporine also occasionally is used to treat exacerbations of Crohn's disease and approximately two thirds of patients will note some improvement. Improvement generally is apparent within 2 weeks of beginning cyclosporine therapy. Long-term use of cyclosporine is limited by its significant toxicity.

Methotrexate is a folate antagonist that also has been used to treat inflammatory bowel disease. Although the efficacy of this agent is unproven, there are reports that more than 50% of patients will improve with administration of this drug.³⁵

Infliximab (Remicade) is a monoclonal antibody against tumor necrosis factor alpha. IV infusion of this agent decreases inflammation systemically. More than 50% of patients with moderate to severe Crohn's disease will improve with infliximab therapy.³⁶ This agent also has been useful in treating patients with perianal Crohn's disease. Recurrence is common, however, and many patients require infusions on a bimonthly basis. Infliximab has not been used as extensively for treatment of ulcerative colitis; however, there are reports of efficacy in this setting.^{37,38} Other monoclonal antibody agents have been developed and are now being used in clinical trials in patients with inflammatory bowel disease.

Nutrition

Patients with inflammatory bowel disease often are malnourished. Abdominal pain and obstructive symptoms may decrease oral intake. Diarrhea can cause significant protein loss. Ongoing inflammation produces a catabolic physiologic state. Parenteral nutrition should be strongly considered early in the course of therapy for either Crohn's disease or ulcerative colitis. The nutritional status of the patient also should be considered when planning operative intervention and nutritional parameters such as serum albumin, prealbumin, and transferrin should be assessed. In extremely malnourished patients, especially those who also are being treated with corticosteroids, creation of a stoma often is safer than a primary anastomosis.

Ulcerative Colitis

Ulcerative colitis is a dynamic disease characterized by remissions and exacerbations. The clinical spectrum ranges from an inactive or quiescent phase to low-grade active disease to fulminant disease. The onset of ulcerative colitis may be insidious, with minimal bloody stools, or the onset can be abrupt, with severe diarrhea and bleeding, tenesmus, abdominal pain, and fever. The severity of symptoms depends upon the degree and extent of inflammation. Although anemia is common, massive hemorrhage is rare. Physical findings often are nonspecific.

Diagnosis of ulcerative colitis almost always is made endoscopically. Because the rectum is invariably involved, proctoscopy may be adequate to establish the diagnosis. The earliest manifestation is mucosal edema, which results in a loss of the normal vascular pattern. In more advanced disease, characteristic findings include mucosal friability and ulceration. Pus and mucus also may be present. Although mucosal biopsy often is diagnostic in the chronic phase of ulcerative colitis, biopsy in the acute phase often will reveal only nonspecific inflammation. A complete evaluation with colonoscopy or barium enema during an acute flare is contraindicated because of the risk of perforation.

Barium enema has been used to diagnose ulcerative colitis and to determine the extent of disease. However, this modality is less sensitive than colonoscopy and may not detect early disease. In long-standing ulcerative colitis, the colon is foreshortened and lacks haustral markings ("lead pipe" colon). Because the inflammation in ulcerative colitis is purely mucosal, strictures are highly uncommon. Any stricture diagnosed in a patient with ulcerative colitis must be presumed to be malignant until proven otherwise.

INDICATIONS FOR SURGERY

Indications for surgery in ulcerative colitis may be emergent or elective. Emergency surgery is required for patients with massive life-threatening *hemorrhage*, *toxic megacolon*, or *fulminant colitis* who fail to respond rapidly to medical therapy. Patients with signs and symptoms of fulminant colitis should be treated aggressively with bowel rest, hydration, broad-spectrum antibiotics, and parenteral corticosteroids. Colonoscopy and barium enema are contraindicated, and antidiarrheal agents should be avoided. Deterioration in clinical condition or failure to improve within 24 to 48 hours mandates surgery.

Indications for elective surgery include intractability despite maximal medical therapy and high-risk development of major complications of medical therapy, such as aseptic necrosis of joints secondary to chronic steroid use. Elective surgery also is indicated in patients at significant risk of developing colorectal carcinoma. Risk of malignancy increases with pancolonic disease and the duration of symptoms is approximately 2% after 10 years, 8% after 20 years, and 18% after 30 years. Unlike sporadic colorectal cancers, carcinoma developing in the context of ulcerative colitis is more likely to arise from areas of *flat dysplasia* and may be difficult to diagnose at an early stage. For this reason, it is recommended that patients with long-standing ulcerative colitis undergo colonoscopic surveillance with multiple (40 to 50), random biopsies to identify dysplasia before invasive malignancy develops. However, the adequacy of this type of screening is controversial. Recently, magnifying chromoendoscopy has been used to improve sensitivity.^{39,40} This technique uses topical dyes that are applied to the colonic mucosa at the time of endoscopy (Lugol's solution, methylene blue, indigo carmine, and others). These dyes highlight contrast between normal and dysplastic epithelium, allowing more precise biopsy of suspicious areas.⁴¹ Surveillance is recommended annually after 8 years in patients with pancolitis, and annually after 15 years in patients with left-sided colitis. Although low-grade dysplasia was long thought to represent minimal risk, more recent studies show that invasive cancer may be present in up to 20% of patients with low-grade dysplasia. For this reason, any patient with dysplasia should be advised to undergo proctocolectomy. Controversy exists over whether prophylactic proctocolectomy should be recommended for patients who have had chronic ulcerative colitis for >10 years in the absence of dysplasia. Proponents of this approach note that surveillance colonoscopy with multiple biopsies samples only a small fraction of the colonic mucosa and dysplasia and carcinoma are often missed. Opponents cite the relatively low risk of progression to carcinoma if all biopsies have lacked dysplasia (approximately 2.4%). Neither approach has been definitively shown to decrease mortality from colorectal cancer.

OPERATIVE MANAGEMENT

Emergent Operation

In a patient with fulminant colitis or toxic megacolon, total abdominal colectomy with end ileostomy, rather than total proctocolectomy, is recommended. Although the rectum is invariably diseased, most patients improve dramatically after an abdominal colectomy, and this operation avoids a difficult and time-consuming pelvic dissection in a critically ill patient. Rarely, a loop ileostomy and decompressing colostomy may be necessary if the patient is too unstable to withstand colectomy. Definitive surgery may then be undertaken at a later date once the patient has recovered. Complex techniques such as an ileal pouch anal reconstruction generally are contraindicated in the emergent setting. However, massive hemorrhage that includes bleeding from the rectum may necessitate proctectomy and either a permanent ileostomy or ileal pouch anal anastomosis.

Elective Operation

In the past, *abdominal colectomy with ileorectal anastomosis* often was recommended for patients with relatively quiescent rectal disease. The risk of ongoing inflammation, the risk of malignancy, and the availability of restorative proctocolectomy have led most surgeons to now recommend elective operations that include resection of the rectum. Abdominal colectomy with ileorectal anastomosis is still an appropriate operation for a patient with indeterminate colitis and rectal sparing. *Total proctocolectomy with end ileostomy* has been the "gold standard" for patients with chronic ulcerative colitis. This operation removes the entire affected intestine and avoids the functional disturbances associated with ileal pouch–anal reconstruction. Most patients function well physically and psychologically after this operation. *Total proctocolectomy with continent ileostomy (Kock's pouch)* was developed to improve function and quality of life after total proctocolectomy, but morbidity is significant and restorative proctocolectomy generally is preferred today. Since its reintroduction in 1980, *restorative proctocolectomy with ileal pouch–anal anastomosis* has become the procedure of choice for most patients who require total proctocolectomy but wish to avoid a permanent ileostomy (see Figs. 29-11 and 29-12).¹⁸

Crohn's Disease

Like ulcerative colitis, Crohn's disease is characterized by exacerbations and remissions. Crohn's disease, however, may affect any portion of the intestinal tract, from mouth to anus. Diagnosis may be made by colonoscopy or esophagogastroduodenoscopy, or by barium small bowel study or enema, depending upon which part of the intestine is most affected. Skip lesions are key in differentiating Crohn's colitis from ulcerative colitis, and rectal sparing occurs in approximately 40% of patients. The most common site of involvement in Crohn's disease is the terminal ileum and cecum (*ileocolic* Crohn's disease), followed by the small bowel, and then by the colon and rectum. Perianal and anal canal Crohn's disease manifest by complex anal fistulas and/or abscesses, anal ulcers, and large skin tags may be the initial site of presentation in up to 4% of cases.

INDICATIONS FOR SURGERY

Because Crohn's disease can affect any part of the GI tract, the therapeutic rationale is fundamentally different from that of ulcerative colitis. Ulcerative colitis may be cured by removal of the affected intestinal segment (the colon and rectum). In Crohn's disease, it is impossible to remove all of the at-risk intestine; therefore, surgical therapy is reserved for complications of the disease.

Crohn's disease may present as an *acute inflammatory* process or as a *chronic fibrotic* process. During the acute inflammatory phase, patients may present with intestinal inflammation complicated by fistulas and/or intra-abdominal abscesses. Maximal medical therapy should be instituted, including anti-inflammatory medications, bowel rest, and antibiotics. Parenteral nutrition should be considered if the patient is malnourished. Most intra-abdominal abscesses can be drained percutaneously with the use of CT scan guidance. Although the majority of these patients will ultimately require surgery to remove the diseased segment of bowel, these interventions allow the patient's condition to stabilize, nutrition to be optimized, and inflammation to decrease before embarking upon a surgical resection.

Chronic fibrosis may result in strictures in any part of the GI tract. Because the fibrotic process is gradual, free perforation proximal to the obstructing stricture is rare, and, instead, adjacent structures "wall off" the site of perforation. The result often is development of enteric and colonic internal fistulas to other segments of intestine and other viscera (bladder, uterus, vagina) and retroperitoneal sites. Chronic strictures almost never improve with medical therapy. Optimal timing for surgery should take into account the patient's underlying medical and nutritional status. Strictures may be treated with *resection* or *stricturoplasty*. Associated fistulas generally require resection of the segment of bowel with active Crohn's disease; the secondary sites of the fistula often are otherwise normal and generally do not require resection after division of the fistula. Simple closure of the secondary fistula site usually suffices.

Once an operation is undertaken for Crohn's disease, several principles should guide intraoperative decision making. In general, a laparotomy for Crohn's disease should be done through a *midline incision* because of the possible need for a stoma. *Laparoscopy* also is increasingly used in this setting. Because many patients with Crohn's disease will require multiple operations, *the length of bowel removed should be minimized*. Bowel should be resected to an area with *grossly normal margins*; frozen sections are not necessary. Finally, a primary anastomosis may be safely created if the patient is medically stable, nutritionally replete, and taking few immunosuppressive medications. *Creation of a stoma should be strongly considered* in any patient who is hemodynamically unstable, septic, malnourished, or receiving high-dose immunosuppressive therapy and in patients with extensive intra-abdominal contamination.

ILEOCOLIC AND SMALL BOWEL CROHN'S DISEASE

The terminal ileum and cecum are involved in Crohn's disease in up to 41% of patients; the small intestine is involved in up to 35% of patients. The most common indications for surgery are *internal fistula or abscess* (30 to 38% of patients) and *obstruction* (35 to 37% of patients). *Psoas abscess* may result from ileocolic Crohn's disease. Sepsis should be controlled with percutaneous drainage of abscess(es) and antibiotics, if possible. Parenteral nutrition may be necessary in patients with chronic obstruction. The extent of resection depends on the amount of involved intestine. Short segments of inflamed small intestine and right colon should be resected and a primary anastomosis created if the patient is stable, nutrition is adequate, and immunosuppression is minimal. Isolated chronic strictures also should be resected. In patients with multiple fibrotic strictures that would require extensive small bowel resection, *stricturoplasty* is a safe and effective alternative to resection. Short strictures are amenable to a transverse stricturoplasty, while longer strictures may be treated with a side-to-side small bowel anastomosis (Fig. 29-18).

Fig. 29-18.

Risk of recurrence after resection for ileocolic and small bowel Crohn's disease is high. More than 50% of patients will experience a recurrence within 10 years, and the majority of these will require a second operation.

CROHN'S COLITIS

Crohn's disease of the large intestine may present as *fulminant colitis* or *toxic megacolon*. In this setting, treatment is identical to treatment of fulminant colitis and toxic megacolon secondary to ulcerative colitis. Resuscitation and medical therapy with bowel rest, broad-spectrum antibiotics, and parenteral corticosteroids should be instituted. If the patient's condition worsens or fails to rapidly improve, total abdominal colectomy with end ileostomy is recommended. An elective proctectomy may be required if the patient has refractory Crohn's proctitis. Alternatively, if the rectum is spared, an ileorectal anastomosis may be appropriate once the patient has recovered.

Other indications for surgery in chronic Crohn's colitis are *intractability*, *complications of medical therapy*, and *risk of or development of malignancy*. Unlike ulcerative colitis, Crohn's colitis may be segmental and rectal sparing often is observed. A segmental colectomy may be appropriate if the remaining colon and/or rectum appear normal. An isolated colonic stricture also may be treated by segmental colectomy. Although it was long thought that Crohn's disease did not increase the risk of colorectal carcinoma, it is now recognized that Crohn's colitis (especially pancolitis) carries nearly the same risk for cancer as ulcerative colitis. Annual surveillance

colonoscopy with multiple biopsies is recommended for patients with long-standing Crohn's colitis (>7 years duration). As in ulcerative colitis, dysplasia is an indication for total proctocolectomy. Ileal pouch–anal reconstruction is not recommended in these patients because of the risk for development of Crohn's disease within the pouch and the high risk of complications—fistula, abscess, stricture, pouch dysfunction, and pouch failure.

ANAL AND PERIANAL CROHN'S DISEASE

Anal and perianal manifestations of Crohn's disease are very common. Anal or perianal disease occurs in 35% of all patients with Crohn's disease. Isolated anal Crohn's disease is uncommon, affecting only 3 to 4% of patients. Detection of anal Crohn's disease, therefore, should prompt evaluation of the remainder of the GI tract.

The most common perianal lesions in Crohn's disease are *skin tags* that are minimally symptomatic. *Fissures* also are common. Typically, a fissure from Crohn's disease is particularly deep or broad and perhaps better described as an anal ulcer. They often are multiple and located in a lateral position rather than anterior or posterior midline as seen in an idiopathic fissure in ano. A classic appearing fissure in ano located laterally should raise the suspicion of Crohn's disease. *Perianal abscess* and *fistulas* are common and can be particularly challenging. Fistulas tend to be complex and often have multiple tracts (Fig. 29-19). *Hemorrhoids* are not more common in patients with Crohn's disease than in the general population, although many patients tend to attribute any anal or perianal symptom to "hemorrhoids."

Fig. 29-19.

Treatment of anal and perianal Crohn's disease focuses on alleviation of symptoms. Perianal skin irritation from diarrhea often responds to medical therapy directed at small bowel or colonic disease. In general, skin tags and hemorrhoids should *not* be excised unless they are extremely symptomatic because of the risk of creating chronic, nonhealing wounds. Fissures may respond to local or systemic therapy; sphincterotomy is relatively contraindicated because of the risk of creating a chronic, nonhealing wound, and because of the increased risk of incontinence in a patient with diarrhea from underlying colitis or small bowel disease. Anal ulcers associated with Crohn's disease usually are not very painful unless there is an underlying abscess. Thus, in patients with significant anal pain, an examination under anesthesia is indicated to exclude an underlying abscess or fistula and to assess the rectal mucosa. In the absence of active Crohn's proctitis, one can proceed cautiously with a partial internal sphincterotomy if the examination under anesthesia reveals a classic-appearing posterior or anterior fissure and anal stenosis.

Recurrent abscess(es) or complex anal fistulas should raise the possibility of Crohn's disease. Treatment focuses on *control of sepsis*, *delineation of complex anatomy*, *treatment of underlying mucosal disease*, and *sphincter preservation*. Abscesses often can be drained locally, and mushroom catheters are useful for maintaining drainage. Endoanal ultrasound and pelvic MRI are useful for mapping complex fistulous tracts. Liberal use of setons can control many fistulas and avoid division of the sphincter. Many patients with anal Crohn's disease function well with multiple setons left in place for years. Endoanal advancement flaps may be considered for definitive therapy if the rectal mucosa is uninvolved. In 10 to 15% of cases, intractable perianal sepsis requires proctectomy.

Rectovaginal fistula can be a particularly difficult problem in these patients. A rectal or vaginal mucosal advancement flap may be used if the rectal mucosa appears

healthy and scarring of the rectovaginal septum is minimal. Occasionally, proctectomy is the best option for women with highly symptomatic rectovaginal fistula. Although proximal diversion often is used to protect complex perianal reconstruction, there is no evidence that diversion alone increases healing of anal and perianal Crohn's disease.

Medical treatment of underlying proctitis with salicylate and/or corticosteroid enemas may be helpful; however, control of sepsis is the primary goal of therapy. Metronidazole also has been used with some success in this setting. Infliximab and other similar monoclonal antibody agents have shown some efficacy in healing chronic fistulas secondary to Crohn's disease. The success of infliximab has led to a concerted effort to identify other immunomodulators that might prove useful. Proinflammatory cytokines such as interleukin-12 and interferon- γ are potential targets. Inhibition of immune cell migration also has been suggested as an approach.⁴² However, it is of paramount importance to drain any and all abscesses before initiating immunosuppressive therapy such as corticosteroids or infliximab.

Indeterminate Colitis

Approximately 15% of patients with inflammatory bowel disease manifest clinical and pathologic characteristics of both ulcerative colitis and Crohn's disease. Endoscopy, barium enema, and biopsy may be unable to differentiate ulcerative colitis from Crohn's colitis in this setting. The indications for surgery are the same as those for ulcerative colitis: *intractability, complications of medical therapy, and risk of or development of malignancy* . In the setting of indeterminate colitis in a patient who prefers a sphincter-sparing operation, a *total abdominal colectomy with end ileostomy* may be the best initial procedure. Pathologic examination of the entire colon may then allow a more accurate diagnosis. If the diagnosis suggests ulcerative colitis, an ileal pouch–anal anastomosis procedure can be performed. If the diagnosis remains in question, the safest surgical option is completion proctectomy with end ileostomy (similar to Crohn's colitis). Ileal pouch–anal reconstruction also may be considered with the understanding that the pouch failure rate is between 15 and 20%.

DIVERTICULAR DISEASE

Diverticular disease is a clinical term used to describe the presence of symptomatic diverticula. *Diverticulosis* refers to the presence of diverticula without inflammation. *Diverticulitis* refers to inflammation and infection associated with diverticula. The majority of colonic diverticula are *false diverticula* in which the mucosa and muscularis mucosa have herniated through the colonic wall. These diverticula occur between the taeniae coli, at points where the main blood vessels penetrate the colonic wall (presumably creating an area of relative weakness in the colonic muscle). They are thought to be *pulsion* diverticula resulting from high intraluminal pressure. *Diverticular bleeding* can be massive, but usually is self limited. *True diverticula*, which comprise all layers of the bowel wall, are rare and are usually congenital in origin.

Diverticulosis is extremely common in the United States and Europe. It is estimated that half of the population older than age 50 years has colonic diverticula. The sigmoid colon is the most common site of diverticulosis (Fig. 29-20). Diverticulosis is thought to be an acquired disorder, but the etiology is poorly understood. The most accepted theory is that a lack of dietary fiber results in smaller stool volume, requiring high intraluminal pressure and high colonic wall tension for propulsion. Chronic contraction then results in muscular hypertrophy and development of the process of segmentation in which the colon acts like separate segments instead of functioning as a continuous tube. As segmentation progresses, the high pressures are directed radially toward the colon wall rather than to development of propulsive waves that move stool distally. The high radial pressures directed against the bowel wall create pulsion diverticula. A loss of tensile strength and a decrease in elasticity of the bowel wall with age also have been proposed etiologies. While none of these theories has been proven, a high-fiber diet does appear to decrease the incidence of diverticulosis. Although diverticulosis is common, most cases are asymptomatic and complications occur in the minority of people with this condition.

Inflammatory Complications (Diverticulitis)

Diverticulitis refers to inflammation and infection associated with a diverticulum and is estimated to occur in 10 to 25% of people with diverticulosis. Peridiverticular and pericolic infection results from a perforation (either macroscopic or microscopic) of a diverticulum, which leads to contamination, inflammation, and infection. The spectrum of disease ranges from mild, uncomplicated diverticulitis that can be treated in the outpatient setting, to free perforation and diffuse peritonitis that requires emergency laparotomy. Most patients present with left-sided abdominal pain, with or without fever, and leukocytosis. A mass may be present. Plain radiographs are useful for detecting free intra-abdominal air. CT scan is extremely useful for defining pericolic inflammation, phlegmon, or abscess. Contrast enemas and/or endoscopy are relatively contraindicated because of the risk of perforation. The differential diagnosis includes malignancy, ischemic colitis, infectious colitis, and inflammatory bowel disease.

UNCOMPLICATED DIVERTICULITIS

Uncomplicated diverticulitis is characterized by left lower quadrant pain and tenderness. CT findings include pericolic soft tissue stranding, colonic wall thickening, and/or phlegmon. Most patients with uncomplicated diverticulitis will respond to outpatient therapy with broad-spectrum oral antibiotics and a low-residue diet. Antibiotics should be continued for 7 to 10 days. About 10 to 20% of patients with more severe pain, tenderness, fever, and leukocytosis are treated in the hospital with parenteral antibiotics and bowel rest. Most patients improve within 48 to 72 hours. Failure to improve may suggest abscess formation. CT can be extremely useful in this setting and many pericolic abscesses can be drained percutaneously (see below in Complicated Diverticulitis). Deterioration in a patient's clinical condition and/or the development of peritonitis are indications for laparotomy.

Most patients with uncomplicated diverticulitis will recover without surgery, and 50 to 70% will have no further episodes. However, the risk of complications increases with recurrent disease. For this reason, elective sigmoid colectomy often is recommended after the second episode of diverticulitis, especially if the patient has required hospitalization. Resection often has been recommended after the first episode in very young patients and often is recommended after the first episode of *complicated diverticulitis*. These general guidelines have been questioned in recent years. Many surgeons now will not advise colectomy even after two documented episodes of diverticulitis assuming the patient is completely asymptomatic and that carcinoma has been excluded by colonoscopy. Immunosuppressed patients generally are still advised to undergo colectomy after a single episode of documented diverticulitis. Medical comorbidity should be considered when evaluating a patient for elective resection, and the risks of recurrent disease weighed against the risks of the operation. Because colon carcinoma may have an identical clinical presentation to diverticulitis (either complicated or uncomplicated), all patients must be evaluated for malignancy after resolution of the acute episode. Sigmoidoscopy or colonoscopy is recommended 4 to 6 weeks after recovery. Inability to exclude malignancy is another indication for resection.

In the elective setting, a *sigmoid colectomy with a primary anastomosis* is the procedure of choice. The resection should always be extended to the rectum distally because the risk of recurrence is high if a segment of sigmoid colon is retained. The proximal extent of the resection should include all thickened or inflamed bowel; however, resection of all diverticula is unnecessary. Increasingly, laparoscopy is being used for elective sigmoid colectomy for diverticular disease.

COMPLICATED DIVERTICULITIS

Complicated diverticulitis includes diverticulitis with abscess, obstruction, diffuse peritonitis (free perforation), or fistulas between the colon and adjacent structures. Colovesical, colovaginal, and coloenteric fistulas are long-term sequelae of complicated diverticulitis. The *Hinchey staging system* often is used to describe the severity of complicated diverticulitis: Stage I includes colonic inflammation with an associated pericolic abscess; stage II includes colonic inflammation with a retroperitoneal or pelvic abscess; stage III is associated with purulent peritonitis; and stage IV is associated with fecal peritonitis. Treatment depends on the patient's overall clinical condition and the degree of peritoneal contamination and infection. Small abscesses (<2 cm diameter) may be treated with parenteral antibiotics. Larger abscesses are best treated with CT-guided percutaneous drainage (Fig. 29-21).⁴³ The majority of these patients will ultimately require resection, but percutaneous drainage may allow a one-stage, elective procedure and may obviate the need for colectomy if full recovery follows the drainage.

Urgent or emergent laparotomy may be required if an abscess is inaccessible to percutaneous drainage, if the patient's condition deteriorates or fails to improve, or if the patient presents with free intra-abdominal air or peritonitis. In almost all cases, an attempt should be made to resect the affected segment of bowel. Patients with small, localized pericolic or pelvic abscesses (Hinchey stages I and II) may be candidates for a sigmoid colectomy with a primary anastomosis (a one-stage operation). In patients with larger abscesses, peritoneal soiling, or peritonitis, sigmoid colectomy with end colostomy and Hartmann pouch is the most commonly

used procedure.^{44,45} Success also has been reported after sigmoid colectomy, primary anastomosis, ± on-table lavage, and proximal diversion (loop ileostomy). This option may be appropriate in stable patients and offers the great advantage that the subsequent operation to restore bowel continuity is simpler than is takedown of a Hartmann pouch. The presence of inflammation and phlegmon may increase the risk of ureteral damage during mobilization of the sigmoid colon, and preoperative placement of ureteral catheters can be invaluable. In extremely unstable patients, or in the presence of such severe inflammation that resection would harm adjacent organs, proximal diversion and local drainage have been used. However, this approach generally is avoided because of high morbidity and mortality rates, along with the requirement for multiple operations.

Obstructive symptoms occur in approximately 67% of patients with acute diverticulitis, and complete obstruction occurs in 10%. Patients with incomplete obstruction often respond to fluid resuscitation, nasogastric suction, and gentle, low-volume water or Gastrografin enemas. Relief of obstruction allows full bowel preparation and elective resection. A high-volume oral bowel preparation is contraindicated in the presence of obstructive symptoms. Obstruction that does not rapidly respond to medical management mandates laparotomy. Sigmoid colectomy with end colostomy is the safest procedure to perform in this setting. However, colectomy and primary anastomosis, with or without on-table lavage (depending on extent of fecal load in the proximal colon), and proximal diversion may be appropriate if the patient is stable and the proximal and distal bowel appear healthy.

Approximately 5% of patients with complicated diverticulitis develop fistulas between the colon and an adjacent organ. *Colovesical* fistulas are most common, followed by *colovaginal* and *coloenteric* fistulas. *Colocutaneous* fistulas are a rare complication of diverticulitis. Two key points in the evaluation of fistulas are to *define the anatomy of the fistula* and *exclude other diagnoses*. Contrast enema and/or small bowel studies are extremely useful in defining the course of the fistula. CT scan can identify associated abscesses or masses. The differential diagnosis includes *malignancy*, *Crohn's disease*, and *radiation-induced fistulas*. Although Crohn's disease and radiation injury may be suspected based upon the patient's medical history, colonoscopy or sigmoidoscopy usually is required to rule out malignancy. In addition, in a patient who has received radiation therapy, a fistula must be considered to be recurrent cancer until proven otherwise. Once the anatomy of the fistula has been defined and other diagnoses excluded, operative management should include resection of the affected segment of the colon involved with diverticulitis (usually with a primary anastomosis) and simple repair of the secondarily involved organ. Suspicion of carcinoma may mandate a wider, en bloc resection.

Hemorrhage

Bleeding from a diverticulum results from erosion of the peridiverticular arteriole and may result in massive hemorrhage. Most significant lower GI hemorrhage occurs in elderly patients in whom both diverticulosis and angiodysplasia are common. Consequently, the exact bleeding source may be difficult to identify. Fortunately, in 80% of patients, bleeding stops spontaneously. Clinical management should focus on resuscitation and localization of the bleeding site as described for lower GI hemorrhage. Colonoscopy may occasionally identify a bleeding diverticulum that may then be treated with epinephrine injection or cautery. Angiography may be diagnostic and therapeutic in this setting. In the rare instance in which diverticular hemorrhage persists or recurs, laparotomy and segmental colectomy may be required.

Giant Colonic Diverticulum

Giant colonic diverticula are extremely rare. Most occur on the antimesenteric side of the sigmoid colon. Patients may be asymptomatic or may present with vague abdominal complaints such as pain, nausea, or constipation. Plain radiographs may suggest the diagnosis. Barium enema usually is diagnostic. Complications of a giant diverticulum include perforation, obstruction, and volvulus. Resection of the involved colon and diverticulum is recommended.

Right-Sided Diverticula

The cecum and ascending colon infrequently are involved in diverticulosis coli. Even more uncommon is a true solitary diverticulum, which contains all layers of the bowel wall and is thought to be congenital in origin. Right-sided diverticula occur more often in younger patients than do left-sided diverticula, and are more common in people of Asian descent than in other populations. Most patients with right-sided diverticula are asymptomatic. However, diverticulitis does occur occasionally. Because patients are young and present with right lower quadrant pain, they often are thought to suffer from acute appendicitis, and the diagnosis of right-sided diverticulitis is subsequently made in the operating room. If there is a single large diverticulum and minimal inflammation, a diverticulectomy may be performed, but an ileocecal resection usually is the preferred operation in this setting. Hemorrhage rarely occurs and should be treated in the same fashion as hemorrhage from a left-sided diverticulum.

ADENOCARCINOMA AND POLYPS

Incidence

Colorectal carcinoma is the most common malignancy of the GI tract. Over 150,000 new cases are diagnosed annually in the United States and more than 52,000 patients die of this disease each year, making colorectal cancer the second most lethal cancer in the United States.⁴⁶ The incidence is similar in men and women and has remained fairly constant over the past 20 years. The widespread adoption of current national screening programs should dramatically decrease the incidence of this common and lethal disease. Early detection along with improvements in medical and surgical care are thought to be responsible for the decreasing mortality of colorectal cancer observed in recent years.

Epidemiology (Risk Factors)

Identification of risk factors for development of colorectal cancer is essential to establish screening and surveillance programs in appropriately targeted populations.

AGING

Aging is the dominant risk factor for colorectal cancer, with incidence rising steadily after age 50 years. More than 90% of cases diagnosed are in people older than age 50 years. This is the rationale for initiating screening tests of asymptomatic Americans at average risk of developing colorectal cancer at age 50 years. However, individuals of any age can develop colorectal cancer, so symptoms such as a significant change in bowel habits, rectal bleeding, melena, unexplained anemia, or weight loss require a thorough evaluation.

HEREDITARY RISK FACTORS

Approximately 80% of colorectal cancers occur sporadically, while 20% arise in patients with a known family history of colorectal cancer. Advances in the understanding of these familial disorders have led to interest in early diagnosis using genetic testing. Because of the medical, legal, and ethical considerations that are involved in this type of testing, all patients should be offered genetic counseling if a familial syndrome is suspected.

ENVIRONMENTAL AND DIETARY FACTORS

The observation that colorectal carcinoma occurs more commonly in populations that consume diets high in animal fat and low in fiber has lead to the hypothesis that dietary factors contribute to carcinogenesis. A diet high in saturated or polyunsaturated fats increases risk of colorectal cancer, while a diet high in oleic acid (olive oil, coconut oil, fish oil) does not increase risk. Animal studies suggest that fats may be directly toxic to the colonic mucosa and thus may induce early malignant changes. In contrast, a diet high in *vegetable fiber* appears to be protective. A correlation between alcohol intake and incidence of colorectal carcinoma also has been suggested. Ingestion of calcium, selenium, vitamins A, C, and E, carotenoids, and plant phenols may decrease the risk of developing colorectal cancer. Obesity and sedentary lifestyle dramatically increase cancer-related mortality in a number of malignancies, including colorectal carcinoma. This knowledge is the basis for primary prevention strategies to eliminate colorectal cancer by altering diet and lifestyle.^{47,48}

INFLAMMATORY BOWEL DISEASE

Patients with long-standing colitis from inflammatory bowel disease are at increased risk for the development of colorectal cancer.⁴⁹ It is hypothesized that chronic inflammation predisposes the mucosa to malignant changes and there is some evidence that degree of inflammation influences risk. In general, the duration and extent of colitis correlate with risk. Other factors thought to increase risk include the presence of primary sclerosing cholangitis and family history of colorectal cancer. In ulcerative pancolitis, the risk of carcinoma is approximately 2% after 10 years, 8% after 20 years, and 18% after 30 years. Patients with Crohn's pancolitis have similar risk. Left-sided colitis carries somewhat less risk. For this reason, screening colonoscopy with multiple random mucosal biopsies has been recommended annually after 8 years of disease for patients with pancolitis and after 12 to 15 years of disease for patients with left-sided colitis. It is important to note, however, that intensive surveillance has not definitively been shown to improve survival, and some authors are questioning the efficacy of this approach.

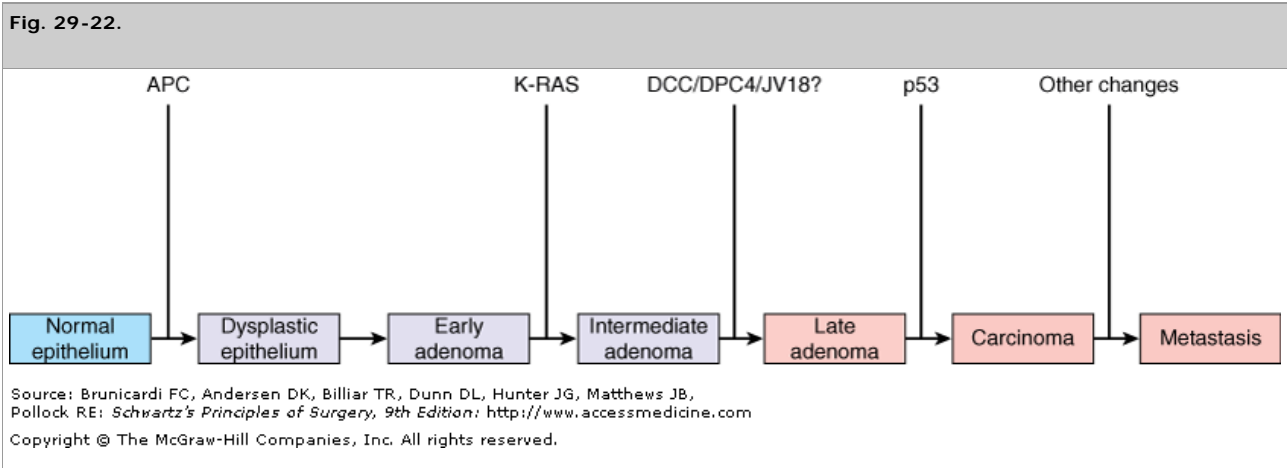

OTHER RISK FACTORS

Cigarette smoking is associated with an increased risk of colonic adenomas, especially after more than 35 years of use. Patients with ureterosigmoidostomy are also at increased risk for both adenoma and carcinoma formation.⁵⁰ Acromegaly, which is associated with increased levels of circulating human growth hormone and insulin-like growth factor I, increases risk as well. Pelvic irradiation may increase the risk of developing rectal carcinoma, although it is unclear if this represents a direct effect of radiation damage or is instead a correlation between the development of rectal cancer and a history of another pelvic malignancy.

Pathogenesis of Colorectal Cancer

GENETIC DEFECTS

Over the past two decades, an intense research effort has focused on elucidating the genetic defects and molecular abnormalities associated with the development and progression of colorectal adenomas and carcinoma. Mutations may cause *activation of oncogenes* (K-ras) and/or *inactivation of tumor-suppressor genes* [APC, DCC (deleted in colorectal carcinoma), p53]. Colorectal carcinoma is thought to develop from adenomatous polyps by accumulation of these mutations (Fig. 29-22).

Schematic showing progression from normal colonic epithelium to carcinoma of the colon.

Defects in the APC gene were first described in patients with *FAP*. By investigating these families, characteristic mutations in the APC gene were identified. They are now known to be present in 80% of sporadic colorectal cancers as well.

The APC gene is a *tumor-suppressor gene*. Mutations in both alleles are necessary to initiate polyp formation. The majority of mutations are premature stop codons, which result in a truncated APC protein. In *FAP*, the site of mutation correlates with the clinical severity of the disease. For example, mutations in either the 3' or 5' end of the gene result in attenuated forms of *FAP*, while mutations in the center of the gene result in more virulent disease. Thus, knowledge of the specific mutation in a family may help guide clinical decision making.

APC inactivation alone does not result in a carcinoma. Instead, this mutation sets the stage for the accumulation of genetic damage that results in malignancy via mutations accumulated in the loss of heterozygosity (LOH) pathway. Additional mutations involved in this pathway include activation of the *K-ras* oncogene, and loss of the tumor-suppressor genes *DCC* and p53.

K-ras is classified as a *proto-oncogene* because mutation of only one allele will perturb the cell cycle. The K-ras gene product is a G protein involved in intracellular signal transduction. When active, K-ras binds guanosine triphosphate (GTP); hydrolysis of GTP to guanosine diphosphate then inactivates the G protein. Mutation of K-ras results in an inability to hydrolyze GTP, thus leaving the G protein permanently in the active form. It is thought that this then leads to uncontrolled cell division.

In 2002, a new mutation in the MYH gene on chromosome 1p was found to be associated with an increased risk of colorectal cancer.⁵¹ MYH is a base excision repair gene, and biallelic deletion results in changes in other downstream molecules. Since its discovery, MYH mutations have been associated with an AFAP phenotype in addition to sporadic cancers.⁵² Unlike APC gene mutations that are expressed in an autosomal dominant pattern, the requirement for biallelic mutation in MYH results in an autosomal recessive pattern of inheritance.

DCC is a tumor-suppressor gene and loss of both alleles is required for malignant degeneration. The role of the DCC gene product is poorly understood. The main role of this molecule appears to be in the central nervous system, where it is involved in differentiation and axonal migration. This observation has led to the hypothesis that DCC may be involved in differentiation and cellular adhesion in colorectal cancer, but this theory remains unproven.⁵³ DCC mutations are present in more than 70% of colorectal carcinomas and may negatively impact prognosis.

The tumor-suppressor gene p53 has been well characterized in a number of malignancies. The p53 protein appears to be crucial for initiating apoptosis in cells with irreparable genetic damage. Mutations in p53 are present in 75% of colorectal cancers.

GENETIC PATHWAYS

Two major pathways for tumor initiation and progression have been described: the *LOH pathway* and the *replication error (RER) pathway*. The LOH pathway is characterized by chromosomal deletions and tumor aneuploidy. Eighty percent of colorectal carcinomas appear to arise from mutations in the LOH pathway. The remaining 20% of colorectal carcinomas are thought to arise from mutations in the RER pathway, which is characterized by errors in mismatch repair during DNA replication. A number of genes have been identified that appear to be crucial for recognizing and repairing DNA RERs. These *mismatch repair genes* include *hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, and *hMSH6/GTBP*. A mutation in one of these genes predisposes a cell to mutations, which may occur in proto-oncogenes or tumor-suppressor genes. Accumulation of these errors then leads to genomic instability and ultimately to carcinogenesis.

The RER pathway is associated with *microsatellite instability* (MSI). Microsatellites are regions of the genome in which short base-pair segments are repeated several times. These areas are particularly prone to RER. Consequently, a mutation in a mismatch repair gene produces variable lengths of these repetitive sequences, a finding that has been described as *microsatellite instability*. Approximately 15% of colorectal cancers are associated with MSI, but most do not have an MMR gene mutation per se. Instead, methylation of the gene promoter causes "silencing" of the gene, resulting in loss of the gene product and a phenotype similar to that present with a true gene mutation.⁹

Tumors associated with MSI appear to have different biologic characteristics than do tumors that result from the LOH pathway. Tumors with MSI are more likely to be right sided, possess diploid DNA, and are associated with a better prognosis than tumors that arise from the LOH pathway that are microsatellite stable. Tumors arising from the LOH pathway tend to occur in the more distal colon, often have chromosomal aneuploidy, and are associated with a poorer prognosis.

Deletion of the tumor suppressor phosphatase and tensin homolog (PTEN) appears to be involved in a number of hamartomatous polyposis syndromes. Deletions in PTEN have been identified in juvenile polyposis, Peutz-Jeghers syndrome, Cowden syndrome, and PTEN-hamartoma syndrome, in addition to multiple endocrine neoplasia IIB.⁹

Polyps

It is now well accepted that the majority of colorectal carcinomas evolve from adenomatous polyps; this sequence of events is the *adenoma–carcinoma sequence*.

Polyp is a nonspecific clinical term that describes any projection from the surface of the intestinal mucosa regardless of its histologic nature. Colorectal polyps may be classified as *neoplastic* (*tubular adenoma*, *villous adenoma*, *tubulovillous adenomas*), *hamartomatous* (*juvenile*, *Peutz-Jeghers*, *Cronkite-Canada*), *inflammatory* (*pseudopolyp*, *benign lymphoid polyp*), or *hyperplastic*.

NEOPLASTIC POLYPS

Adenomatous polyps are common, occurring in up to 25% of the population older than 50 years of age in the United States. By definition, these lesions are

dysplastic. The risk of malignant degeneration is related to both the size and type of polyp. Tubular adenomas are associated with malignancy in only 5% of cases, whereas villous adenomas may harbor cancer in up to 40%. Tubulovillous adenomas are at intermediate risk (22%). Invasive carcinomas are rare in polyps smaller than 1 cm; the incidence increases with size. The risk of carcinoma in a polyp larger than 2 cm is 35 to 50%. Although most neoplastic polyps do not evolve to cancer, most colorectal cancers originate as a polyp. It is this fact that forms the basis for secondary prevention strategies to eliminate colorectal cancer by targeting the neoplastic polyp for removal before malignancy develops.

Polyps may be *pedunculated* or *sessile*. Most pedunculated polyps are amenable to colonoscopic snare excision. Removal of sessile polyps often is more challenging. Special colonoscopic techniques, including saline lift and piecemeal snare excision, facilitate successful removal of many sessile polyps. For rectal sessile polyps, transanal operative excision is preferred because it produces an intact, single pathology specimen that can be used to determine the need for further therapy. Interpretation of the precise depth of invasion of a cancer arising in a sessile polyp after piecemeal excision often is impossible. The site of sessile polypectomies should be marked by injection of methylene blue or India ink to guide follow-up colonoscopy sessions to ensure that the polyp has been completely removed, and to facilitate identification of the involved bowel segment should operative resection be necessary. Colectomy is reserved for cases in which colonoscopic removal is impossible, such as large, flat lesions or if a focus of invasive cancer is confirmed in the specimen. These patients may be ideal candidates for laparoscopic colectomy.

Complications of polypectomy include *perforation* and *bleeding*. A small perforation (*microperforation*) in a fully prepared, stable patient may be managed with bowel rest, broad-spectrum antibiotics, and close observation. Signs of sepsis, peritonitis, or deterioration in clinical condition are indications for laparotomy. Bleeding may occur immediately after polypectomy or may be delayed. The bleeding usually will stop spontaneously, but colonoscopy may be required to re-snare a bleeding stalk or cauterize the lesion. Occasionally, angiography and infusion of vasopressin may be necessary. Rarely, colectomy is required.

HAMARTOMATOUS POLYPS (JUVENILE POLYPS)

In contrast to adenomatous polyps, hamartomatous polyps (juvenile polyps) usually are not premalignant. These lesions are the characteristic polyps of childhood but may occur at any age. Bleeding is a common symptom and intussusception and/or obstruction may occur. Because the gross appearance of these polyps is identical to adenomatous polyps, these lesions should also be treated by polypectomy. In contrast to adenomatous polyposis syndromes, these conditions are often associated with mutation in PTEN.

Familial juvenile polyposis is an autosomal dominant disorder in which patients develop hundreds of polyps in the colon and rectum. Unlike solitary juvenile polyps, these lesions may degenerate into adenomas and, eventually, carcinoma. Annual screening should begin between the ages of 10 and 12 years. Treatment is surgical and depends, in part, upon the degree of rectal involvement. If the rectum is relatively spared, a total abdominal colectomy with ileorectal anastomosis may be performed with subsequent close surveillance of the retained rectum. If the rectum is carpeted with polyps, total proctocolectomy is the more appropriate operation. These patients are candidates for ileal pouch–anal reconstruction to avoid a permanent stoma.

Peutz-Jeghers syndrome is characterized by polyposis of the small intestine and, to a lesser extent, polyposis of the colon and rectum. Characteristic melanin spots often are noted on the buccal mucosa and lips of these patients. The polyps of Peutz-Jeghers syndrome generally are considered to be hamartomas and are not thought to be at significant risk for malignant degeneration. However, carcinoma may occasionally develop. Because the entire length of the GI tract may be affected, surgery is reserved for symptoms such as obstruction or bleeding or for patients in whom polyps develop adenomatous features. Screening consists of a baseline colonoscopy and upper endoscopy at age 20 years, followed by annual flexible sigmoidoscopy thereafter.

Cronkite-Canada syndrome is a disorder in which patients develop GI polyposis in association with alopecia, cutaneous pigmentation, and atrophy of the fingernails and toenails. Diarrhea is a prominent symptom, and vomiting, malabsorption, and protein-losing enteropathy may occur. Most patients die of this disease despite maximal medical therapy, and surgery is reserved for complications of polyposis, such as obstruction.

Cowden syndrome is an autosomal dominant disorder with hamartomas of all three embryonal cell layers. Facial trichilemmomas, breast cancer, thyroid disease, and GI polyps are typical of the syndrome. Patients should be screened for cancers. Treatment is otherwise based upon symptoms.

INFLAMMATORY POLYPS (PSEUDOPOLYPS)

Inflammatory polyps occur most commonly in the context of inflammatory bowel disease, but may also occur after amebic colitis, ischemic colitis, and schistosomal colitis. These lesions are not premalignant, but they cannot be distinguished from adenomatous polyps based upon gross appearance and therefore should be removed. Microscopic examination shows islands of normal, regenerating mucosa (the polyp) surrounded by areas of mucosal loss. Polyposis may be extensive, especially in patients with severe colitis, and may mimic FAP.

HYPERPLASTIC POLYPS

Hyperplastic polyps are extremely common in the colon. These polyps usually are small (<5 mm) and show histologic characteristics of hyperplasia without any dysplasia. They are not considered premalignant, but cannot be distinguished from adenomatous polyps colonoscopically and therefore often are removed. In contrast, large hyperplastic polyps (>2 cm) may have a slight risk of malignant degeneration. Moreover, large polyps may harbor foci of adenomatous tissue and dysplasia. *Hyperplastic polyposis* is a rare disorder in which multiple large hyperplastic polyps occur in young adults. These patients are at slightly increased risk for the development of colorectal cancer.

Inherited Colorectal Carcinoma

Many of the genetic defects originally described in hereditary cancers have subsequently been found in sporadic tumors. Although the majority of colorectal cancer is sporadic, several hereditary syndromes provide paradigms for the study of this disease. Insight gained from studying inherited colorectal cancer syndromes has led to better understanding of the genetics of colorectal carcinoma.

FAMILIAL ADENOMATOUS POLYPOSIS

This rare autosomal dominant condition accounts for only about 1% of all colorectal adenocarcinomas. Nevertheless, this syndrome has provided tremendous insight into the molecular mechanisms underlying colorectal carcinogenesis. The genetic abnormality in FAP is a mutation in the APC gene, located on chromosome 5q. Of patients with FAP, APC mutation testing is positive in 75% of cases. Although most patients with FAP will have a known family history of the disease, up to 25% present without other affected family members. Clinically, patients develop hundreds to thousands of adenomatous polyps shortly after puberty. The lifetime risk of colorectal cancer in FAP patients approaches 100% by age 50 years.

Flexible sigmoidoscopy of first-degree relatives of FAP patients beginning at age 10 to 15 years has been the traditional mainstay of screening. Today, following genetic counseling, APC gene testing may be used to screen family members, providing an APC mutation has been identified in a family member. If APC testing is positive in a relative of a patient with a known APC mutation, annual flexible sigmoidoscopy beginning at age 10 to 15 years is done until polyps are identified. If APC testing is negative, the relative can be screened starting at age 50 years per average-risk guidelines. If APC testing is refused, annual flexible sigmoidoscopy beginning at age 10 to 15 years is performed until age 24 years. Screening flexible sigmoidoscopy is then done every 2 years until age 34 years, every 3 years until age 44 years, and then every 3 to 5 years. If an APC mutation is not found in the family, either APC testing can be done for at-risk family members or traditional screening by flexible sigmoidoscopy can be initiated.

FAP patients also are at risk for the development of adenomas anywhere in the GI tract, particularly in the duodenum. Periampullary carcinoma is a particular concern. Upper endoscopy therefore is recommended for surveillance every 1 to 3 years beginning at age 25 to 30 years.

Once the diagnosis of FAP has been made and polyps are developing, treatment is surgical. Four factors affect the choice of operation: age of the patient; presence and severity of symptoms; extent of rectal polyposis; and presence and location of cancer or desmoid tumors. Three operative procedures can be considered: total proctocolectomy with either an end (Brooke) ileostomy or continent (Kock) ileostomy; total abdominal colectomy with ileorectal anastomosis; and restorative proctocolectomy with ileal pouch–anal anastomosis with or without a temporary ileostomy. Most patients elect to have an ileal pouch–anal anastomosis in the absence of a distal rectal cancer, a mesenteric desmoid tumor that prevents the ileum from reaching the anus or poor sphincter function. Mucosectomy has been advocated in patients with FAP undergoing ileal pouch–anal anastomosis because of the risk of neoplasia in the anal transition zone, but the requirement for this procedure remains controversial. Although patient satisfaction with this procedure remains high, function may not be ideal, and up to 50% of patients experience some degree of incontinence. Total proctocolectomy with continent ileostomy (Kock pouch) has largely been abandoned because of the success of ileal pouch–anal reconstruction. Total abdominal colectomy with an ileorectal anastomosis is also an option in these patients, but requires vigilant surveillance of the retained rectum for development of rectal cancer.⁵⁴ There is increasing data suggesting that the administration of COX-2 inhibitors (celecoxib, sulindac) may slow or prevent the development of polyps.⁵⁵

FAP may be associated with extraintestinal manifestations such as congenital hypertrophy of the retinal pigmented epithelium, desmoid tumors, epidermoid cysts, mandibular osteomas (Gardner's syndrome), and central nervous system tumors (Turcot's syndrome). Desmoid tumors in particular can make surgical management difficult and are a source of major morbidity and mortality in these patients. Desmoid tumors are often hormone responsive and growth may be inhibited in some patients with tamoxifen. COX-2 inhibitors and NSAIDs also may be beneficial in this setting.

ATTENUATED FAP

AFAP is a recently recognized variant of FAP associated with mutations at the 3' or 5' end of the APC gene. Patients present later in life with fewer polyps (usually 10 to 100) dominantly located in the right colon, when compared to classic FAP. Colorectal carcinoma develops in more than 50% of these patients, but occurs later (average age 55 years). Patients are also at risk for duodenal polyposis. However, in contrast to FAP, APC gene mutations are present in only about 30% of patients with AFAP. When present, these mutations are expressed in an autosomal dominant pattern.

Mutations in MYH also result in the AFAP phenotype, but are expressed in an autosomal recessive pattern. It has been suggested that MYH mutations may be responsible for AFAP in patients who do not have a detectable APC gene mutation.⁵³

Genetic testing often is offered to patients with suspected AFAP. When positive, genetic counseling and testing may be used to screen at-risk family members. If the family mutation is unknown, screening colonoscopy is recommended beginning at age 13 to 15 years, then every 4 years to age 28 years, and then every 3 years. These patients are often candidates for a total abdominal colectomy with ileorectal anastomosis because the limited polyposis in the rectum can usually be treated by colonoscopic snare excision. Prophylaxis with COX-2 inhibitors also may be appropriate. Because of the more subtle phenotype in these patients, it is important to rule out other familial syndromes such as hereditary nonpolyposis colon cancer (HNPCC; Lynch syndrome) and more common familial colorectal cancer.⁹

HEREDITARY NONPOLYPOSIS COLON CANCER (LYNCH SYNDROME)

HNPCC (or Lynch syndrome) is more common than FAP, but is still extremely rare (1 to 3%). The genetic defects associated with HNPCC arise from errors in *mismatch repair*, and study of this syndrome has elucidated many of the details of the RER pathway. HNPCC is inherited in an autosomal dominant pattern and is characterized by the development of colorectal carcinoma at an early age (average age: 40 to 45 years). Approximately 70% of affected individuals will develop

colorectal cancer. Cancers appear in the proximal colon more often than in sporadic colorectal cancer and have a better prognosis regardless of stage. The risk of synchronous or metachronous colorectal carcinoma is 40%. HNPCC also may be associated with extracolonic malignancies, including endometrial, which is most common, ovarian, pancreas, stomach, small bowel, biliary, and urinary tract carcinomas. The diagnosis of HNPCC is made based upon family history. The *Amsterdam criteria* for clinical diagnosis of HNPCC are three affected relatives with histologically verified adenocarcinoma of the large bowel (one must be a first-degree relative of one of the others) in two successive generations of a family with one patient diagnosed before age 50 years. The presence of other HNPCC-related carcinomas should raise the suspicion of this syndrome.⁹ In a patient with an established diagnosis of colorectal cancer, tumor testing for presence of MMR gene products (immunohistochemistry) and/or MSI can sometimes serve as screening for this syndrome.

HNPCC results from mutations in mismatch repair genes, and, like FAP, specific mutations are associated with different phenotypes. For example, mutations in PMS2 or MSH6 result in a more attenuated form of HNPCC when compared to mutations in other genes. MSH6 inactivation also appears to be associated with a higher risk for endometrial cancer.⁵⁶ Further significance of these specific mutations remains to be determined.

Screening colonoscopy is recommended annually for at-risk patients beginning at either age 20 to 25 years or 10 years younger than the youngest age at diagnosis in the family, whichever comes first.⁵⁷ Because of the high risk of endometrial carcinoma, transvaginal ultrasound or endometrial aspiration biopsy also is recommended annually after age 25 to 35 years. Because there is a 40% risk of developing a second colon cancer, total colectomy with ileorectal anastomosis is recommended once adenomas or a colon carcinoma is diagnosed, or if prophylactic colectomy is decided upon. Annual proctoscopy is necessary because the risk of developing rectal cancer remains high. Similarly, prophylactic hysterectomy and bilateral salpingo-oophorectomy should be considered in women who have completed childbearing.

FAMILIAL COLORECTAL CANCER

Nonsyndromic familial colorectal cancer accounts for 10 to 15% of patients with colorectal cancer. The lifetime risk of developing colorectal cancer increases with a family history of the disease. The lifetime risk of colorectal cancer in a patient with no family history of this disease (average-risk population) is approximately 6%, but rises to 12% if one first-degree relative is affected and to 35% if two first-degree relatives are affected. Age of onset also impacts risk and a diagnosis before the age of 50 years is associated with a higher incidence in family members. Screening colonoscopy is recommended every 5 years beginning at age 40 years or beginning 10 years before the age of the earliest diagnosed patient in the pedigree. Although there are no specific genetic abnormalities that are associated with familial colorectal cancer, any of the defects found in either the LOH pathway or RER pathway may be present in these patients.

Prevention: Screening and Surveillance

Because the majority of colorectal cancers are thought to arise from adenomatous polyps, preventive measures focus upon identification and removal of these premalignant lesions. In addition, many cancers are asymptomatic and screening may detect these tumors at an early and curable stage (Table 29-1). Although screening for colorectal cancer decreases the incidence of cancer and cancer-related mortality, the optimal method of screening remains controversial. Screening guidelines are meant for *asymptomatic* patients.^{58–60} Any patient with a GI complaint (bleeding, change in bowel habits, pain, etc.) requires a complete evaluation, usually by colonoscopy.

Table 29-1 Advantages and Disadvantages of Screening Modalities for Asymptomatic Individuals		
	Advantages	Disadvantages
Fecal occult blood testing	Ease of use and noninvasive	May not detect most polyps
	Low cost	Low specificity
	Good sensitivity with repeat testing	Colonoscopy required for positive result
		Poor compliance with serial testing
Sigmoidoscopy	Examines colon most at risk	Invasive
	Very sensitive for polyp detection in left colon	Uncomfortable
		Slight risk of perforation or bleeding
	Does not require full bowel preparation (enemas only)	May miss proximal lesions
Colonoscopy		Colonoscopy required if polyp identified
	Examines entire colon	Most invasive
	Highly sensitive and specific	Uncomfortable and requires sedation
	Therapeutic	Requires bowel preparation
		Risk of perforation or bleeding
Double-contrast barium enema		Costly
	Examines entire colon	Requires bowel preparation
	Good sensitivity for polyps >1 cm	Less sensitivity for polyps <1 cm
		May miss lesions in the sigmoid colon
		Colonoscopy required for positive result
Computed tomographic colonography (virtual colonoscopy)	Examines entire colon	Requires bowel preparation
	Noninvasive	Insensitive for small polyps

	Sensitivity may be as good as colonoscopy	Minimal experience and data
		Colonoscopy required for positive result
		Costly

FECAL OCCULT BLOOD TESTING

The University of Minnesota Colon Cancer Control Study, a large, prospective, randomized trial, was the first of several large studies to conclude that FOBT screening reduces colorectal cancer mortality by 33% and metastatic cases by 50%. However, FOBT is relatively insensitive, missing up to 50% of cancers and the majority of adenomas. Its specificity is low because 90% of patients with positive tests do not have colorectal cancer. Compliance with annual testing is low and costs are significant if one includes the colonoscopy examinations done to evaluate patients with positive FOBT. Nonetheless, the direct evidence that FOBT screening is efficacious and decreases both the incidence and mortality of colorectal cancer is so strong that national guidelines recommend annual FOBT screening for asymptomatic, average-risk Americans older than 50 years of age as one of several accepted strategies. As noted earlier under Clinical Evaluation, newer immunohistochemical methods for detecting human globin may prove to be more sensitive and specific.⁶¹ A positive FOBT test should be followed by colonoscopy.

FLEXIBLE SIGMOIDOSCOPY

Screening by flexible sigmoidoscopy every 5 years may lead to a 60 to 70% reduction in mortality from colorectal cancer, chiefly by identifying high-risk individuals with adenomas. Presumed high cost has prohibited its use in mass screening in the past, but a randomized, multicenter, controlled trial of screening sigmoidoscopy was initiated by the National Cancer Institute in 1992, and data are currently undergoing analysis. Studies show that trained nurse endoscopists may achieve similar results in polyp detection as their physician colleagues, which may reduce costs considerably. Patients found to have a polyp, cancer, or other lesion on flexible sigmoidoscopy will require colonoscopy.

FECAL OCCULT BLOOD TESTING AND FLEXIBLE SIGMOIDOSCOPY

The FOBT trials from Mandel and associates (University of Minnesota), Hardcastle and associates (England), and Kronberg and associates (Denmark) all showed that FOBT screening was least effective at detecting rectosigmoid cancers.^{62,63} Two thirds of interval cancers arose in the rectosigmoid in the English series. This is precisely the area screened by flexible sigmoidoscopy; thus, the combination of the two tests has been suggested as a reasonable screening strategy. Winawer, in a study of 12,479 subjects, showed that the combination of FOBT annually with flexible sigmoidoscopy every 5 years resulted in lower mortality from colorectal cancer and better survival in those patients with colorectal cancer.⁶⁴ Such data led to the American Cancer Society recommendations that one of the acceptable screening regimens for average-risk Americans is the combination of FOBT annually and flexible sigmoidoscopy every 5 years; this combination was preferred over either test alone.

COLONOSCOPY

Colonoscopy is currently the most accurate and most complete method for examining the large bowel.⁶⁰ This procedure is highly sensitive for detecting even small polyps (<1 cm) and allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. However, colonoscopy does require mechanical bowel preparation and the discomfort associated with the procedure requires conscious sedation in most patients. Colonoscopy also is considerably more expensive than other screening modalities and requires a well-trained endoscopist. The risk of a major complication after colonoscopy (perforation and hemorrhage) is extremely low (0.2 to 0.3%). Nevertheless, deaths have been reported.

AIR-CONTRAST BARIUM ENEMA

Air-contrast barium enema also is highly sensitive for detecting polyps greater than 1 cm in diameter (90% sensitivity). Unfortunately, there are no studies proving its efficacy for screening large populations. Accuracy is greatest in the proximal colon but may be compromised in the sigmoid colon if there is significant diverticulosis. For this reason, barium enema often is combined with flexible sigmoidoscopy for screening purposes. The major disadvantages of barium enema are the need for mechanical bowel preparation and the requirement for colonoscopy if a lesion is discovered.

COMPUTED TOMOGRAPHIC COLONOGRAPHY (VIRTUAL COLONOSCOPY)

Advances in imaging technology have created a number of less invasive but highly accurate tools for screening. CT colonography makes use of helical CT technology and three-dimensional reconstruction to image the intraluminal colon. Patients require a mechanical bowel preparation. The colon is then insufflated with air, a spiral CT is performed, and both two-dimensional and three-dimensional images are generated. In the hands of a qualified radiologist, sensitivity appears to be as good as colonoscopy for colorectal cancers and polyps greater than 1 cm in size.⁶⁵ Colonoscopy is required if a lesion is identified. CT colonography may also prove useful for imaging the proximal colon in cases of obstruction. Limitations of this technique include false-positive results from retained stool, diverticular disease, haustral folds, motion artifacts, and an inability to detect flat adenomas.

GUIDELINES FOR SCREENING

Current American Cancer Society guidelines advocate screening for the average-risk population (asymptomatic, no family history of colorectal carcinoma, no personal history of polyps or colorectal carcinoma, no familial syndrome) beginning at age 50 years.⁴ Recommended procedures include yearly FOBT, flexible sigmoidoscopy every 5 years, FOBT and flexible sigmoidoscopy in combination, air-contrast barium enema every 5 years, or colonoscopy every 10 years. Patients with other risk factors should be screened earlier and more frequently (Table 29-2).

Table 29-2 Screening Guidelines for Colorectal Cancer

Population	Initial Age	Recommended Screening Test
Average risk	50 y	Annual FOBT or
		Flexible sigmoidoscopy every 5 y or
		Annual FOBT and flexible sigmoidoscopy every 5 y or
		Air-contrast barium enema every 5 y or
		Colonoscopy every 10 y
Adenomatous polyps	50 y	Colonoscopy at first detection; then colonoscopy in 3 y
		If no further polyps, colonoscopy every 5 y
		If polyps, colonoscopy every 3 y
		Annual colonoscopy for >5 adenomas
Colorectal cancer	At diagnosis	Pretreatment colonoscopy; then at 12 mo after curative resection; then colonoscopy after 3 y; then colonoscopy every 5 y, if no new lesions
Ulcerative colitis, Crohn's colitis	At diagnosis; then after 8 y for pancolitis, after 15 y for left-sided colitis	Colonoscopy with multiple biopsies every 1–2 y
FAP	10–12 y	Annual flexible sigmoidoscopy
		Upper endoscopy every 1–3 y after polyps appear
Attenuated FAP	20 y	Annual flexible sigmoidoscopy
		Upper endoscopy every 1–3 y after polyps appear
HNPCC	20–25 y	Colonoscopy every 1–2 y
		Endometrial aspiration biopsy every 1–2 y
Familial colorectal cancer first-degree relative	40 y or 10 y before the age of the youngest affected relative	Colonoscopy every 5 y
		Increase frequency if multiple family members are affected, especially before 50 y

FAP = familial adenomatous polyposis; FOBT = fecal occult blood testing; HNPCC = hereditary nonpolyposis colon cancer.

Routes of Spread and Natural History

Carcinoma of the colon and rectum arises in the mucosa. The tumor subsequently invades the bowel wall and eventually adjacent tissues and other viscera. Tumors may become bulky and circumferential, leading to colon obstruction. Local extension (especially in the rectum) may occasionally cause obstruction of other organs such as the ureter.

Regional lymph node involvement is the most common form of spread of colorectal carcinoma and usually precedes distant metastasis or the development of carcinomatosis. The likelihood of nodal metastasis increases with tumor size, poorly differentiated histology, lymphovascular invasion, and depth of invasion. The T stage (depth of invasion) is the single most significant predictor of lymph node spread. Carcinoma in situ (Tis) in which there is no penetration of the muscularis mucosa (basement membrane) also has been called *high-grade dysplasia* and should carry no risk of lymph node metastasis. Small lesions confined to the bowel wall (T1 and T2) are associated with lymph node metastasis in 5 to 20% of cases, while larger tumors that invade through the bowel wall or into adjacent organs (T3 and T4) are likely to have lymph node metastasis in more than 50% of cases. The number of lymph nodes with metastases correlates with the presence of distant disease and inversely with survival. Four or more involved lymph nodes predict a poor prognosis. In colon cancer, lymphatic spread usually follows the major venous outflow from the involved segment of the colon. Lymphatic spread from the rectum follows two routes. In the upper rectum, drainage ascends along the superior rectal vessels to the inferior mesenteric nodes. In the lower rectum, lymphatic drainage may course along the middle rectal vessels. Nodal spread along the inferior rectal vessels to the internal iliac nodes or groin is rare unless the tumor involves the anal canal or the proximal lymphatics are blocked with tumor (Fig. 29-23).

The most common site of distant metastasis from colorectal cancer is the liver. These metastases arise from hematogenous spread via the portal venous system. Like lymph node metastasis, the risk of hepatic metastasis increases with tumor size and tumor grade. However, even small tumors may produce distant metastasis. The lung is also a site of hematogenous spread for colorectal carcinoma. Pulmonary metastases rarely occur in isolation. Carcinomatosis (diffuse peritoneal metastases) occurs by peritoneal seeding and has a dismal prognosis.

Staging and Preoperative Evaluation

CLINICAL PRESENTATION

Symptoms of colon and rectal cancers are nonspecific and generally develop when the cancer is locally advanced. The classic first symptoms are a change in bowel habits and rectal bleeding. Abdominal pain, bloating, and other signs of obstruction typically occur with larger tumors and suggest more advanced disease. Because of the caliber of the bowel and the consistency of the stool, left-sided tumors are more likely to cause obstruction than are right-sided tumors. Rectal tumors may cause bleeding, tenesmus, and pain. Alternatively, patients may be asymptomatic and/or present with unexplained anemia, weight loss, or poor appetite.

STAGING

Colorectal cancer staging is based upon tumor depth and the presence or absence of nodal or distant metastases. Older staging systems, such as the Dukes' Classification and its Astler-Coller modification, have been largely replaced by the tumor, nodes, and metastasis (TNM) staging system (Table 29-3).⁶⁶ Stage I disease includes adenocarcinomas that are invasive through the muscularis mucosa but are confined to the submucosa (T1) or the muscularis propria (T2) in the absence of nodal metastases. Stage II disease consists of tumors that invade through the bowel wall into the subserosa or nonperitonealized pericolic or perirectal tissues (T3) or into other organs or tissues or through the visceral peritoneum (T4) without nodal metastases. Stage III disease includes any T stage with nodal metastases, and stage IV disease denotes distant metastases.

Table 29-3 TNM Staging of Colorectal Carcinoma	
Tumor stage (T)	Definition
TX	Cannot be assessed
T0	No evidence of cancer
Tis	Carcinoma in situ
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into subserosa or into nonperitonealized pericolic or perirectal tissues
T4	Tumor directly invades other organs or tissues or perforates the visceral peritoneum of specimen
Nodal stage (N)	
NX	Regional lymph nodes cannot be assessed
N0	No lymph node metastasis

N1	Metastasis to one to three pericolic or perirectal lymph nodes
N2	Metastasis to four or more pericolic or perirectal lymph nodes
N3	Metastasis to any lymph node along a major named vascular trunk
Distant metastasis (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

The preoperative evaluation usually identifies stage IV disease. In colon cancer, differentiating stages I, II, and III depends upon examination of the resected specimen. In rectal cancer, endorectal ultrasound may predict the stage (ultrasound stage, uTXNX) preoperatively, but the final determination depends upon pathology examination of the resected tumor and adjacent lymph nodes (pathologic stage, pT XNX). Disease stage correlates with 5-year survival. Patients with stages I and II disease can expect excellent survival rates. The presence of nodal metastases (stage III) decreases survival to roughly 40% (Table 29-4). The 5-year survival rate with stage IV disease is less than 16%. In rectal cancer, staging has been further refined and outcomes suggest that subgroups of patients within each stage may have very different prognoses (Table 29-5).⁶⁷ If the mesorectum around a rectal cancer is involved or threatened (only 1 to 2 mm of clearance), there is a very high likelihood of local recurrence and a poor prognosis. This circumferential or radial margin is probably best assessed preoperatively by MRI. While nodal involvement is the single most important prognostic factor in colorectal carcinoma, tumor characteristics, such as degree of differentiation, mucinous or signet-ring cell histology, vascular invasion, and DNA aneuploidy, also affect prognosis.

Table 29-4 TNM Staging of Colorectal Carcinoma and 5-Year Survival		
Stage	TNM	5-Y Survival (%)
I	T1–2, N0, M0	70–95
II	T3–4, N0, M0	54–65
III	<i>T any</i> , N1–3, M0	39–60
IV	<i>T any</i> , <i>N any</i> , M1	0–16

PREOPERATIVE EVALUATION

Once a colon or rectal carcinoma has been diagnosed, a staging evaluation should be undertaken. The colon must be evaluated for synchronous tumors, usually by colonoscopy. Synchronous disease will be present in up to 5% of patients. For rectal cancers, digital rectal examination and rigid proctoscopy with biopsy should be done to assess tumor size, location, morphology, histology, and fixation. Endorectal ultrasound can be invaluable in staging rectal cancer and is used to classify the ultrasound T and N stage of rectal cancers (Fig. 29-24). A chest/abdominal/pelvic CT scan should be obtained to evaluate for distant metastases. Pelvic CT scan, and sometimes MRI, can be invaluable in large rectal tumors and in recurrent disease to determine the extent of local invasion. In patients with obstructive symptoms, a water-soluble contrast study (Gastrografen enema) may be useful for delineating the degree of obstruction. It is important to avoid mechanical bowel preparation (for either colonoscopy or surgery) in a patient who appears to be obstructed. PET scan may be useful in evaluating lesions seen on CT scan, and in patients in whom a risky or highly morbid operation is planned (pelvic exenteration, sacrectomy). Preoperative CEA often is obtained, and may be useful for postoperative follow-up.

Therapy for Colonic Carcinoma

PRINCIPLES OF RESECTION

The objective in treatment of carcinoma of the colon is to remove the primary tumor along with its lymphovascular supply. Because the lymphatics of the colon accompany the main arterial supply, the length of bowel resected depends upon which vessels are supplying the segment involved with the cancer. Any adjacent organ or tissue, such as the omentum, that has been invaded should be resected en bloc with the tumor. If all of the tumor cannot be removed, a palliative procedure should be considered.

The presence of synchronous cancers or adenomas or a strong family history of colorectal neoplasms suggests that the entire colon is at risk for carcinoma (often called a *field defect*) and a subtotal or total colectomy should be considered. Metachronous tumors (a *second primary colon cancer*) identified during follow-up studies should be treated similarly. However, the surgeon must be aware of which mesenteric vessels have been ligated at the initial colectomy because that may influence the choice of procedure.

The number of lymph nodes recovered in the surgical specimen has long served as a proxy for the oncologic adequacy of resection. A number of studies previously have suggested that a minimum of 12 lymph nodes in the resected specimen are necessary for adequate staging. In addition, patients in whom more nodes are harvested have better long-term outcome.⁶⁸ As such, a 12-node minimum has been suggested as an appropriate benchmark for assessing quality of care.⁶⁹ However, several investigators recently have called this into question, noting that the number of lymph nodes examined does not correlate with staging, use of adjuvant chemotherapy, or patient survival.⁷⁰ Others have suggested that the number of negative lymph nodes and/or the lymph node ratio (positive lymph nodes:total lymph nodes) may further improve staging.^{71–73}

If unexpected metastatic disease is encountered at the time of a laparotomy, the primary tumor should be resected, if technically feasible and safe. Consideration can be given to a primary anastomosis if the bowel appears healthy, is not involved in carcinomatosis, and the patient is stable. In the rare instance in which the primary tumor is not resectable, a palliative procedure can be performed and usually involves a proximal stoma or bypass. Hemorrhage in an unresectable tumor can sometimes be controlled with angiographic embolization. External beam radiation also has been used for palliation.

STAGE-SPECIFIC THERAPY

Stage 0 (Tis, N0, M0)

Polyps containing carcinoma in situ (high-grade dysplasia) carry no risk of lymph node metastasis. However, the presence of high-grade dysplasia increases the risk of finding an invasive carcinoma within the polyp. For this reason, these polyps should be excised completely and pathologic margins should be free of dysplasia. Most pedunculated polyps and many sessile polyps may be completely removed endoscopically. These patients should be followed with frequent colonoscopy to ensure that the polyp has not recurred and that an invasive carcinoma has not developed. In cases where the polyp cannot be removed entirely, a segmental resection is recommended.

Stage I: The Malignant Polyp (T1, N0, M0)

Occasionally, a polyp that was thought to be benign will be found to harbor invasive carcinoma after polypectomy. Treatment of a *malignant polyp* is based upon the risk of local recurrence and the risk of lymph node metastasis.⁵⁸ The risk of lymph node metastases depends primarily upon the depth of invasion. Invasive carcinoma in the head of a pedunculated polyp with no stalk involvement carries a low risk of metastasis (<1%) and may be completely resected endoscopically. However, lymphovascular invasion, poorly differentiated histology, or tumor within 1 mm of the resection margin greatly increases the risk of local recurrence and metastatic spread. Segmental colectomy is then indicated. Invasive carcinoma arising in a sessile polyp extends into the submucosa and is usually best treated with segmental colectomy (Fig. 29-25).

Fig. 29-25.

Stages I and II: Localized Colon Carcinoma (T1–3, N0, M0)

The majority of patients with stages I and II colon cancer will be cured with surgical resection. Few patients with completely resected stage I disease will develop either local or distant recurrence, and adjuvant chemotherapy does not improve survival in these patients. However, up to 46% of patients with completely resected stage II disease will ultimately die from colon cancer. For this reason, adjuvant chemotherapy has been suggested for selected patients with stage II disease (young patients, tumors with "high-risk" histologic findings). Data are controversial as to whether chemotherapy improves survival rates in these patients. Improved staging to detect micrometastases and/or more sensitive prognostic tumor markers may improve patient selection for adjuvant therapy.

Stage III: Lymph Node Metastasis (Tany, N1, M0)

Patients with lymph node involvement are at significant risk for both local and distant recurrence, and adjuvant chemotherapy has been recommended routinely in these patients. 5-fluorouracil (5-FU)-based regimens (with levamisole or leucovorin) reduce recurrences and improve survival in this patient population. Newer chemotherapeutic agents such as capecitabine, irinotecan, oxaliplatin, angiogenesis inhibitors, and immunotherapy also show promise.

Stage IV: Distant Metastasis (Tany, Nany, M1)

Survival is extremely limited in stage IV colon carcinoma. However, unlike many other malignancies, highly selected patients with isolated, resectable metastases may benefit from resection (metastasectomy). The most common site of metastasis is the liver. Of patients with systemic disease, approximately 15% will have metastases limited to the liver. Of these, 20% are potentially resectable for cure. Survival is improved in these patients (20 to 40% 5-year survival) when compared to patients who do not undergo resection. Hepatic resection of synchronous metastases from colorectal carcinoma may be performed as a combined procedure or in two stages. All patients require adjuvant chemotherapy. The second most common site of metastasis is the lung, occurring in approximately 20% of patients with colorectal carcinoma. Although very few of these patients will be potentially resectable, among those who are (about 1 to 2% of all colorectal cancer patients), long-term survival benefit can be expected in 30 to 40%.⁷⁴ There are limited reports of successful resection of metastases in other sites (ovary and retroperitoneum are most common).

The remainder of patients with stage IV disease cannot be cured surgically; and therefore, the focus of treatment should be palliation. Management of the primary tumor in the setting of systemic disease has been controversial. Traditionally, resection of the primary tumor has been recommended to prevent complications such as obstruction and bleeding. However, major abdominal surgery may delay definitive chemotherapy. Moreover, newer chemotherapeutic regimens have significantly improved response and tumor shrinkage. For this reason, some oncologists now advocate for chemotherapy without resection of the primary tumor in stage IV disease. Long-term outcome in this setting will require prospective study. Methods such as colonic stenting for obstructing lesions of the left colon also provide good palliation. More limited surgical intervention such as a diverting stoma may be appropriate in patients with stage IV disease who develop obstruction.

Therapy for Rectal Carcinoma

PRINCIPLES OF RESECTION

The biology of rectal adenocarcinoma is identical to the biology of colonic adenocarcinoma, and the operative principles of complete resection of the primary tumor, its lymphatic bed, and any other involved organ apply to surgical resection of rectal carcinoma. However, the anatomy of the pelvis and proximity of other structures (ureters, bladder, prostate, vagina, iliac vessels, and sacrum) make resection more challenging and often require a different approach than for colonic adenocarcinoma. Moreover, it is more difficult to achieve negative radial margins in rectal cancers that extend through the bowel wall because of the anatomic limitations of the pelvis. Therefore, local recurrence is higher than with similar stage colon cancers. However, unlike the intraperitoneal colon, the relative paucity of small bowel and other radiation-sensitive structures in the pelvis makes it easier to treat rectal tumors with radiation. Therapeutic decisions, therefore, are based upon the location and depth of the tumor and its relationship to other structures in the pelvis.

LOCAL THERAPY

The distal 10 cm of the rectum are accessible transanally. For this reason, several local approaches have been proposed for treating rectal neoplasms. *Transanal excision* (full thickness or mucosal) is an excellent approach for noncircumferential, benign, villous adenomas of the rectum. Although this technique can be used for selected T1 and, possibly, some T2 carcinomas, local excision does not allow pathologic examination of the lymph nodes, and might, therefore, understage patients. Local recurrence rates are high without the addition of adjuvant chemoradiation therapy. *Transanal endoscopic microsurgery* makes use of a specially designed proctoscope, magnifying system, and instruments similar to those used in laparoscopy to allow local excision of lesions higher in the rectum (up to 15 cm). Local excision of any rectal neoplasm should be considered an *excisional biopsy* because final pathologic examination of the specimen may reveal an invasive carcinoma that then mandates more radical therapy.

Ablative techniques such as electrocautery or endocavitary radiation also have been used. The disadvantage of these techniques is that no pathologic specimen is retrieved to confirm the tumor stage. Fulguration generally is reserved for extremely high-risk patients with a limited life span who cannot tolerate more radical surgery.

RADICAL RESECTION

Radical resection is preferred to local therapy for most rectal carcinomas. Radical resection involves removal of the involved segment of the rectum along with its lymphovascular supply. Although any microscopically negative margin has been suggested to be adequate, most surgeons still attempt to obtain a 2-cm distal mural margin for curative resections.

Total mesorectal excision (TME) is a technique that uses sharp dissection along anatomic planes to ensure complete resection of the rectal mesentery during low and extended low anterior resections. For upper rectal or rectosigmoid resections, a partial mesorectal excision of at least 5 cm distal to the tumor appears adequate. TME both decreases local recurrence rates and improves long-term survival rates. Moreover, this technique is associated with less blood loss and less risk to the pelvic nerves and presacral plexus than is blunt dissection. The principles of TME should be applied to all radical resections for rectal cancer.

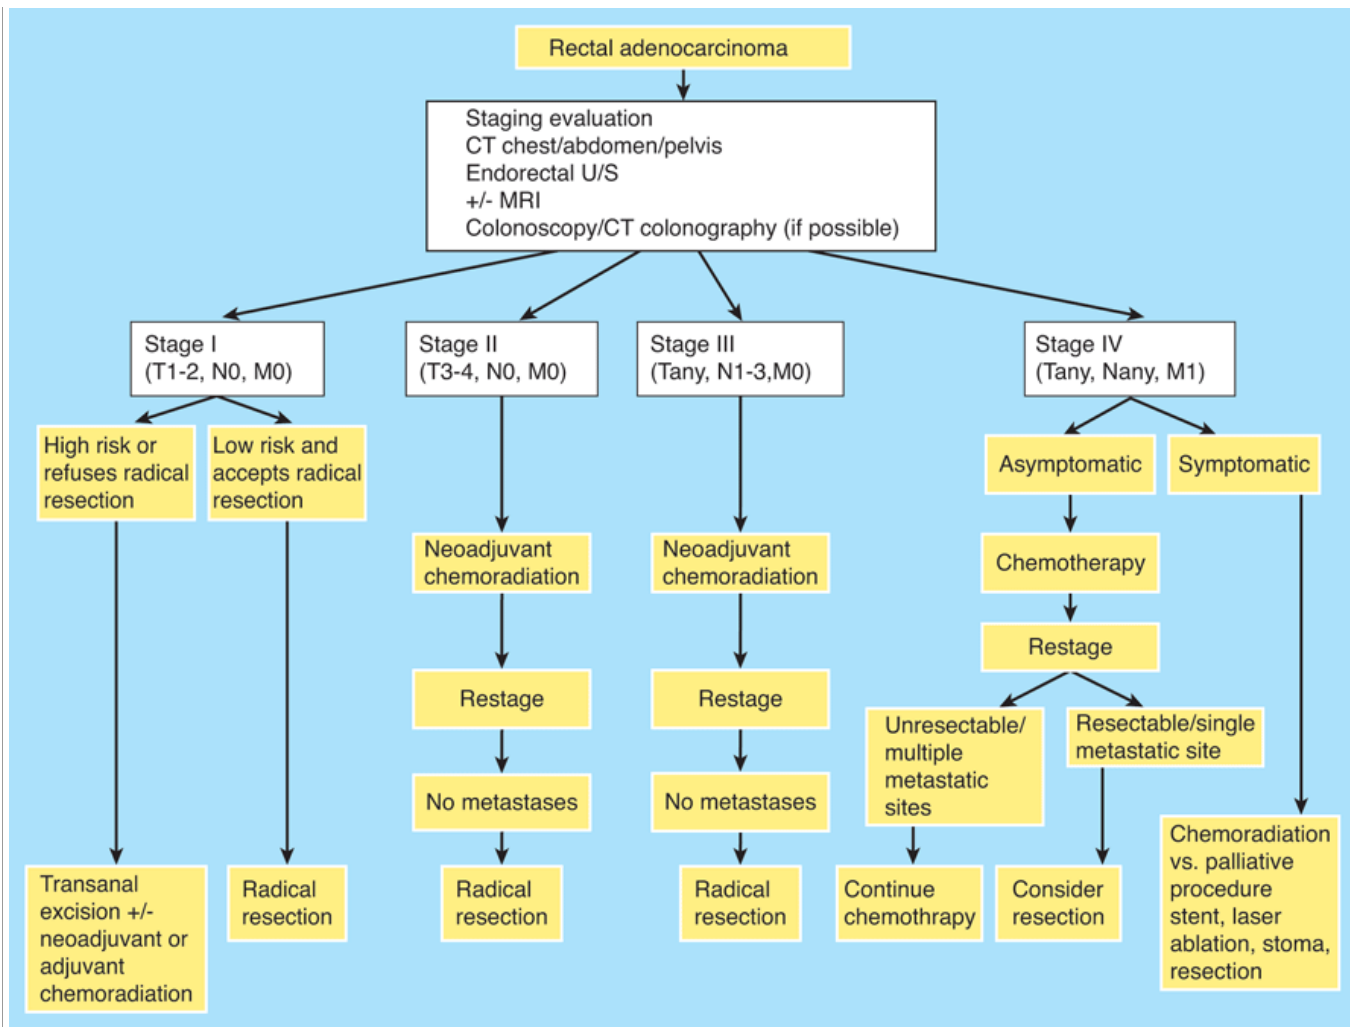

Recurrence of rectal cancer generally has a poor prognosis. Extensive involvement of other pelvic organs (usually occurring in the setting of tumor recurrence) may require a *pelvic exenteration*. The rectal and perineal portions of this operation are similar to an abdominoperineal resection (APR) but en bloc resection of the ureters, bladder, and prostate or uterus and vagina also are performed. A permanent colostomy and an ileal conduit to drain the urinary tract may be necessary. The sacrum may also be resected if necessary (*sacrectomy*) up to the level of the S2–S3 junction. These operations are best performed in tertiary centers with multidisciplinary teams consisting of a colon and rectal surgeon, urologist, neurosurgeon, and plastic surgeon.

STAGE-SPECIFIC THERAPY

(FIG. 29-26)

Pretreatment staging of rectal carcinoma often relies on endorectal ultrasound to determine the T and N status of a rectal cancer. Ultrasound is highly accurate at assessing tumor depth, but less accurate in diagnosing nodal involvement.⁵ Ultrasound evaluation can guide choice of therapy in most patients. MRI is useful to assess mesorectal involvement. When the radial margin is threatened or involved, neoadjuvant chemoradiation is recommended.

Diagnostic algorithm for rectal cancer. CT = computed tomography; MRI = magnetic resonance imaging; U/S = ultrasound.

Stage 0 (Tis, N0, M0)

Villous adenomas harboring carcinoma in situ (high-grade dysplasia) are ideally treated with local excision. A 1-cm margin should be obtained. Rarely, radical resection will be necessary if transanal excision is not technically possible (large circumferential lesions).

Stage I: Localized Rectal Carcinoma (T1–2, N0, M0)

Invasive carcinoma confined to the head of a pedunculated polyp carries a very low risk of metastasis (<1%). Polypectomy with clear margins is appropriate therapy. Although local excision has been used for small, favorable sessile uT1N0 and uT2N0 rectal cancers, local recurrence rates may be as high as 20 and 40%, respectively.⁶¹ For this reason, radical resection is strongly recommended in all good-risk patients. Lesions with unfavorable histologic characteristics and those located in the distal third of the rectum, in particular, are prone to recurrence. In high-risk patients and in those patients who refuse radical surgery because of the risk of need for a permanent colostomy, local excision may be adequate, but strong consideration should be given to adjuvant or neoadjuvant chemoradiation to improve local control. Uncontrolled studies suggest that the addition of such therapy improves outcome.^{13–19}

Locally Advanced Rectal Cancer (Stages II and III)

Stage II: Localized Rectal Carcinoma (T3–4, N0, M0)

Larger rectal tumors, especially if located in the distal rectum, are more likely to recur locally. There are two schools of thought, each differing in their approach to control local recurrences. Advocates of total mesorectal resection suggest that optimization of operative technique will obviate the need for any adjuvant chemoradiation to control local recurrence after resection of stages I, II, and III rectal cancers. The opposing school suggests that stages II and III rectal cancers will benefit from chemoradiation. They argue that such therapy reduces local recurrences and prolongs survival whether given preoperatively or postoperatively. The advantages of preoperative chemoradiation include tumor shrinkage, increased likelihood of resection and of a sphincter-sparing procedure, tumor downstaging by treating locally involved lymph nodes, and decreased risk to the small intestine. Disadvantages include possible overtreatment of early stage tumors, impaired wound healing, and pelvic fibrosis increasing the risk of operative complications. Postoperative radiation allows accurate pathologic staging of the resected tumor and lymph

nodes, and avoids the wound healing problems associated with preoperative radiation. However, bulky tumors, tumors involving adjacent organs, and very low rectal tumors may be much more difficult to resect without preoperative radiation and may require a more extensive operation.

Stage III: Lymph Node Metastasis (*Tany*, N1, M0)

Many surgeons now recommend chemotherapy and radiation either pre- or postoperatively for node-positive rectal cancers. The advantages and disadvantages are similar to those listed for stage II disease, except that the likelihood of overtreating an early stage lesion is considerably less.

Over the past two decades, a wide variety of studies have addressed the issue of adjuvant and neoadjuvant therapy for locally advanced rectal cancer. Many of these studies demonstrated both improved local control and prolonged survival, and resulted in the 1990 National Institutes of Health consensus conference recommendation for postoperative chemoradiation therapy in these patients. There is little controversy regarding chemoradiation therapy for stage III (node positive) disease. However, advances in surgical technique, such as TME, for locally advanced node negative cancers (T3–4, N0; stage II) have improved local control with surgery alone, prompting some authors to abandon adjuvant chemoradiation in these patients especially for those with proximally based rectal cancers. Although the data from these studies are intriguing, other reports have shown that chemoradiation improves local control and survival even in patients who undergo TME. Thus, most colorectal surgeons in the United States continue to recommend adjuvant or neoadjuvant therapy for patients with locally advanced disease. Many European surgeons now rely heavily on MRI staging to determine the need for neoadjuvant chemoradiation. They use neoadjuvant chemoradiation if the radial margin is threatened or involved by the cancer or if anal sphincter or other local organ invasion is present. In the United States, chemoradiation therapy still is recommended for all patients with stage III disease and the majority of patients with stage II disease. In well-selected patients with T3 tumors, favorable histology, and negative radial margins, chemoradiation may not be necessary, but larger prospective studies are required before this approach can be recommended.

Appropriate timing of chemoradiation for locally advanced rectal cancer has been debated. Historically, preoperative chemoradiation has been advocated based on tumor shrinkage/downstaging, improved resectability, and the possibility of performing a sphincter-sparing operation in some patients. In addition, the absence of small bowel adhesions in the pelvis may decrease toxicity. However, preoperative radiation therapy may increase operative complications and impairs wound healing. Although preoperative endorectal ultrasound and MRI have improved our ability to stage rectal cancer, clinical "overstaging" can be problematic, and neoadjuvant therapy may, therefore, overtreat patients with pT1–2, N0 tumors. Advocates of postoperative radiation therapy cite more accurate pathologic staging and fewer operative/postoperative complications. However, large, bulky tumors may be unresectable or require a more extensive operation (APR, pelvic exenteration) without preoperative therapy. In addition, postoperative pelvic radiation may compromise function of the neorectum.

Comparison of perioperative toxicity and oncologic outcome recently have been addressed by the German CAO/ARO/AIO-94 trial. In this study, pre- and postoperative chemoradiation were associated with equivalent acute toxicity and equivalent postoperative complication rate. Postoperative chemoradiation, however, doubled the risk of postoperative stricture formation. In addition, preoperative chemoradiation halved the risk of local recurrence (6% vs. 12%). Based upon these data, most surgeons consider preoperative chemoradiation to be the most appropriate therapy for locally advanced rectal cancer.⁷⁵

Stage IV: Distant Metastasis (*Tany*, *Nany*, M1)

As with stage IV colon carcinoma, survival is limited in patients with distant metastasis from rectal carcinoma. Isolated hepatic and/or pulmonary metastases are rare, but, when present, may be resected for cure in selected patients. Most patients will require palliative procedures. Radical resection may be required to control pain, bleeding, or tenesmus, but highly morbid procedures such as pelvic exenteration and sacrectomy should generally be avoided in this setting. Local therapy using cautery, endocavitary radiation, or laser ablation may be adequate to control bleeding or prevent obstruction. Intraluminal stents may be useful in the uppermost rectum, but often cause pain and tenesmus lower in the rectum. Occasionally, a proximal diverting colostomy will be required to alleviate obstruction. A mucus fistula should be created, if possible, to vent the distal colon.

Follow-Up and Surveillance

Patients who have been treated for one colorectal cancer are at risk for the development of recurrent disease (either locally or systemically) or metachronous disease (a second primary tumor). In theory, metachronous cancers should be preventable by using surveillance colonoscopy to detect and remove polyps before they progress to invasive cancer. For most patients, a colonoscopy should be performed within 12 months after the diagnosis of the original cancer (or sooner if the colon was not examined in its entirety before the original resection). If that study is normal, colonoscopy should be repeated every 3 to 5 years thereafter.

The optimal method of following patients for recurrent cancer remains controversial. The goal of close follow-up observation is to *detect resectable recurrence* and to *improve survival*. Re-resection of local recurrence and resection of distant metastasis to liver, lung, or other sites often is technically challenging and highly morbid, with only a limited chance of achieving long-term survival. Thus, only selected patients who would tolerate such an approach should be followed intensively. Because most recurrences occur within 2 years of the original diagnosis, surveillance focuses on this time period. Patients who have undergone local resection of rectal tumors also probably should be followed with frequent endorectal ultrasound examinations (every 4 months for 3 years, then every 6 months for 2 years). The role of endorectal ultrasound after radical resection is less clear. CEA often is followed every 2 to 3 months for 2 years. CT scans are not routinely used but may be useful if CEA is elevated. More intensive surveillance is appropriate in high-risk patients such as those with possible HNPCC syndrome or T3 N + cancers. Although intensive surveillance improves detection of resectable recurrences, it is important to note that a survival benefit has never been proven. Therefore, the risks and benefits of intensive surveillance must be weighed and treatment individualized.

Treatment of Recurrent Colorectal Carcinoma

Between 20 and 40% of patients who have undergone curative intent surgery for colorectal carcinoma will eventually develop recurrent disease. Most recurrences occur within the first 2 years after the initial diagnosis, but preoperative chemoradiation therapy may delay recurrence. Although most of these patients will present with distant metastases, a small proportion will have isolated local recurrence and may be considered for *salvage surgery*. Recurrence after colon cancer resection usually occurs at the local site within the abdomen or in the liver or lungs. Resection of other involved organs may be necessary. Recurrence of rectal cancer can be considerably more difficult to manage because of the proximity of other pelvic structures. If the patient has not received chemotherapy and radiation, then adjuvant therapy should be administered before salvage surgery. Radical resection may require extensive resection of pelvic organs (pelvic exenteration with or without sacrectomy). Ideally, the aim of a salvage operation should be to resect all of the tumor with negative margins. However, if the ability to achieve a negative margin is in question, the addition of intraoperative radiation therapy (usually brachytherapy) can help improve local control. Pelvic MRI is useful for identifying tumor extension that would prevent successful resection (extension of tumor into the pelvic sidewall, involvement of the iliac vessels or bilateral sacral nerves, sacral invasion above the S2–S3 junction). Patients should also undergo a thorough preoperative evaluation to identify distant metastases (CT of chest, abdomen, and pelvis, and PET scan) before undergoing such an extensive procedure. Nevertheless, radical salvage surgery can prolong survival in selected patients.

Sentinel Lymph Node Biopsy for Colorectal Carcinoma

The technique of sentinel lymph node biopsy has been applied to a number of malignancies and is commonly used in both breast cancer and melanoma. The goal of sentinel lymph node biopsy is to identify the first node(s) in the lymphatic basin because this site should be most likely to harbor metastases. Unlike sentinel lymph node biopsy in breast cancer and melanoma, the goal of this technique in colorectal carcinoma is not to avoid radical lymphadenectomy, but instead to improve staging.⁶⁸ Intensive pathologic examination of the sentinel node(s) with multiple histologic sections, immunohistochemistry, and reverse-transcriptase polymerase chain reaction can detect micrometastases in a significant number of patients who were thought to be node negative by conventional techniques. These patients may then be candidates for further adjuvant treatment. However, whether this increased sensitivity will translate into improved survival remains to be seen.

MINIMALLY INVASIVE TECHNIQUES FOR RESECTION

Laparoscopic colectomy for cancer has been controversial. Early reports of high port site recurrence dampened enthusiasm for this technique.⁷⁶ The ability to perform an adequate oncologic resection for cancer also has been questioned. Several recent trials have laid to rest many of these fears. The Clinical Outcomes of Surgical Therapy Study Group (COST), the Colon Carcinoma Laparoscopic or Open Resection (COLOR) trial, and the United Kingdom Medical Research Council Conventional vs. Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASSICC) trial have all shown oncologic equivalence between open and laparoscopic techniques. In these multi-institutional studies, the rates of cancer recurrence, survival, and quality of life were similar, suggesting that, in the hands of an appropriately trained surgeon, laparoscopic colectomy is appropriate for cancer.^{77–79}

OTHER NEOPLASMS

Rare Colorectal Tumors

CARCINOID TUMORS

Carcinoid tumors occur most commonly in the GI tract, and up to 25% of these tumors are found in the rectum. Most small rectal carcinoids are benign, and overall survival is greater than 80%. However, the risk of malignancy increases with size, and more than 60% of tumors greater than 2 cm in diameter are associated with distant metastases. Interestingly, rectal carcinoids appear to be less likely to secrete vasoactive substances than carcinoids in other locations, and carcinoid syndrome is uncommon in the absence of hepatic metastases. Small carcinoids can be locally resected, either transanally or using transanal endoscopic microsurgery. Larger tumors or tumors with obvious invasion into the muscularis require more radical surgery. Carcinoid tumors in the proximal colon are less common and are more likely to be malignant. Size also correlates with risk of malignancy, and tumors less than 2 cm in diameter rarely metastasize. However, the majority of carcinoid tumors in the proximal colon present as bulky lesions and up to two thirds will have metastatic spread at the time of diagnosis. These tumors usually should be treated with radical resection. Because carcinoid tumors are typically slow growing, patients with distant metastases may expect reasonably long survival. Symptoms of carcinoid syndrome often can be alleviated with somatostatin analogues (octreotide) and/or interferon- α . Tumor debulking can offer effective palliation in selected patients.

CARCINOID CARCINOMAS

Composite carcinoid carcinomas (adenocarcinoids) have histologic features of both carcinoid tumors and adenocarcinomas. The natural history of these tumors more closely parallels that of adenocarcinomas than carcinoid tumors, and regional and systemic metastases are common. Carcinoid carcinoma of the colon and rectum should be treated according to the same oncologic principles as followed for management of adenocarcinoma.

LIPOMAS

Lipomas occur most commonly in the submucosa of the colon and rectum. They are benign lesions, but rarely may cause bleeding, obstruction, or intussusception, especially when greater than 2 cm in diameter. Small asymptomatic lesions do not require resection. Larger lipomas should be resected by colonoscopic techniques or by a colotomy and enucleation or limited colectomy.

LYMPHOMA

Lymphoma involving the colon and rectum is rare, but accounts for about 10% of all GI lymphomas. The cecum is most often involved, probably as a result of spread

from the terminal ileum. Symptoms include bleeding and obstruction, and these tumors may be clinically indistinguishable from adenocarcinomas. Bowel resection is the treatment of choice for isolated colorectal lymphoma. Adjuvant therapy may be given based upon the stage of disease.

LEIOMYOMA AND LEIOMYOSARCOMA

Leiomyomas are benign tumors of the smooth muscle of the bowel wall and occur most commonly in the upper GI tract. Most patients are asymptomatic, but large lesions can cause bleeding or obstruction. Because it is difficult to differentiate a benign leiomyoma from a malignant leiomyosarcoma, these lesions should be resected. Recurrence is common after local resection, but most small leiomyomas can be adequately treated with limited resection. Lesions larger than 5 cm should be treated with radical resection because the risk of malignancy is high.

Leiomyosarcoma is rare in the GI tract. When this malignancy occurs in the large intestine, the rectum is the most common site. Symptoms include bleeding and obstruction. A radical resection is indicated for these tumors.

Retrorectal/Presacral Tumors

Tumors occurring in the retrorectal space are rare. This region lies between the upper two thirds of the rectum and the sacrum above the rectosacral fascia. It is bound by the rectum anteriorly, the presacral fascia posteriorly, and the endopelvic fascia laterally (lateral ligaments). The retrorectal space contains multiple embryologic remnants derived from a variety of tissues (neuroectoderm, notochord, and hindgut). Tumors that develop in this space are often heterogeneous.

Congenital lesions are most common, comprising almost two thirds of retrorectal lesions. The remainder are classified as neurogenic, osseous, inflammatory, or miscellaneous lesions. Malignancy is more common in the pediatric population than in adults, and solid lesions are more likely to be malignant than are cystic lesions. Inflammatory lesions may be solid or cystic (abscess) and usually represent extensions of infection either in the perirectal space or in the abdomen.

Developmental cysts constitute the majority of congenital lesions and may arise from all three germ cell layers. Dermoid and epidermoid cysts are benign lesions that arise from the ectoderm. Enterogenous cysts arise from the primitive gut. Anterior meningocele and myelomeningocele arise from herniation of the dural sac through a defect in the anterior sacrum. A "scimitar sign" (sacrum with a rounded, concave border without any bony destruction) is the pathognomonic radiographic appearance of this condition.

Solid lesions include teratomas, chordomas, neurologic tumors, or osseous lesions. Teratomas are true neoplasms and contain tissue from each germ cell layer. They often contain both cystic and solid components. Teratomas are more common in children than in adults, but, when found in adults, 30% are malignant. Chordomas arise from the notochord and are the most common malignant tumor in this region. These are slow-growing, invasive cancers that show characteristic bony destruction. Neurogenic tumors include neurofibromas and sarcomas, neurilemmomas, ependymomas, and ganglioneuromas. Osseous lesions include osteomas and bone cysts, as well as neoplasms such as osteogenic sarcoma, Ewing's tumor, chondromyxosarcoma, and giant cell tumor.

Patients may present with pain (lower back, pelvic, or lower extremity), GI symptoms, or urinary tract symptoms. Most lesions are palpable on digital rectal examination. While plain x-rays and CT scans often are used to evaluate these lesions, pelvic MRI is the most sensitive and specific imaging study. Myelogram occasionally is necessary if there is central nervous system involvement. Biopsy is not indicated, especially if the lesion appears to be resectable, because of the risk of infection and/or tumor seeding. Treatment is almost always surgical resection. The approach depends, in part, upon the nature of the lesion and its location. High lesions may be approached via a transabdominal route, whereas low lesions may be resected transsacrally. Intermediate lesions may require a combined abdominal and sacral operation. Although survival is excellent after resection of benign lesions, local recurrence is not uncommon. Prognosis after resection of malignant lesions is highly variable and reflects the biology of the underlying tumor. If a retrorectal tumor does not appear to be resectable, biopsy may be appropriate to direct further therapy (chemotherapy and/or radiation).⁸⁰

Anal Canal and Perianal Tumors

Cancers of the anal canal are uncommon and account for approximately 2% of all colorectal malignancies. Neoplasms of the anal canal can be divided into those affecting the *anal margin* (distal to the dentate line) and those affecting the *anal canal* (proximal to the dentate line). Lymphatics from the anal canal proximal to the dentate line drain cephalad via the superior rectal lymphatics to the inferior mesenteric nodes and laterally along both the middle rectal vessels and inferior rectal vessels through the ischiorectal fossa to the internal iliac nodes. Lymph from the anal canal distal to the dentate line usually drains to the inguinal nodes. It can also drain to the superior rectal lymph nodes or along the inferior rectal lymphatics to the ischiorectal fossa if primary drainage routes are blocked with tumor (Fig. 29-27). In many cases, therapy depends upon whether the tumor is located in the anal canal or at the anal margin.

ANAL INTRAEPITHELIAL NEOPLASIA (BOWEN'S DISEASE)

Bowen's disease refers to squamous cell carcinoma in situ of the anus. Pathologically, carcinomas in situ and high-grade squamous intraepithelial dysplasia appear identical. The terms *high-grade squamous intraepithelial lesions* (HSILs) and *anal intraepithelial neoplasia* (AIN) recently have been used to describe these lesions. Like cervical intraepithelial neoplasia, AIN is a precursor to an invasive squamous cell carcinoma (epidermoid carcinoma), and generally is classified as AIN1 (least dysplastic), AIN2, or AIN3 (most dysplastic). AIN may appear as a plaque-like lesion, or may only be apparent with high-resolution anoscopy and application of acetic acid or Lugol's iodine solution. AIN is associated with infection with the human papillomavirus (HPV), especially HPV types 16 and 18. The incidence of both AIN and epidermoid carcinoma of the anus has increased dramatically among HIV-positive, homosexual men. This increase is thought to result from increased rates of HPV infection along with immunosuppression. Treatment of AIN is *ablation*. Because of a high recurrence and/or reinfection rate, these patients require extremely close surveillance. High-risk patients should be followed with frequent anal Papanicolaou smears every 3 to 6 months. An abnormal Papanicolaou smear should be followed by an examination under anesthesia and anal mapping using high-resolution anoscopy. High-resolution anoscopy shows areas with abnormal telangiectasias that are consistent with high-grade dysplasia (AIN3/HSIL). Many centers now consider this technique for ablation of AIN3 to be the optimal method for following these patients.⁸¹ Rarely, extensive disease may require resection with flap closure. Medical therapy for HPV also has been proposed. Topical immunomodulators such as imiquimod (Aldara) have been shown to induce regression in some series.⁸² Topical 5-FU also has been used in this setting. Finally, the recent introduction of a vaccine against HPV may help decrease the incidence of this disease in the future.

EPIDERMOID CARCINOMA

Epidermoid carcinoma of the anus includes squamous cell carcinoma, cloacogenic carcinoma, transitional carcinoma, and basaloid carcinoma. The clinical behavior and natural history of these tumors is similar. Epidermoid carcinoma is a slow-growing tumor, and usually presents as an anal or perianal mass. Pain and bleeding may be present. Epidermoid carcinoma of the anal margin may be treated in a similar fashion as squamous cell carcinoma of the skin in other locations because adequate surgical margins usually can be achieved without resecting the anal sphincter. Wide local excision usually is adequate treatment for these lesions. Epidermoid carcinoma occurring in the anal canal or invading the sphincter cannot be excised locally, and first-line therapy relies upon chemotherapy and radiation (the *Nigro protocol*: 5-FU, mitomycin C, and 3000 cGy external beam radiation). More than 80% of these tumors can be cured by using this regimen. Recurrence usually requires radical resection (APR). Metastasis to inguinal lymph nodes is a poor prognostic sign.

VERRUCOUS CARCINOMA (BUSCHKE-LOWENSTEIN TUMOR, GIANT CONDYLOMA ACUMINATA)

Verrucous carcinoma is a locally aggressive form of condyloma acuminata. Although these lesions do not metastasize, they can cause extensive local tissue destruction and may be grossly indistinguishable from epidermoid carcinoma. Wide local excision is the treatment of choice when possible, but radical resection may sometimes be required.

BASAL CELL CARCINOMA

Basal cell carcinoma of the anus is rare and resembles basal cell carcinoma elsewhere on the skin (raised, pearly edges with central ulceration). This is a slow-growing tumor that rarely metastasizes. Wide local excision is the treatment of choice, but recurrence occurs in up to 30% of patients. Radical resection and/or

radiation therapy may be required for large lesions.

ADENOCARCINOMA

Adenocarcinoma of the anus is extremely rare, and usually represents downward spread of a low rectal adenocarcinoma. Adenocarcinoma may occasionally arise from the anal glands or may develop in a chronic fistula. Radical resection with or without adjuvant chemoradiation usually is required.

Extramammary perianal *Paget's disease* is *adenocarcinoma in situ* arising from the apocrine glands of the perianal area. The lesion is typically plaque-like and may be indistinguishable from Bowen's disease. Characteristic *Paget's cells* are seen histologically. These tumors often are associated with a synchronous GI adenocarcinoma, so a complete evaluation of the intestinal tract should be performed. Wide local excision is usually adequate treatment for perianal Paget's disease.

MELANOMA

Anorectal melanoma is rare, comprising less than 1% of all anorectal malignancies and 1 to 2% of melanomas. Despite many advances in the treatment of melanoma, prognosis for patients with anorectal disease remains poor. Overall 5-year survival is less than 10%, and many patients present with systemic metastasis and/or deeply invasive tumors at the time of diagnosis. A few patients with anorectal melanoma, however, present with isolated local or locoregional disease that is potentially resectable for cure, and both radical resection (APR) and wide local excision have been advocated. Recurrence is common and usually occurs systemically regardless of the initial surgical procedure. Local resection with free margins does not increase the risk of local or regional recurrence, and APR offers no survival advantage over local excision. Because of the morbidity associated with APR, wide local excision is recommended for initial treatment of localized anal melanoma.^{83,84} In some patients, wide local excision may not be technically feasible and APR may be required if the tumor involves a significant portion of the anal sphincter or is circumferential. The addition of adjuvant chemotherapy, biochemotherapy, vaccines, or radiotherapy may be of benefit in some patients, but efficacy remains unproven.

OTHER BENIGN COLORECTAL CONDITIONS

Rectal Prolapse and Solitary Rectal Ulcer Syndrome

Rectal prolapse refers to a circumferential, full-thickness protrusion of the rectum through the anus and also has been called *first-degree prolapse*, *complete prolapse*, or *procidencia*.⁸⁵ Internal prolapse occurs when the rectal wall intussuscepts but does not protrude, and is probably more accurately described as internal intussusception. Mucosal prolapse is a partial-thickness protrusion often associated with hemorrhoidal disease and usually is treated with banding or hemorrhoidectomy.

In adults, this condition is far more common among women, with a female:male ratio of 6:1. Prolapse becomes more prevalent with age in women and peaks in the seventh decade of life. In men, prevalence is unrelated to age. Symptoms include tenesmus, a sensation of tissue protruding from the anus that may or may not spontaneously reduce, and a sensation of incomplete evacuation. Mucus discharge and leakage may accompany the protrusion. Patients also present with a myriad of functional complaints, from incontinence and diarrhea to constipation and outlet obstruction.

A thorough preoperative evaluation, including colonic transit studies, anorectal manometry, tests of pudendal nerve terminal motor latency, electromyography (EMG), and cinedefecography, may be useful. The colon should be evaluated by colonoscopy or air-contrast barium enema to exclude neoplasms or diverticular disease. Cardiopulmonary condition should be thoroughly evaluated because comorbidities may influence the choice of surgical procedure.

The primary therapy for rectal prolapse is surgery, and more than 100 different procedures have been described to treat this condition. Operations can be categorized as either *abdominal* or *perineal*. Abdominal operations have taken three major approaches: (a) reduction of the perineal hernia and closure of the cul-de-sac (*Moschcowitz's operation*); (b) fixation of the rectum, either with a prosthetic sling (*Ripstein* and *Wells rectopexy*) or by *suture rectopexy*; or (c) resection of redundant sigmoid colon (Fig. 29-28). In some cases, resection is combined with rectal fixation (*resection rectopexy*). Abdominal rectopexy with or without resection also is increasingly performed laparoscopically. Perineal approaches have focused on tightening the anus with a variety of prosthetic materials, reefing the rectal mucosa (*Delorme procedure*), or resecting the prolapsed bowel from the perineum (*perineal rectosigmoidectomy* or *Altemeier procedure*) (Fig. 29-29).

Perineal rectosigmoidectomy shown in lithotomy position. **A.** A circular incision is made 2 cm proximal to the dentate line. **B.** The anterior peritoneal reflection is opened. **C.** The mesentery is divided and ligated. **D.** The peritoneum may be sutured to the bowel wall. **E.** The bowel is resected. **F.** A handsewn anastomosis is performed.

Because rectal prolapse occurs most commonly in elderly women, the choice of operation depends in part upon the patient's overall medical condition. Abdominal rectopexy (with or without sigmoid resection) offers the most durable repair, with recurrence occurring in fewer than 10% of patients. Perineal rectosigmoidectomy avoids an abdominal operation and may be preferable in high-risk patients, but is associated with a higher recurrence rate. Reefing the rectal mucosa is effective for patients with limited prolapse. Anal encirclement procedures generally have been abandoned.

Solitary rectal ulcer syndrome and colitis cystica profunda are commonly associated with internal intussusception. Patients may complain of pain, bleeding, mucus discharge, or outlet obstruction. In solitary rectal ulcer syndrome, one or more ulcers are present in the distal rectum, usually on the anterior wall. In colitis cystica profunda, nodules or a mass may be found in a similar location. Evaluation should include anorectal manometry, defecography, and either colonoscopy or barium enema to exclude other diagnoses. Biopsy of an ulcer or mass is mandatory to exclude malignancy. Nonoperative therapy (high-fiber diet, defecation training to avoid straining, and laxatives or enemas) is effective in the majority of patients. Biofeedback also has been reported to be effective in some patients. Surgery (either abdominal or perineal repair of prolapse as described above) is reserved for highly symptomatic patients for whom all other medical interventions have failed.⁸⁶

Volvulus

Volvulus occurs when an air-filled segment of the colon twists about its mesentery. The sigmoid colon is involved in up to 90% of cases, but volvulus can involve the cecum (<20%) or transverse colon. A volvulus may reduce spontaneously, but more commonly produces bowel obstruction, which can progress to strangulation, gangrene, and perforation. Chronic constipation may produce a large, redundant colon (*chronic megacolon*) that predisposes to volvulus, especially if the mesenteric base is narrow.

The symptoms of volvulus are those of acute bowel obstruction. Patients present with abdominal distention, nausea, and vomiting. Symptoms rapidly progress to generalized abdominal pain and tenderness. Fever and leukocytosis are heralds of gangrene and/or perforation. Occasionally, patients will report a long history of intermittent obstructive symptoms and distention, suggesting intermittent chronic volvulus.

SIGMOID VOLVULUS

Sigmoid volvulus often can be differentiated from cecal or transverse colon volvulus by the appearance of plain x-rays of the abdomen. Sigmoid volvulus produces a characteristic *bent inner tube* or *coffee bean* appearance, with the convexity of the loop lying in the right upper quadrant (opposite the site of obstruction).

Gastrografin enema shows a narrowing at the site of the volvulus and a pathognomonic *bird's beak* (Fig. 29-30).

Fig. 29-30.

Unless there are obvious signs of gangrene or peritonitis, the initial management of sigmoid volvulus is resuscitation followed by endoscopic detorsion. Detorsion is usually most easily accomplished by using a rigid proctoscope, but a flexible sigmoidoscope or colonoscope might also be effective. A rectal tube may be inserted to maintain decompression. Although these techniques are successful in reducing sigmoid volvulus in the majority of patients, the risk of recurrence is high (40%). For this reason, an elective sigmoid colectomy should be performed after the patient has been stabilized and undergone an adequate bowel preparation.

Clinical evidence of gangrene or perforation mandates immediate surgical exploration without an attempt at endoscopic decompression. Similarly, the presence of necrotic mucosa, ulceration, or dark blood noted on endoscopy examination suggests strangulation and is an indication for operation. If dead bowel is present at laparotomy, a sigmoid colectomy with end colostomy (Hartmann's procedure) may be the safest operation to perform.

CECAL VOLVULUS

Cecal volvulus results from nonfixation of the right colon. Rotation occurs around the ileocolic blood vessels and vascular impairment occurs early. Plain x-rays of the abdomen show a characteristic kidney-shaped, air-filled structure in the left upper quadrant (opposite the site of obstruction), and a Gastrografen enema confirms obstruction at the level of the volvulus.

Unlike sigmoid volvulus, cecal volvulus can almost never be detorsed endoscopically. Moreover, because vascular compromise occurs early in the course of cecal volvulus, surgical exploration is necessary when the diagnosis is made. Right hemicolectomy with a primary ileocolic anastomosis usually can be performed safely and prevents recurrence. Simple detorsion or detorsion and cecopexy are associated with a high rate of recurrence.

TRANSVERSE COLON VOLVULUS

Transverse colon volvulus is extremely rare. Nonfixation of the colon and chronic constipation with megacolon may predispose to transverse colon volvulus. The radiographic appearance of transverse colon volvulus resembles sigmoid volvulus, but Gastrografen enema will reveal a more proximal obstruction. Although colonoscopic detorsion is occasionally successful in this setting, most patients require emergent exploration and resection.

Megacolon

Megacolon describes a chronically dilated, elongated, hypertrophied large bowel. Megacolon may be congenital or acquired and usually is related to chronic mechanical or functional obstruction. In general, the degree of megacolon is related to the duration of obstruction. Evaluation must always include examination of the colon and rectum (either endoscopically or radiographically) to exclude a surgically correctable mechanical obstruction.

Congenital *megacolon* caused by Hirschsprung's disease results from the failure of migration of neural crest cells to the distal large intestine. The resulting absence of ganglion cells in the distal colon results in a failure of relaxation and causes a functional obstruction. The proximal, healthy bowel becomes progressively dilated. Surgical resection of the aganglionic segment is curative. Although Hirschsprung's disease is primarily a disease of infants and children, it occasionally presents later in adulthood, especially if an extremely short segment of the bowel is affected (*ultrashort-segment Hirschsprung's disease*).

Acquired megacolon may result from infection or chronic constipation. Infection with the protozoan *Trypanosoma cruzi* (*Chagas' disease*) destroys ganglion cells and produces both megacolon and megaesophagus. Chronic constipation from slow transit or secondary to medications (especially anticholinergic medications) or neurologic disorders (paraplegia, poliomyelitis, amyotrophic lateral sclerosis, multiple sclerosis) may produce progressive colonic dilatation. Diverting ileostomy or subtotal colectomy with an ileorectal anastomosis is occasionally necessary in these patients.

Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Colonic pseudo-obstruction (Ogilvie's syndrome) is a functional disorder in which the colon becomes massively dilated in the absence of mechanical obstruction. Pseudo-obstruction most commonly occurs in hospitalized patients and is associated with the use of narcotics, bedrest, and comorbid disease. Pseudo-obstruction is thought to result from autonomic dysfunction and severe adynamic ileus. The diagnosis is made based upon the presence of massive dilatation of the colon (usually predominantly the *right* and *transverse* colon) in the absence of a mechanical obstruction. Initial treatment consists of cessation of narcotics, anticholinergics, or other medications that may contribute to ileus. Strict bowel rest and IV hydration are crucial. Most patients will respond to these measures. In patients who fail to improve, colonoscopic decompression often is effective. However, this procedure is technically challenging and great care must be taken to avoid causing perforation. Recurrence occurs in up to 40% of patients. IV neostigmine (an acetylcholinesterase inhibitor) also is extremely effective in decompressing the dilated colon and is associated with a low rate of recurrence (20%). However, neostigmine may produce transient but profound bradycardia and may be inappropriate in patients with cardiopulmonary disease. Because the colonic dilatation typically is greatest in the proximal colon, placement of a rectal tube is rarely effective. It is crucial to exclude mechanical obstruction (usually with a Gastrografin or barium enema) before medical or endoscopic treatment.

Ischemic Colitis

Intestinal ischemia occurs most commonly in the colon. Unlike small bowel ischemia, colonic ischemia is rarely associated with major arterial or venous occlusion. Instead, most colonic ischemia appears to result from low flow and/or small vessel occlusion. Risk factors include vascular disease, diabetes mellitus, vasculitis, and hypotension. In addition, ligation of the inferior mesenteric artery during aortic surgery predisposes to colonic ischemia. Occasionally, thrombosis or embolism may cause ischemia. Although the splenic flexure is the most common site of ischemic colitis, any segment of the colon may be affected. The rectum is relatively spared because of its rich collateral circulation.

Signs and symptoms of ischemic colitis reflect the extent of bowel ischemia. In mild cases, patients may have diarrhea (usually bloody) without abdominal pain. With more severe ischemia, intense abdominal pain (often out of proportion to the clinical examination), tenderness, fever, and leukocytosis are present. Peritonitis and/or systemic toxicity are signs of full-thickness necrosis and perforation.

The diagnosis of ischemic colitis is often based upon the clinical history and physical examination. Plain films may reveal *thumb printing*, which results from mucosal edema and submucosal hemorrhage. CT often shows nonspecific colonic wall thickening and pericolic fat stranding. Angiography is usually not helpful because major arterial occlusion is rare. Although sigmoidoscopy may reveal characteristic dark, hemorrhagic mucosa, the risk of precipitating perforation is high. For this reason, *sigmoidoscopy is relatively contraindicated* in any patient with significant abdominal tenderness. Contrast studies (Gastrografin or barium enema) are similarly contraindicated during the acute phase of ischemic colitis.

Treatment of ischemic colitis depends upon clinical severity. Unlike ischemia of the small bowel, the majority of patients with ischemic colitis can be treated medically. Bowel rest and broad-spectrum antibiotics are the mainstay of therapy, and 80% of patients will recover with this regimen. Hemodynamic parameters should be optimized, especially if hypotension and low flow appear to be the inciting cause. Long-term sequelae include stricture (10 to 15%) and chronic segmental ischemia (15 to 20%). Colonoscopy should be performed after recovery to evaluate strictures and to rule out other diagnoses such as inflammatory bowel disease or malignancy. Failure to improve after 2 to 3 days of medical management, progression of symptoms, or deterioration in clinical condition are indications for surgical exploration. In this setting, all necrotic bowel should be resected. Primary anastomosis should be avoided. Occasionally, repeated exploration (a *second-look operation*) may be necessary.

Infectious Colitis

PSEUDOMEMBRANOUS COLITIS (*CLOSTRIDIUM DIFFICILE* COLITIS)

Pseudomembranous colitis is caused by *C. difficile*, a gram-positive bacillus. *C. difficile colitis* is extremely common and is the leading cause of nosocomially acquired diarrhea.^{4,79} The spectrum of disease ranges from watery diarrhea to fulminant, life-threatening colitis. *C. difficile* is carried in the large intestine of many healthy adults. Colitis is thought to result from overgrowth of this organism after depletion of the normal commensal flora of the gut with the use of antibiotics. Although clindamycin was the first antimicrobial agent associated with *C. difficile* colitis, almost any antibiotic may cause this disease. Moreover, although risk of *C. difficile* colitis increases with prolonged antibiotic usage, even a single dose of an antibiotic may cause the disease. Immunosuppression, medical comorbidities, prolonged hospitalization or nursing home residence, and bowel surgery increase the risk.

The pathogenic changes associated with *C. difficile* colitis result from production of two toxins: *toxin A* (an enterotoxin) and *toxin B* (a cytotoxin). Diagnosis of this disease was traditionally made by culturing the organism from the stool. Recently, detection of one or both toxins (either by cytotoxic assays or by immunoassays) has proven to be more rapid, sensitive, and specific. The diagnosis may also be made endoscopically by detection of characteristic ulcers, plaques, and pseudomembranes.

Management should include immediate cessation of the offending antimicrobial agent. Patients with mild disease (diarrhea but no fever or abdominal pain) may be

treated as outpatients with a 10-day course of oral metronidazole. Oral vancomycin is a second-line agent used in patients allergic to metronidazole or in patients with recurrent disease. More severe diarrhea associated with dehydration and/or fever and abdominal pain is best treated with bowel rest, IV hydration, and oral metronidazole or vancomycin. Proctosigmoiditis may respond to vancomycin enemas. Recurrent colitis occurs in up to 20% of patients and may be treated by a longer course of oral metronidazole or vancomycin (up to 1 month). Reintroduction of normal flora by ingestion of *probiotics* has been suggested as a possible treatment for recurrent or refractory disease.⁸⁰ Fulminant colitis, characterized by septicemia and/or evidence of perforation, requires emergent laparotomy. A total abdominal colectomy with end ileostomy may be lifesaving.

OTHER INFECTIOUS COLITIDES

A variety of other infections with bacteria, parasites, fungi, or viruses may cause colonic inflammation. Common bacterial infections include enterotoxigenic *E. coli*, *Campylobacter jejuni*, *Yersinia enterocolitica*, *Salmonella typhi*, *Shigella*, and *Neisseria gonorrhoeae*. Less commonly, *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *Actinomycosis israelii*, or *Treponemapallidum* (syphilis) may cause colitis or proctitis. Parasitic infections such as amebiasis, cryptosporidiosis, and giardiasis also are relatively common. Fungal infections (*Candida* species, histoplasmosis) are extremely rare in otherwise healthy individuals. The most common viral infections that produce colitic symptoms are the herpes simplex viruses, HIV, and cytomegalovirus (CMV).

Most symptoms are nonspecific and consist of diarrhea (with or without bleeding), crampy abdominal pain, and malaise. A thorough history may offer clues to the etiology (other medical conditions, especially immunosuppression; recent travel or exposures; and ingestions). Diagnosis usually is made by identification of a pathogen in the stool, either by microscopy or culture. Serum immunoassays may also be useful (amebiasis, HIV, CMV). Occasionally, endoscopy with biopsy may be required. Treatment is tailored to the infection.

ANORECTAL DISEASES

Any patient with anal/perianal symptoms requires a careful history and physical, including a digital rectal examination. Other studies such as defecography, manometry, CT scan, MRI, contrast enema, endoscopy, endoanal ultrasound, or examination under anesthesia may be required to arrive at an accurate diagnosis.

Hemorrhoids

Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth-muscle fibers that are located in the anal canal (see Fig. 29-4). Three hemorrhoidal cushions are found in the left lateral, right anterior, and right posterior positions. Hemorrhoids are thought to function as part of the continence mechanism and aid in complete closure of the anal canal at rest. Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. Excessive straining, increased abdominal pressure, and hard stools increase venous engorgement of the hemorrhoidal plexus and cause prolapse of hemorrhoidal tissue. Bleeding, thrombosis, and symptomatic hemorrhoidal prolapse may result.

External hemorrhoids are located distal to the dentate line and are covered with anoderm. Because the anoderm is richly innervated, thrombosis of an external hemorrhoid may cause significant pain. It is for this reason that external hemorrhoids should not be ligated or excised without adequate local anesthetic. A *skin tag* is redundant fibrotic skin at the anal verge, often persisting as the residua of a thrombosed external hemorrhoid. Skin tags are often confused with symptomatic hemorrhoids. External hemorrhoids and skin tags may cause itching and difficulty with hygiene if they are large. Treatment of external hemorrhoids and skin tags are only indicated for symptomatic relief.

Internal hemorrhoids are located proximal to the dentate line and covered by insensate anorectal mucosa. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis and necrosis (usually related to severe prolapse, incarceration, and/or strangulation). Internal hemorrhoids are graded according to the extent of prolapse. *First-degree hemorrhoids* bulge into the anal canal and may prolapse beyond the dentate line on straining. *Second-degree hemorrhoids* prolapse through the anus but reduce spontaneously. *Third-degree hemorrhoids* prolapse through the anal canal and require manual reduction. *Fourth-degree hemorrhoids* prolapse but cannot be reduced and are at risk for strangulation.

Combined internal and external hemorrhoids straddle the dentate line and have characteristics of both internal and external hemorrhoids. Hemorrhoidectomy often is required for large, symptomatic, combined hemorrhoids. *Postpartum hemorrhoids* result from straining during labor, which results in edema, thrombosis, and/or strangulation. Hemorrhoidectomy is often the treatment of choice, especially if the patient has had chronic hemorrhoidal symptoms. *Portal hypertension* was long thought to increase the risk of hemorrhoidal bleeding because of the anastomoses between the portal venous system (middle and upper hemorrhoidal plexuses) and the systemic venous system (inferior rectal plexuses). It is now understood that hemorrhoidal disease is no more common in patients with portal hypertension than in the normal population. *Rectal varices*, however, may occur and may cause hemorrhage in these patients. In general, rectal varices are best treated by lowering portal venous pressure. Rarely, suture ligation may be necessary if massive bleeding persists. Surgical hemorrhoidectomy should be avoided in these patients because of the risk of massive, difficult-to-control variceal bleeding.

TREATMENT

Medical Therapy

Bleeding from first- and second-degree hemorrhoids often improves with the addition of dietary fiber, stool softeners, increased fluid intake, and avoidance of straining. Associated pruritus may often improve with improved hygiene. Many over-the-counter topical medications are desiccants and are relatively ineffective for treating hemorrhoidal symptoms.

Rubber Band Ligation

Persistent bleeding from first-, second-, and selected third-degree hemorrhoids may be treated by rubber band ligation.

Mucosa located 1 to 2 cm proximal to the dentate line is grasped and pulled into a rubber band applicator. After firing the ligator, the rubber band strangulates the underlying tissue, causing scarring and preventing further bleeding or prolapse (Fig. 29-31). In general, only one or two quadrants are banded per visit. Severe pain will occur if the rubber band is placed at or distal to the dentate line where sensory nerves are located. Other complications of rubber band ligation include *urinary retention*, *infection*, and *bleeding*. Urinary retention occurs in approximately 1% of patients and is more likely if the ligation has inadvertently included a portion of the internal sphincter. *Necrotizing infection* is an uncommon but life-threatening complication. Severe pain, fever, and urinary retention are early signs of infection and should prompt immediate evaluation of the patient usually with an examination under anesthesia. Treatment includes débridement of necrotic tissue, drainage of associated abscesses, and broad-spectrum antibiotics. *Bleeding* may occur approximately 7 to 10 days after rubber band ligation, at the time when the ligated pedicle necroses and sloughs. Bleeding is usually self limited, but persistent hemorrhage may require examination under anesthesia and suture ligation of the pedicle.

Fig. 29-31.

Rubber band ligation of internal hemorrhoids. The mucosa just proximal to the internal hemorrhoids is banded.

Infrared Photocoagulation

Infrared photocoagulation is an effective office treatment for small first- and second-degree hemorrhoids. The instrument is applied to the apex of each hemorrhoid to coagulate the underlying plexus. All three quadrants may be treated during the same visit. Larger hemorrhoids and hemorrhoids with a significant amount of prolapse are not effectively treated with this technique.

Sclerotherapy

The injection of bleeding internal hemorrhoids with sclerosing agents is another effective office technique for treatment of first-, second-, and some third-degree hemorrhoids. One to 3 mL of a sclerosing solution (phenol in olive oil, sodium morrhuate, or quinine urea) are injected into the submucosa of each hemorrhoid. Few complications are associated with sclerotherapy, but infection and fibrosis have been reported.

Excision of Thrombosed External Hemorrhoids

Acutely thrombosed external hemorrhoids generally cause intense pain and a palpable perianal mass during the first 24 to 72 hours after thrombosis. The thrombosis can be effectively treated with an elliptical excision performed in the office under local anesthesia. Because the clot is usually loculated, simple incision and drainage is rarely effective. After 72 hours, the clot begins to resorb, and the pain resolves spontaneously. Excision is unnecessary, but sitz baths and analgesics often are helpful.

Operative Hemorrhoidectomy

A number of surgical procedures have been described for elective resection of symptomatic hemorrhoids. All are based on decreasing blood flow to the hemorrhoidal plexuses and excising redundant anoderm and mucosa.

Closed Submucosal Hemorrhoidectomy

The Parks or Ferguson hemorrhoidectomy involves resection of hemorrhoidal tissue and closure of the wounds with absorbable suture. The procedure may be performed in the prone or lithotomy position under local, regional, or general anesthesia. The anal canal is examined and an anal speculum inserted. The hemorrhoid cushions and associated redundant mucosa are identified and excised using an elliptical incision starting just distal to the anal verge and extending proximally to the anorectal ring. It is crucial to identify the fibers of the internal sphincter and carefully brush these away from the dissection to avoid injury to the sphincter. The apex of the hemorrhoidal plexus is then ligated and the hemorrhoid excised. The wound is then closed with a running absorbable suture. All three hemorrhoidal cushions may be removed using this technique; however, care should be taken to avoid resecting a large area of perianal skin to avoid postoperative anal stenosis (Fig. 29-32).

Fig. 29-32.

Technique of closed submucosal hemorrhoidectomy. **A.** The patient is in prone jackknife position. **B.** A Fansler anoscope is used for exposure. **C.** A narrow ellipse of anoderm is excised. **D.** A submucosal dissection of the hemorrhoidal plexus from the underlying anal sphincter is performed. **E.** Redundant mucosa is anchored to the proximal anal canal, and the wound is closed with a running absorbable suture. **F.** Additional quadrants are excised to complete the procedure.

Open Hemorrhoidectomy

This technique, often called the *Milligan and Morgan hemorrhoidectomy*, follows the same principles of excision described above in Submucosal Hemorrhoidectomy,

but the wounds are left open and allowed to heal by secondary intention.

Whitehead's Hemorrhoidectomy

Whitehead's hemorrhoidectomy involves circumferential excision of the hemorrhoidal cushions just proximal to the dentate line. After excision, the rectal mucosa is then advanced and sutured to the dentate line. Although some surgeons still use the Whitehead hemorrhoidectomy technique, most have abandoned this approach because of the risk of ectropion (*Whitehead's deformity*).

Procedure for Prolapse and Hemorrhoids/Stapled Hemorrhoidectomy

Procedure for prolapse and hemorrhoids (PPH) has been proposed as an alternative surgical approach. The term *PPH* has largely replaced stapled hemorrhoidectomy because the procedure does not involve excision of hemorrhoidal tissue, but instead fixes the redundant mucosa above the dentate line. PPH removes a short circumferential segment of rectal mucosa proximal to the dentate line using a circular stapler. This effectively ligates the venules feeding the hemorrhoidal plexus and fixes redundant mucosa higher in the anal canal. Critics suggest that this technique is only appropriate for patients with large, bleeding, internal hemorrhoids, and is ineffective in management of external or combined hemorrhoids. Nevertheless, several recent studies suggest that this procedure is safe and effective, is associated with less postoperative pain and disability, and has an equivalent risk of postoperative complications when compared to traditional hemorrhoidectomy.^{87,88}

Complications of Hemorrhoidectomy

Postoperative pain following excisional hemorrhoidectomy requires analgesia usually with oral narcotics. NSAIDs, muscle relaxants, topical analgesics, and comfort measures, including sitz baths, are often useful as well. Urinary retention is a common complication following hemorrhoidectomy and occurs in 10 to 50% of patients. The risk of urinary retention can be minimized by limiting intraoperative and perioperative IV fluids, and by providing adequate analgesia. Pain also can lead to *fecal impaction*. Risk of impaction may be decreased by preoperative enemas or a limited mechanical bowel preparation, liberal use of laxatives postoperatively, and adequate pain control. Although a small amount of *bleeding*, especially with bowel movements, is to be expected, massive hemorrhage can occur after hemorrhoidectomy. Bleeding may occur in the immediate postoperative period (often in the recovery room) as a result of inadequate ligation of the vascular pedicle. This type of hemorrhage mandates an urgent return to the operating room where suture ligation of the bleeding vessel will often solve the problem. Bleeding may also occur 7 to 10 days after hemorrhoidectomy when the necrotic mucosa overlying the vascular pedicle sloughs. Although some of these patients may be safely observed, others will require an examination under anesthesia to ligate the bleeding vessel or to oversee the wounds if no specific site of bleeding is identified. *Infection* is uncommon after hemorrhoidectomy; however, necrotizing soft tissue infection can occur with devastating consequences. Severe pain, fever, and urinary retention may be early signs of infection. If infection is suspected, an emergent examination under anesthesia, drainage of abscess, and/or débridement of all necrotic tissue are required.

Long-term sequelae of hemorrhoidectomy include *incontinence*, *anal stenosis*, and *ectropion* (*Whitehead's deformity*). Many patients experience transient incontinence to flatus, but these symptoms usually are short lived, and few patients have permanent fecal incontinence. Anal stenosis may result from scarring after extensive resection of perianal skin. Ectropion may occur after a Whitehead's hemorrhoidectomy. This complication is usually the result of suturing the rectal mucosa too far distally in the anal canal and can be avoided by ensuring that the mucosa is sutured at or just above the dentate line.

Anal Fissure

A fissure in ano is a tear in the anoderm distal to the dentate line. The pathophysiology of anal fissure is thought to be related to trauma from either the passage of hard stool or prolonged diarrhea. A tear in the anoderm causes spasm of the internal anal sphincter, which results in pain, increased tearing, and decreased blood supply to the anoderm. This cycle of pain, spasm, and ischemia contributes to development of a poorly healing wound that becomes a *chronic fissure*. The vast majority of anal fissures occur in the posterior midline. Ten to 15% occur in the anterior midline. Less than 1% of fissures occur off midline.

SYMPTOMS AND FINDINGS

Anal fissure is extremely common.^{88,89} Characteristic symptoms include tearing pain with defecation and hematochezia (usually described as blood on the toilet paper). Patients also may complain of a sensation of intense and painful anal spasm lasting for several hours after a bowel movement. On physical examination, the fissure often can be seen in the anoderm by gently separating the buttocks. Patients are often too tender to tolerate digital rectal examination, anoscopy, or proctoscopy. An *acute fissure* is a superficial tear of the distal anoderm and almost always heals with medical management. *Chronic fissures* develop ulceration and heaped-up edges with the white fibers of the internal anal sphincter visible at the base of the ulcer. There often is an associated external skin tag and/or a hypertrophied anal papilla internally. These fissures are more challenging to treat and may require surgery. A lateral location of a chronic anal fissure may be evidence of an underlying disease such as Crohn's disease, HIV, syphilis, tuberculosis, or leukemia. If the diagnosis is in doubt or there is suspicion of another cause for the perianal pain, such as abscess or fistula, an examination under anesthesia may be necessary.

TREATMENT

Therapy focuses on breaking the cycle of pain, spasm, and ischemia thought responsible for development of fissure in ano. First-line therapy to minimize anal trauma includes bulk agents, stool softeners, and warm sitz baths. The addition of 2% lidocaine jelly or other analgesic creams can provide additional symptomatic relief. Nitroglycerin ointment (0.2%) has been used locally to improve blood flow but often causes severe headaches. Both oral and topical calcium channel blockers (diltiazem and nifedipine) also have been used to heal fissures and may have fewer side effects than topical nitrates. Newer agents, such as arginine (a nitric oxide

donor) and topical bethanechol (a muscarinic agonist), also have been used to treat fissures. Medical therapy is effective in most acute fissures, but will heal only approximately 50 to 60% of chronic fissures.

Botulinum toxin (Botox) causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals. Injection of botulinum toxin is used in some centers as an alternative to surgical sphincterotomy for chronic fissure. Although there are few long-term complications from the use of Botox, healing appears to be equivalent to other medical therapies.⁹⁰

Surgical therapy traditionally has been recommended for chronic fissures that have failed medical therapy, and lateral internal sphincterotomy is the procedure of choice for most surgeons. The aim of this procedure is to decrease spasm of the internal sphincter by dividing a portion of the muscle. Approximately 30% of the internal sphincter fibers are divided laterally by using either an open (Fig. 29-33) or closed (Fig. 29-34) technique. Healing is achieved in more than 95% of patients by using this technique, and most patients experience immediate pain relief.⁹⁰ Recurrence occurs in less than 10% of patients and the risk of incontinence (usually to flatus) ranges from 5 to 15%.

Anorectal Sepsis and Cryptoglandular Abscess

RELEVANT ANATOMY

The majority of anorectal suppurative disease results from infections of the anal glands (cryptoglandular infection) found in the intersphincteric plane. Their ducts traverse the internal sphincter and empty into the anal crypts at the level of the dentate line. Infection of an anal gland results in the formation of an abscess that enlarges and spreads along one of several planes in the perianal and perirectal spaces. The *perianal space* surrounds the anus and laterally becomes continuous with the fat of the buttocks. The *intersphincteric space* separates the internal and external anal sphincters. It is continuous with the perianal space distally and extends cephalad into the rectal wall. The *ischiorectal space (ischiorectal fossa)* is located lateral and posterior to the anus and is bounded medially by the external sphincter, laterally by the ischium, superiorly by the levator ani, and inferiorly by the transverse septum. The ischiorectal space contains the inferior rectal vessels and lymphatics. The two ischiorectal spaces connect posteriorly above the anococcygeal ligament but below the levator ani muscle, forming the *deep postanal space*. The *supralelevator spaces* lie above the levator ani on either side of the rectum and communicate posteriorly. The anatomy of these spaces influences the location and spread of cryptoglandular infection (Fig. 29-35).

Fig. 29-35.

Anatomy of perianorectal spaces. **A.** Anterior view and **(B)** lateral view. m = muscle.

As an abscess enlarges, it spreads in one of several directions. A *perianal abscess* is the most common manifestation and appears as a painful swelling at the anal verge. Spread through the external sphincter below the level of the puborectalis produces an *ischioanal abscess*. These abscesses may become extremely large and may not be visible in the perianal region. Digital rectal exam will reveal a painful swelling laterally in the ischioanal fossa. *Intersphincteric abscesses* occur in the intersphincteric space and are notoriously difficult to diagnose, often requiring an examination under anesthesia. *Pelvic* and *supralevator abscesses* are uncommon and may result from extension of an intersphincteric or ischioanal abscess upward, or extension of an intraperitoneal abscess downward (Fig. 29-36).

Fig. 29-36.

DIAGNOSIS

Severe anal pain is the most common presenting complaint. Walking, coughing, or straining can aggravate the pain. A palpable mass often is detected by inspection of the perianal area or by digital rectal examination. Occasionally, patients will present with fever, urinary retention, or life-threatening sepsis. The diagnosis of a perianal or ischiorectal abscess usually can be made with physical examination alone (either in the office or in the operating room). However, complex or atypical presentations may require imaging studies such as CT or MRI to fully delineate the anatomy of the abscess.

TREATMENT

Anorectal abscesses should be treated by drainage as soon as the diagnosis is established. If the diagnosis is in question, an examination under anesthesia is often the most expeditious way both to confirm the diagnosis and to treat the problem. Delayed or inadequate treatment may occasionally cause extensive and life-threatening suppurative necrosis with massive tissue necrosis and septicemia. Antibiotics are only indicated if there is extensive overlying cellulitis or if the patient is immunocompromised, has diabetes mellitus, or has valvular heart disease. Antibiotics alone are ineffective at treating perianal or perirectal infection.

Perianal Abscess

Most perianal abscesses can be drained under local anesthesia in the office, clinic, or emergency room. Larger, more complicated abscesses may require drainage in the operating room. A cruciate skin and subcutaneous incision is made over the most prominent part of the abscess and the "dog ears" are excised to prevent premature closure. No packing is necessary and sitz baths are started the next day (Fig. 29-37).

A through C. Technique of drainage of perianal abscess.

Ischiorectal Abscesses

An ischiorectal abscess causes diffuse swelling in the ischiorectal fossa that may involve one or both sides, forming a "horseshoe" abscess. Simple ischiorectal abscesses are drained through an incision in the overlying skin. Horseshoe abscesses require drainage of the deep postanal space and often require counterincisions over one or both ischiorectal spaces (Fig. 29-38).

Fig. 29-38.

Drainage of horseshoe abscess. The deep postanal space is entered, incising the anococcygeal ligament. Counter drainage incisions are made for each limb of the ischioanal space.

Intersphincteric Abscess

Intersphincteric abscesses are notoriously difficult to diagnose because they produce little swelling and few perianal signs of infection. Pain is typically described as being deep and "up inside" the anal area, and usually is exacerbated by coughing or sneezing. The pain is so intense that it usually precludes a digital rectal examination. The diagnosis is made based upon a high index of suspicion and usually requires an examination under anesthesia. Once identified, an intersphincteric abscess can be drained through a limited, usually posterior, internal sphincterotomy.

Supralevator Abscess

This type of abscess is uncommon and can be difficult to diagnose. Because of its proximity to the peritoneal cavity, supralevator abscesses can mimic intra-abdominal conditions. Digital rectal examination may reveal an indurated, bulging mass above the anorectal ring. It is essential to identify the origin of a supralevator abscess before treatment. If the abscess is secondary to an upward extension of an intersphincteric abscess, it should be drained through the rectum. If it is drained through the ischioanal fossa, a complicated, suprasphincteric fistula may result. If a supralevator abscess arises from the upward extension of an ischioanal abscess, it should be drained through the ischioanal fossa. Drainage of this type of abscess through the rectum may result in an extrasphincteric fistula. If the abscess is secondary to intra-abdominal disease, the primary process requires treatment and the abscess is drained via the most direct route (transabdominally, rectally, or through the ischioanal fossa).

Perianal Sepsis in the Immunocompromised Patient

The immunocompromised patient with perianal pain presents a diagnostic dilemma. Because of leukopenia, these patients may develop serious perianal infection without any of the cardinal signs of inflammation. Although broad-spectrum antibiotics may cure some of these patients, an examination under anesthesia should not be delayed because of neutropenia. An increase in pain or fever, and/or clinical deterioration mandates an examination under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.⁹¹

Necrotizing Soft Tissue Infection of the Perineum

Necrotizing soft tissue infection of the perineum is a rare, but lethal, condition. Most of these infections are polymicrobial and synergistic. The source of sepsis is commonly an undrained or inadequately drained cryptoglandular abscess or a urogenital infection. Occasionally, these infections may be encountered postoperatively (e.g., after inguinal hernia repair). Immunocompromised patients and diabetic patients are at increased risk.

Physical examination may reveal necrotic skin, bullae, or crepitus. Patients often have signs of systemic toxicity and may be hemodynamically unstable. A high index of suspicion is necessary because perineal signs of severe infection may be minimal and prompt surgical intervention can be lifesaving.

Surgical débridement of all nonviable tissue is required to treat all necrotizing soft tissue infections. Multiple operations may be necessary to ensure that all necrotic tissue has been resected. Broad-spectrum antibiotics are frequently used, but adequate surgical débridement remains the mainstay of therapy. Colostomy may be

required if extensive resection of the sphincter is required or if stool contamination of the perineum makes wound management difficult. Despite early recognition and adequate surgical therapy, the mortality of necrotizing perineal soft tissue infections remains approximately 50%.

Fistula in Ano

Drainage of an anorectal abscess results in cure for about 50% of patients. The remaining 50% develop a persistent *fistula in ano*. The fistula usually originates in the infected crypt (*internal opening*) and tracks to the *external opening*, usually the site of prior drainage. The course of the fistula often can be predicted by the anatomy of the previous abscess.

Although the majority of fistulas are cryptoglandular in origin, trauma, Crohn's disease, malignancy, radiation, or unusual infections (tuberculosis, actinomycosis, and chlamydia) may also produce fistulas. A complex, recurrent, or nonhealing fistula should raise the suspicion of one of these diagnoses.

DIAGNOSIS

Patients present with persistent drainage from the internal and/or external openings. An indurated tract often is palpable. Although the external opening is often easily identifiable, identification of the internal opening may be more challenging. Goodsall's rule can be used as a guide in determining the location of the internal opening (Fig. 29-39). In general, fistulas with an external opening *anteriorly* connect to the internal opening by a *short, radial tract*. Fistulas with an external opening *posteriorly* track in a *curvilinear fashion to the posterior midline*. However, exceptions to this rule often occur if an anterior external opening is greater than 3 cm from the anal margin. Such fistulas usually track to the posterior midline. Fistulas are categorized based upon their relationship to the anal sphincter complex, and treatment options are based upon these classifications. An *intersphincteric fistula* tracks through the distal internal sphincter and intersphincteric space to an external opening near the anal verge (Fig. 29-40A). A *transsphincteric fistula* often results from an ischiorectal abscess and extends through both the internal and external sphincters (Fig. 29-40B). A *suprasphincteric fistula* originates in the intersphincteric plane and tracks up and around the entire external sphincter (Fig. 29-40C). An *extrasphincteric fistula* originates in the rectal wall and tracks around both sphincters to exit laterally, usually in the ischiorectal fossa (Fig. 29-40D).

TREATMENT

The goal of treatment of fistula in ano is eradication of sepsis without sacrificing continence. Because fistulous tracks encircle variable amounts of the sphincter complex, surgical treatment is dictated by the location of the internal and external openings and the course of the fistula. The external opening usually is visible as a red elevation of granulation tissue with or without concurrent drainage. The internal opening may be more difficult to identify. Injection of hydrogen peroxide or dilute methylene blue may be helpful. Care must be taken to avoid creating an artificial internal opening (thus often converting a simple fistula into a complex fistula).

Simple intersphincteric fistulas often can be treated by *fistulotomy* (opening the fistulous tract), curettage, and healing by secondary intention (see Fig. 29-40A).

"Horseshoe" fistulas usually have an internal opening in the posterior midline and extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space. Treatment of a transsphincteric fistula depends upon its location in the sphincter complex. Fistulas that include less than 30% of the sphincter muscles often can be treated by sphincterotomy without significant risk of major incontinence (see Fig. 29-40B). High transsphincteric fistulas, which encircle a greater amount of muscle, are more safely treated by initial placement of a *seton* (see paragraph below). Similarly, suprasphincteric fistulas usually are treated with seton placement (see Fig. 29-40C). Extrasphincteric fistulas are rare, and treatment depends upon both the anatomy of the fistula and its etiology. In general, the portion of the fistula outside the sphincter should be opened and drained. A primary tract at the level of the dentate line may also be opened, if present. Complex fistulas with multiple tracts may require numerous procedures to control sepsis and facilitate healing. Liberal use of drains and setons is helpful. Failure to heal may ultimately require fecal diversion (see Fig. 29-40D). Complex and/or nonhealing fistulas may result from Crohn's disease, malignancy, radiation proctitis, or unusual infection. Proctoscopy should be performed in all cases of complex and/or nonhealing fistulas to assess the health of the rectal mucosa. Biopsies of the fistula tract should be taken to rule out malignancy.

A *seton* is a drain placed through a fistula to maintain drainage and/or induce fibrosis. *Cutting setons* consist of a suture or a rubber band that is placed through the fistula and intermittently tightened in the office. Tightening the seton results in fibrosis and gradual division of the sphincter, thus eliminating the fistula while maintaining continuity of the sphincter. A *noncutting seton* is a soft plastic drain (often a vessel loop) placed in the fistula to maintain drainage. The fistula tract may subsequently be laid open with less risk of incontinence because scarring prevents retraction of the sphincter. Alternatively, the seton may be left in place for chronic drainage. Higher fistulas may be treated by an *endorectal advancement flap* (see below in Rectovaginal Fistula: Treatment). *Fibrin glue* and a variety of collagen-based plugs also have been used to treat persistent fistulas with variable results.

Rectovaginal Fistula

A rectovaginal fistula is a connection between the vagina and the rectum or anal canal proximal to the dentate line. Rectovaginal fistulas are classified as *low* (rectal opening close to the dentate line and vaginal opening in the fourchette), *middle* (vaginal opening between the fourchette and cervix), or *high* (vaginal opening near the cervix). Low rectovaginal fistulas are commonly caused by obstetric injuries or trauma from a foreign body. Midrectovaginal fistulas may result from more severe obstetric injury, but also occur after surgical resection of a midrectal neoplasm, radiation injury, or extension of an undrained abscess. High rectovaginal fistulas result from operative or radiation injury. Complicated diverticulitis may cause a colovaginal fistula. Crohn's disease can cause rectovaginal fistulas at all levels, as well as colovaginal and enterovaginal fistulas.

DIAGNOSIS

Patients describe symptoms varying from the sensation of passing flatus from the vagina to the passage of solid stool from the vagina. Most patients experience some degree of fecal incontinence. Contamination may result in *vaginitis*. Large fistulas may be obvious on anoscopic and/or vaginal speculum examination, but smaller fistulas may be difficult to locate. Occasionally, a barium enema or vaginogram may identify these fistulas. Endorectal ultrasound also may be useful. With the patient in the prone position, installation of methylene blue into the rectum while a tampon is in the vagina may confirm the presence of a small fistula.

TREATMENT

The treatment of rectovaginal fistula depends upon the size, location, etiology, and condition of surrounding tissues. Because up to 50% of fistulas caused by obstetric injury heal spontaneously, it is prudent to wait 3 to 6 months before embarking upon surgical repair in these patients. If the fistula was caused by a cryptoglandular abscess, drainage of the abscess may allow spontaneous closure.

Low and midrectovaginal fistulas usually are best treated with an endorectal advancement flap. The principle of this procedure is based upon the advancement of healthy mucosa, submucosa, and circular muscle over the rectal opening (the high-pressure side of the fistula) to promote healing (Fig. 29-41). If a sphincter injury is present, an overlapping sphincteroplasty should be performed concurrently. Fecal diversion is rarely required. High rectovaginal, colovaginal, and enterovaginal fistulas are usually best treated via a transabdominal approach. The diseased tissue, which caused the fistula (upper rectum, sigmoid colon, or small bowel), is resected and the hole in the vagina closed. Healthy tissue such as omentum or muscle is frequently interposed between the bowel anastomosis and the vagina to prevent recurrence.

Endorectal advancement flap for rectovaginal fistula.

[Reproduced with permission from Gordon PH, Nivatvongs S (eds): *Principles and Practice of Surgery for the Colon, Rectum, and Anus*, 2nd ed. New York: Marcel Dekker, Inc., 1999, p 412.]

Rectovaginal fistulas caused by Crohn's disease, radiation injury, or malignancy almost never heal spontaneously. In Crohn's disease, treatment is based on adequate drainage of perianal sepsis and nutritional support. An endorectal advancement flap may be performed if the rectum is spared from active Crohn's disease. Fistulas resulting from radiation damage are not amenable to local repair with an advancement flap because of damage to the surrounding rectal and vaginal tissues. Mid- and high rectovaginal fistulas are occasionally repaired successfully with a transabdominal approach in which healthy tissue (omentum, muscle, or nonradiated bowel) is interposed between the damaged rectum and vagina. Fistulas caused by malignancy should be treated with resection of the tumor. Because differentiating radiation damage from malignancy can be extremely difficult, all fistulas resulting from radiation should be biopsied to rule out cancer.

Perianal Dermatitis

PRURITUS ANI

Pruritus ani (severe perianal itching) is a common problem with a multitude of etiologies. Surgically correctable (anatomic) causes include prolapsing hemorrhoids,

ectropion, fissure, fistula, and neoplasms. Perianal infection may also present with pruritus ani. Infections may be caused by fungus (*Candida* species, *Monilia*, and *Epidermophyton* organisms), parasites [*Enterobius vermicularis* (pinworms), *Pediculuspubis* (a louse), and *Sarcoptescabiei* (scabies)], bacteria [*Corynebacterium minutissimum* (erythrasma) and *Treponema pallidum* (syphilis)], or viruses [HPV (condyloma acuminata)]. Antibiotic use may also cause itching, usually by precipitating fungal infection. Noninfectious dermatologic causes include seborrhea, psoriasis, and contact dermatitis. Contact dermatitis can be particularly troublesome because many over-the-counter topical agents used by patients to relieve itching may exacerbate the problem. Occasionally, systemic diseases such as jaundice and diabetes may present with pruritus ani.

Despite this myriad of causes, the majority of pruritus ani is idiopathic and probably related to local hygiene, neurogenic, or psychogenic causes. Treatment focuses on removal of irritants, improving perianal hygiene, dietary adjustments, and avoiding scratching. Biopsy and/or culture may be required to rule out an infectious or dermatologic cause. Hydrocortisone ointment 0.5 to 1.0% can provide symptomatic relief but should not be used for prolonged periods of time because of dermal atrophy. Skin barriers such as Calmoseptine also can provide relief. Systemic antihistamines or tricyclic antidepressants also have been used with some success.

NONPRURITIC LESIONS

Several perianal skin conditions may present with perianal skin changes. Leprosy, amebiasis, actinomycosis, and lymphogranuloma venereum produce characteristic perianal lesions. Neoplasms such as Bowen's disease, Paget's disease, and invasive carcinomas may also appear first in the perianal skin. Biopsy usually can distinguish these diagnoses.

Sexually Transmitted Diseases

BACTERIAL INFECTIONS

Proctitis is a common symptom of anorectal bacterial infection.^{92,93} *N. gonorrhoeae* is the most common bacterial cause of proctitis and causes pain, tenesmus, rectal bleeding, and mucus discharge. *C. trachomatis* infection may be asymptomatic or may produce similar symptoms. *T. pallidum*, the microbe causing syphilis, causes a chancre at the site of inoculation, which may be asymptomatic or may present as an atypical fissure (primary syphilis). Condyloma lata are characteristic of secondary syphilis. Chancroid, caused by *Haemophilus ducreyi*, is a disease manifested by multiple painful, bleeding lesions. Inguinal lymphadenopathy and fluctuant, draining lymph nodes are characteristic. *Donovania granulomatis* infection produces shiny, red masses on the perineum (granuloma inguinale). Diarrheal illnesses caused by organisms such as *Campylobacter* or *Shigella* also may be sexually transmitted. Treatment consists of antimicrobial agents directed against the infecting organism.

PARASITIC INFECTIONS

Entamoeba histolytica is an increasingly common sexually transmitted disease. Amebas produce ulcerations in the GI mucosa and can infect any part of the gut. Symptoms include diarrhea, abdominal pain, and tenesmus. *Giardia lamblia* is also common and produces diarrhea, abdominal pain, and malaise.

VIRAL INFECTIONS

Herpes Simplex Virus

Herpes proctitis is extremely common. Proctitis usually is caused by type II herpes simplex virus and less commonly by type I herpes simplex virus. Patients complain of severe, intractable perianal pain and tenesmus. Pain often precedes the development of characteristic vesicles, and these patients may require an examination under anesthesia to exclude another diagnosis such as an intersphincteric abscess. Diagnosis is confirmed by viral culture of tissue or vesicular fluid.

Human Papillomavirus

HPV causes condyloma acuminata (anogenital warts) and is associated with AIN and squamous cell carcinoma (see Anal Canal and Perianal Tumors above). Condylomas occur in the perianal area or in the squamous epithelium of the anal canal. Occasionally, the mucosa of the lower rectum may be affected. There are approximately 30 serotypes of HPV. HPV types 16 and 18, in particular, appear to predispose to malignancy and often cause flat dysplasia in skin unaffected by warts. In contrast, HPV types 6 and 11 commonly cause warts, but do not appear to cause malignant degeneration.

Treatment of anal condyloma depends on the location and extent of disease. Small warts on the perianal skin and distal anal canal may be treated in the office with topical application of bichloroacetic acid or podophyllin. Although 60 to 80% of patients will respond to these agents, recurrence and reinfection are common. Imiquimod (Aldara) is an immunomodulator that recently was introduced for topical treatment of several viral infections, including anogenital condyloma.⁹⁴ Initial reports suggest that this agent is highly effective in treating condyloma located on the perianal skin and distal anal canal.⁹⁵ Larger and/or more numerous warts require excision and/or fulguration in the operating room. Excised warts should be sent for pathologic examination to rule out dysplasia or malignancy. It is important to note that prior use of podophyllin may induce histologic changes that mimic dysplasia. The recent introduction of a vaccine against HPV holds promise for preventing anogenital condylomas.

Human Immunodeficiency Virus

See The Immunocompromised Patient below.

Pilonidal Disease

Pilonidal disease (cyst, infection) consists of a hair-containing sinus or abscess occurring in the intergluteal cleft. Although the etiology is unknown, it is speculated

that the cleft creates a suction that draws hair into the midline pits when a patients sits. These ingrown hairs may then become infected and present acutely as an abscess in the sacrococcygeal region. Once an acute episode has resolved, recurrence is common.

An acute abscess should be incised and drained as soon as the diagnosis is made. Because these abscesses are usually very superficial, this procedure often can be performed in the office, clinic, or emergency room under local anesthetic. Because midline wounds in the region heal poorly, some surgeons recommend using an incision *lateral* to the intergluteal cleft. A number of procedures have been proposed to treat a chronic pilonidal sinus. The simplest method involves unroofing the tract, curetting the base, and marsupializing the wound. The wound must then be kept clean and free of hair until healing is complete (often requiring weekly office visits for wound care). Alternatively, a small lateral incision can be created and the pit excised. This method is effective for most primary pilonidal sinuses. In general, extensive resection should be avoided. Complex and/or recurrent sinus tracts may require more extensive resection and closure with a Z-plasty, advancement flap, or rotational flap.

Hidradenitis Suppurativa

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. Infected glands rupture and form subcutaneous sinus tracts. The infection may mimic complex anal fistula disease, but stops at the anal verge because there are no apocrine glands in the anal canal. Treatment involves incision and drainage of acute abscesses and unroofing of all chronically inflamed fistulas and débridement of granulation tissue. Radical excision and skin grafting is almost never necessary.

TRAUMA

Penetrating Colorectal Injury

Colorectal injury is common following penetrating trauma to the abdomen and has historically been associated with high mortality. In the first half of the twentieth century, the mortality rate from colorectal injury was as high as 90%. The introduction of exteriorization of colonic injuries and fecal diversion during World War II dramatically decreased mortality, and this principle has governed the management of large-bowel injury for over 50 years. Recently, however, this practice was challenged and trauma surgeons are increasingly performing primary repairs in selected patients.

Management of colonic injury depends upon the mechanism of injury, the delay between the injury and surgery, the overall condition and stability of the patient, the degree of peritoneal contamination, and the condition of the injured colon. A primary repair may be considered in hemodynamically stable patients with few additional injuries and minimal contamination if the colon appears otherwise healthy. Contraindications to primary repair include shock, injury to more than two other organs, mesenteric vascular damage, and extensive fecal contamination. A delay of greater than 6 hours between the injury and the operation also is associated with increased morbidity and mortality and is a relative contraindication to primary repair. Injuries caused by high-velocity gunshot wounds or blast injuries often are associated with multiple intra-abdominal injuries and tissue loss and therefore usually are treated by fecal diversion after débridement of all nonviable tissue. Patient factors, such as medical comorbidities, advanced age, and the presence of tumor or radiation injury, must also be considered (Table 29-6).

Table 29-6 Criteria for Use of an Ostomy
Injuring agent factors
High-velocity bullet wounds
Shotgun wounds
Explosive blast wounds
Crush injury
Patient factors
Presence of tumor
Radiated tissue
Medical condition
Advanced age
Injury factors
Inflamed tissue
Advanced infection
Distal obstruction
Local foreign body
Impaired blood supply
Mesenteric vascular damage
Shock with blood pressure <80/60 mmHg
Hemorrhage >1000 mL
More than two organs (especially kidney) injured
Interval to operation >6 h (pancreatic, splenic, hepatic)
Extensive injury requiring resection

Major abdominal wall loss
Thoracoabdominal penetration

Like injuries to the intraperitoneal colon, penetrating trauma to the rectum traditionally has been associated with high morbidity and mortality. Primary repair of the rectum is more difficult than primary repair of the colon, however, and most rectal injuries are associated with significant contamination. For that reason, the majority of penetrating rectal injuries should be treated with proximal fecal diversion and copious irrigation of the rectum (distal rectal washout). If there is extensive fecal contamination, presacral drains may be useful. Small, clean rectal injuries may be closed primarily without fecal diversion in an otherwise stable patient. Intractable rectal bleeding may require angiographic embolization. Very rarely, hemorrhage or extensive tissue loss (especially if the anal sphincter is severely damaged) may require an emergent abdominoperineal resection. However, this operation should be avoided, if at all possible, because of the morbidity associated with an extensive pelvic dissection in a severely injured patient.

Blunt Colorectal Injury

Blunt injury to the colon and rectum is considerably less common than penetrating injury. Nevertheless, blunt trauma can cause colon perforation, and shear injury to the mesentery can devascularize the intestine. Management of these injuries should follow the same principles outlined for management of penetrating injuries. Small perforations with little contamination in a stable patient may be closed primarily; more extensive injury requires fecal diversion. A serosal hematoma alone does not mandate resection, but the bowel should be carefully inspected to ensure that there is not an associated perforation or significant bowel ischemia.

Blunt injury to the rectum may result from significant trauma, such as a pelvic crush injury, or may result from local trauma caused by an enema or foreign body. Crush injuries, especially with an associated pelvic fracture, often are associated with significant rectal damage and contamination. These patients require débridement of all nonviable tissue, proximal fecal diversion, and a distal rectal washout, with or without drain placement. Blunt trauma from an enema or foreign body may produce a mucosal hematoma, which requires no surgical treatment if the mucosa is intact. Small mucosal tears may be closed primarily if the bowel is relatively clean and there is little contamination.

Iatrogenic Injury

INTRAOPERATIVE INJURY

The colon and rectum are at risk for inadvertent injury during other procedures, especially during pelvic operations. The key to managing these injuries is *early recognition*. The vast majority of iatrogenic colorectal injuries may be closed primarily if there is little contamination and if the patient is otherwise stable. Delayed recognition of colorectal injuries may result in significant peritonitis and life-threatening sepsis. In these cases, fecal diversion almost always is required and the patient may need repeated exploration for drainage of abscesses.

INJURY FROM BARIUM ENEMA

Colorectal injury from a barium enema is an extremely rare complication associated with a high rate of morbidity and mortality. Perforation with spillage of barium, especially above the peritoneal reflection, may result in profound peritonitis, sepsis, and a systemic inflammatory response. If the perforation is recognized early, it may be closed primarily and the abdomen irrigated to remove stool and barium. However, if the patient has developed sepsis, fecal diversion (with or without bowel resection) is almost always required. Rarely, a small mucosal injury to the extraperitoneal rectum may be managed with bowel rest, broad-spectrum antibiotics, and close observation.

COLONOSCOPIC PERFORATION

Perforation is the most common major complication after either diagnostic or therapeutic colonoscopy. Fortunately, this complication is rare and occurs in less than 1% of procedures. Perforation may result from trauma from the tip of the instrument, from shear forces related to the formation of a "loop" in the colonoscope, or from barotrauma from insufflation. Biopsy or fulguration also can cause perforation. Polypectomy using electrocautery may produce a full-thickness burn, resulting in *postpolypectomy syndrome*, in which a patient develops abdominal pain, fever, and leukocytosis without evidence of diffuse peritonitis.

Management of colonoscopic perforation depends on the *size of the perforation*, the *duration of time* since the injury, and the *overall condition of the patient*. A large perforation recognized during the procedure requires surgical exploration. Because the bowel almost always has been prepared before the colonoscopy, there is usually little contamination associated with these injuries and most can be repaired primarily. If there is significant contamination, if there has been a delay in diagnosis with resulting peritonitis, or if the patient is hemodynamically unstable, proximal diversion with or without resection is the safest approach. Occasionally, a patient will develop abdominal pain and localized signs of perforation after what was thought to be an uneventful colonoscopy. Many of these patients will have a "microperforation" that will resolve with bowel rest, broad-spectrum antibiotics, and close observation. Evidence of peritonitis or any deterioration in clinical condition mandates exploration. Similarly, free retroperitoneal or intraperitoneal air may be discovered incidentally after colonoscopy. In a completely asymptomatic patient, this finding is thought to result from barotrauma and dissection of air through tissue planes without a free perforation. Many of these patients can be successfully treated with bowel rest and broad-spectrum antibiotics. Surgical exploration is indicated for any clinical deterioration.

Anal Sphincter Injury and Incontinence

The most common cause of anal sphincter injury is obstetric trauma during vaginal delivery. The risk of sphincter injury is increased by a laceration that extends into the rectum (fourth-degree tear), infection of an episiotomy or laceration repair, prolonged labor, and possibly by use of a midline episiotomy. Sphincter damage also may result from hemorrhoidectomy, sphincterotomy, abscess drainage, or fistulotomy. Patients with incontinence and a suspected sphincter injury can be evaluated with anal manometry, EMG, and endoanal ultrasound. Mild incontinence, even in the presence of a sphincter defect, may respond to dietary changes and/or biofeedback. More severe incontinence may require surgical repair.

The anal sphincter also can be injured by penetrating or blunt mechanisms (impalement, blast injury, crush injuries of the pelvis). Because damage to the anal sphincter is not life threatening, definitive repair of the sphincter is often deferred until other injuries have been repaired and the patient's clinical condition is stable. Isolated sphincter injuries that do not involve the rectum may be repaired primarily. Rectal injury accompanied by sphincter injury should be treated with fecal diversion, distal rectal washout, and drain placement. Significant perineal tissue loss may require extensive débridement and a diverting colostomy.

SURGICAL REPAIRS

The most common method of repair of the anal sphincter is a *wrap-around sphincteroplasty* (Fig. 29-42).⁹⁶ The procedure involves mobilization of the divided sphincter muscle and reapproximation without tension. The internal and external sphincters may be overlapped together or separately. *Postanal intersphincteric levatorplasty* is less commonly used to repair sphincter defects but may be useful for incontinence caused by prolapse and/or loss of the anorectal angle (see Continence above). The approach is via the intersphincteric plane posteriorly. It may be performed concomitantly with a perineal repair of rectal prolapse. The levator ani muscle is approximated to restore the anorectal angle and the puborectalis and external sphincter muscle are tightened with sutures. These elective procedures usually do not require a diverting colostomy.

Fig. 29-42.

In cases where there has been significant loss of sphincter muscle, or in which prior repairs have failed, more complex techniques, such as *gracilis muscle transposition* with or without chronic, low-frequency electrostimulation, have been used with some success.⁹⁷ In this procedure, the gracilis muscle is mobilized from the thigh, detached from its insertion on the tibial tuberosity, tunneled through the perineum, and wrapped around the anal canal. Another alternative in patients who have failed other repairs is the *artificial anal sphincter*. This device consists of an inflatable silastic cuff, a pressure-regulating balloon, and a control pump. Patients deflate the cuff manually to open the anal canal; the cuff then reinflates spontaneously to maintain closure of the anal canal. *Sacral nerve stimulation* via an implanted pulse generator is a new technique used for neurogenic incontinence when the sphincter is intact.^{12,13} In some patients, an end stoma provides the best

relief for intractable incontinence.

Foreign Body

Foreign-body entrapment in the rectum is not uncommon. Depending upon the level of entrapment, a foreign body may cause damage to the rectum, rectosigmoid, or descending colon. Generalized abdominal pain suggests intraperitoneal perforation. Evaluation of the patient includes inspection of the perineum and a careful abdominal examination to detect any evidence of perforation. Plain films of the abdomen are mandatory to detect free intra-abdominal air.

Foreign bodies lodged low in the rectum may often be removed under conscious sedation with or without a local anesthetic block. Objects impacted higher in the rectum may require regional or general anesthesia for removal. Only rarely will a laparotomy be required to remove the object. After removal of the foreign body, it is crucial to evaluate the rectum and sigmoid colon for injury. Proctoscopy and/or flexible sigmoidoscopy should be performed. A hematoma without evidence of perforation requires no surgical treatment. Perforation of the rectum or sigmoid colon should be managed as described in the preceding section, Penetrating Colorectal Injury.

THE IMMUNOCOMPROMISED PATIENT

Human Immunodeficiency Virus

Patients infected with HIV may present with a myriad of GI symptoms. Diarrhea, in particular, is extremely common. The severity of GI disease depends, in part, upon the degree of immunosuppression; however, both ordinary and opportunistic pathogens may affect patients at any stage of the disease. Opportunistic infections with bacteria (*Salmonella*, *Shigella*, *Campylobacter*, *Chlamydia*, and *Mycobacterium* species), fungi (*Histoplasmosis*, *Coccidiosis*, *Cryptococcus*), protozoa (*Toxoplasmosis*, *Cryptosporidiosis*, *Isosporiasis*), and viruses (*CMV*, *herpes simplex virus*) can cause diarrhea, abdominal pain, and weight loss. CMV in particular may cause severe enterocolitis and is the most common infectious cause of emergency laparotomy in AIDS patients. *C. difficile colitis* is a major concern in these patients, especially because many patients are maintained on suppressive antibiotic therapy. The incidence of GI malignancy also is increased in patients with HIV infection.⁹⁹ Kaposi's sarcoma is the most common malignancy in AIDS patients and can affect any part of the GI tract. Patients may be asymptomatic or may develop bleeding or obstruction. GI lymphoma (usually non-Hodgkin's lymphoma) also is common. The incidence of colorectal carcinoma also may be increased in this population, although definitive data are lacking.

Perianal disease is extremely common in patients with HIV infection. Because HIV is sexually transmitted, it is common to find concomitant infection with other sexually transmitted diseases such as *Chlamydia*, *herpes simplex virus*, and *HPV (anal condyloma)*. *Anal condyloma* in particular is very common and the incidence of dysplasia (AIN, HSIL) is high in the HIV-infected population.¹⁰⁰ Abscesses and fistulas may be more difficult to diagnose in these patients and may be complex. Many patients require an examination under anesthesia with biopsy and cultures to determine the etiology of many of these perianal problems. The introduction of highly active antiretroviral therapy has changed the natural history of HIV infection, but it remains to be seen how these medications will affect the incidence and outcome of colorectal disease in this patient population.

IMMUNOSUPPRESSION FOR TRANSPLANTATION

The GI tract is a common site for posttransplantation complications that are responsible for significant morbidity and mortality. In these patients, infection and medication are the most common causes of diarrhea. Immunosuppressant medications, in particular, may cause diarrhea. CMV infection is common and may be severe. *C. difficile colitis* also occurs commonly. Diverticulitis appears to be more common in some populations of transplant patients and may be more likely to present with abscess or free perforation. Elective resection after recovery from one episode of confirmed diverticulitis may be indicated in the transplant population. Graft-versus-host disease is unique to transplant patients and often requires endoscopy and biopsy to diagnose GI involvement. Patients are subject to the same opportunistic infections outlined above in Human Immunodeficiency Virus; however, sexually transmitted infections and Kaposi's sarcoma are somewhat less prevalent. Perianal disease is somewhat less common in the transplant population than in patients infected with HIV; however, similar infections may occur and immunosuppression often makes diagnosis challenging.

With increasing long-term survival among transplant recipients, the development of posttransplant malignancy has become a major concern. Posttransplant lymphoproliferative disease is increasingly common and may occur anywhere in the GI tract. The risk of colorectal carcinoma is increased in patients with predisposing conditions such as ulcerative colitis. However, immunosuppression alone does not appear to increase the incidence of colorectal cancer, and current screening recommendations are similar to those for the average risk population. In contrast, the incidence of anal squamous cell carcinoma is dramatically increased in transplant patients and patients with known HPV infection should undergo more vigorous screening.

THE NEUTROPENIC PATIENT

Neutropenic enterocolitis (typhlitis) is a life-threatening problem with a mortality rate of greater than 50%. This syndrome is characterized by abdominal pain and distention, fever, diarrhea (often bloody), nausea, and vomiting in a patient with fewer than 1000 neutrophils from any cause (bone marrow transplantation, solid organ transplantation, or chemotherapy). CT scan of the abdomen often shows a dilated cecum with pericolic stranding. However, a normal-appearing CT scan does not exclude the diagnosis. Some patients will respond to bowel rest, broad-spectrum antibiotics, parenteral nutrition, and granulocyte infusion or colony-stimulating factors. Evidence of perforation, generalized peritonitis, or deterioration in clinical condition is an indication for operation.

Neutropenic patients often develop perianal pain, and diagnosis may be difficult because of a lack of inflammatory response to infection. Although broad-spectrum

antibiotics may cure some of these patients, an examination under anesthesia should not be delayed because of neutropenia. An increase in pain or fever, and/or clinical deterioration mandates an examination under anesthesia. Any indurated area should be incised and drained, biopsied to exclude a leukemic infiltrate, and cultured to aid in the selection of antimicrobial agents.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 30. The Appendix >

KEY POINTS

1. Appendectomy for appendicitis is the most commonly performed emergency operation in the world.
2. Despite the increased use of ultrasonography, computed tomographic scanning, and laparoscopy, the rate of misdiagnosis of appendicitis has remained constant (15.3%), as has the rate of appendiceal rupture. The percentage of misdiagnosed cases of appendicitis is significantly higher among women than among men.
3. Appendicitis is a polymicrobial infection, with some series reporting up to 14 different organisms cultured in patients with perforation. The principal organisms seen in the normal appendix, in acute appendicitis, and in perforated appendicitis are *Escherichia coli* and *Bacteroides fragilis*.
4. Antibiotic prophylaxis is effective in the prevention of postoperative wound infection and intra-abdominal abscess. Antibiotic coverage is limited to 24 to 48 hours in cases of nonperforated appendicitis. For perforated appendicitis, 7 to 10 days of treatment is recommended.
5. Compared with younger patients, elderly patients with appendicitis often pose a more difficult diagnostic problem because of the atypical presentation, expanded differential diagnosis, and communication difficulty. These factors contribute to the disproportionately high perforation rate seen in the elderly.
6. The overall incidence of fetal loss after appendectomy is 4% and the risk of early delivery is 7%. Rates of fetal loss are considerably higher in women with complex appendicitis than in those with negative appendectomy and those with simple appendicitis. Removing a normal appendix is associated with a 4% risk of fetal loss and 10% risk of early delivery.
7. Recent data on appendiceal malignancies from the Surveillance, Epidemiology, and End Results program identified mucinous adenocarcinoma as the most frequent histologic diagnosis, followed by adenocarcinoma, carcinoid, goblet cell carcinoma, and signet-ring cell carcinoma.

ANATOMY AND FUNCTION

The appendix first becomes visible in the eighth week of embryologic development as a protuberance off the terminal portion of the cecum. During both antenatal and postnatal development, the growth rate of the cecum exceeds that of the appendix, so that the appendix is displaced medially toward the ileocecal valve. The relationship of the base of the appendix to the cecum remains constant, whereas the tip can be found in a retrocecal, pelvic, subcecal, preileal, or right pericolic position (Fig. 30-1). These anatomic considerations have significant clinical importance in the context of acute appendicitis. The three taeniae coli converge at the junction of the cecum with the appendix and can be a useful landmark to identify the appendix. The appendix can vary in length from <1 cm to >30 cm; most appendices are 6 to 9 cm long. Appendiceal absence, duplication, and diverticula have all been described.^{1–4}

Fig. 30-1.

For many years, the appendix was erroneously viewed as a vestigial organ with no known function. It is now well recognized that the appendix is an immunologic organ that actively participates in the secretion of immunoglobulins, particularly immunoglobulin A. Although there is no clear role for the appendix in the development of human disease, recent studies demonstrate a potential correlation between appendectomy and the development of inflammatory bowel disease. There appears to be a negative age-related association between prior appendectomy and subsequent development of ulcerative colitis. In addition, comparative analysis clearly shows that prior appendectomy is associated with a more benign phenotype in ulcerative colitis and a delay in onset of disease. The association between Crohn's disease and appendectomy is less clear. Although earlier studies suggested that appendectomy increases the risk of developing Crohn's disease, more recent studies that carefully assessed the timing of appendectomy in relation to the onset of Crohn's disease demonstrated a negative correlation. These data suggest that appendectomy may protect against the subsequent development of inflammatory bowel disease; however, the mechanism is unclear.⁴

Lymphoid tissue first appears in the appendix approximately 2 weeks after birth. The amount of lymphoid tissue increases throughout puberty, remains steady for the next decade, and then begins a steady decrease with age. After the age of 60 years, virtually no lymphoid tissue remains within the appendix, and complete obliteration of the appendiceal lumen is common.¹⁻⁴

ACUTE APPENDICITIS

Historical Background

Although ancient texts have scattered descriptions of surgery being undertaken for ailments sounding like appendicitis, credit for performing the first appendectomy goes to Claudius Amyand, a surgeon at St. George's Hospital in London and Sergeant Surgeon to Queen Ann, King George I, and King George II. In 1736, he operated on an 11-year-old boy with a scrotal hernia and a fecal fistula. Within the hernial sac, Amyand found the appendix perforated by a pin. He successfully removed the appendix and repaired the hernia.⁵

The appendix was not identified as an organ capable of causing disease until the nineteenth century. In 1824, Louyer-Villermay presented a paper before the Royal Academy of Medicine in Paris. He reported on two autopsy cases of appendicitis and emphasized the importance of the condition. In 1827, François Melier, a French physician, expounded on Louyer-Villermay's work. He reported six autopsy cases and was the first to suggest the antemortem recognition of appendicitis.⁵ This work was discounted by many physicians of the era, including Baron Guillaume Dupuytren. Dupuytren believed that inflammation of the cecum was the main cause of pathology of the right lower quadrant. The term *typhlitis* or *perityphlitis* was used to describe right lower quadrant inflammation. In 1839, a textbook authored by Bright and Addison entitled *Elements of Practical Medicine* described the symptoms of appendicitis and identified the primary cause of inflammatory processes of the right lower quadrant.⁶ Reginald Fitz, a professor of pathologic anatomy at Harvard, is credited with coining the term *appendicitis*. His landmark paper definitively identified the appendix as the primary cause of right lower quadrant inflammation.⁷

Initial surgical therapy for appendicitis was primarily designed to drain right lower quadrant abscesses that occurred secondary to appendiceal perforation. It appears that the first surgical treatment for appendicitis or perityphlitis without abscess was carried out by Hancock in 1848. He incised the peritoneum and drained the right lower quadrant without removing the appendix. The first published account of appendectomy for appendicitis was by Krönlein in 1886. However, this patient died 2 days after operation. Fergus, in Canada, performed the first elective appendectomy in 1883.⁵

The greatest contributor to the advancement in the treatment of appendicitis was Charles McBurney. In 1889, he published his landmark paper in the *New York State Medical Journal* describing the indications for early laparotomy for the treatment of appendicitis. It is in this paper that he described the McBurney point as follows: "maximum tenderness, when one examines with the fingertips is, in adults, one half to two inches inside the right anterior spinous process of the ilium on a line drawn to the umbilicus."⁸ McBurney subsequently published a paper in 1894 describing the incision that bears his name.⁹ However, McBurney later credited McArthur with first describing this incision. Semm is widely credited with performing the first successful laparoscopic appendectomy in 1982.¹⁰

The surgical treatment of appendicitis is one of the great public health advances of the last 150 years. Appendectomy for appendicitis is the most commonly performed emergency operation in the world. Appendicitis is a disease of the young, with 40% of cases occurring in patients between the ages of 10 and 29 years.¹¹ In 1886, Fitz reported the associated mortality rate of appendicitis to be at least 67% without surgical therapy.⁷ Currently, the mortality rate for acute appendicitis with treatment is reported to be <1%.¹²

Incidence

The lifetime rate of appendectomy is 12% for men and 25% for women, with approximately 7% of all people undergoing

appendectomy for acute appendicitis during their lifetime. Over the 10-year period from 1987 to 1997, the overall appendectomy rate decreased in parallel with a decrease in incidental appendectomy.^{11,13} However, the rate of appendectomy for appendicitis has remained constant at 10 per 10,000 patients per year.¹⁴ Appendicitis is most frequently seen in patients in their second through fourth decades of life, with a mean age of 31.3 years and a median age of 22 years. There is a slight male:female predominance (1.2 to 1.3:1).^{11,13}

Despite the increased use of ultrasonography, computed tomography (CT), and laparoscopy, the rate of misdiagnosis of appendicitis has remained constant (15.3%), as has the rate of appendiceal rupture. The percentage of misdiagnosed cases of appendicitis is significantly higher among women than among men (22.2 vs. 9.3%). The negative appendectomy rate for women of reproductive age is 23.2%, with the highest rates in women aged 40 to 49 years. The highest negative appendectomy rate is reported for women >80 years of age (Fig. 30-2).^{13,14}

Etiology and Pathogenesis

Obstruction of the lumen is the dominant etiologic factor in acute appendicitis. Fecaliths are the most common cause of appendiceal obstruction. Less common causes are hypertrophy of lymphoid tissue, inspissated barium from previous x-ray studies, tumors, vegetable and fruit seeds, and intestinal parasites. The frequency of obstruction rises with the severity of the inflammatory process. Fecaliths are found in 40% of cases of simple acute appendicitis, in 65% of cases of gangrenous appendicitis without rupture, and in nearly 90% of cases of gangrenous appendicitis with rupture.

Traditionally the belief has been that there is a predictable sequence of events leading to eventual appendiceal rupture. The proximal obstruction of the appendiceal lumen produces a closed-loop obstruction, and continuing normal secretion by the

appendiceal mucosa rapidly produces distention. The luminal capacity of the normal appendix is only 0.1 mL. Secretion of as little as 0.5 mL of fluid distal to an obstruction raises the intraluminal pressure to 60 cm H₂O. Distention of the appendix stimulates the nerve endings of visceral afferent stretch fibers, producing vague, dull, diffuse pain in the midabdomen or lower epigastrium. Peristalsis also is stimulated by the rather sudden distention, so that some cramping may be superimposed on the visceral pain early in the course of appendicitis. Distention increases from continued mucosal secretion and from rapid multiplication of the resident bacteria of the appendix. Distention of this magnitude usually causes reflex nausea and vomiting, and the diffuse visceral pain becomes more severe. As pressure in the organ increases, venous pressure is exceeded. Capillaries and venules are occluded, but arteriolar inflow continues, resulting in engorgement and vascular congestion. The inflammatory process soon involves the serosa of the appendix and in turn parietal peritoneum in the region, which produces the characteristic shift in pain to the right lower quadrant.

The mucosa of the GI tract, including the appendix, is susceptible to impairment of blood supply; thus its integrity is compromised early in the process, which allows bacterial invasion. As progressive distention encroaches on first the venous return and subsequently the arteriolar inflow, the area with the poorest blood supply suffers most: ellipsoidal infarcts develop in the antimesenteric border. As distention, bacterial invasion, compromise of vascular supply, and infarction progress, perforation occurs, usually through one of the infarcted areas on the antimesenteric border. Perforation generally occurs just beyond the point of obstruction rather than at the tip because of the effect of diameter on intraluminal tension.

This sequence is not inevitable, however, and some episodes of acute appendicitis apparently subside spontaneously. Many patients who are found at operation to have acute appendicitis give a history of previous similar, but less severe, attacks of right lower quadrant pain. Pathologic examination of the appendices removed from these patients often reveals thickening and scarring, suggesting old, healed acute inflammation.^{15,16} The strong association between delay in presentation and appendiceal perforation supported the proposition that appendiceal perforation is the advanced stage of acute appendicitis; however, recent epidemiologic studies have suggested that nonperforated and perforated appendicitis may, in fact, be different diseases.¹⁷

Bacteriology

The bacterial population of the normal appendix is similar to that of the normal colon. The appendiceal flora remains constant throughout life with the exception of *Porphyromonas gingivalis*. This bacterium is seen only in adults.¹⁸ The bacteria cultured in cases of appendicitis are therefore similar to those seen in other colonic infections such as diverticulitis. The principal organisms seen in the normal appendix, in acute appendicitis, and in perforated appendicitis are *Escherichia coli* and *Bacteroides fragilis*.^{18–21} However, a wide variety of both facultative and anaerobic bacteria and mycobacteria may be present (Table 30-1). Appendicitis is a polymicrobial infection, with some series reporting the culture of up to 14 different organisms in patients with perforation.¹⁸

Table 30-1 Common Organisms Seen in Patients with Acute Appendicitis	
Aerobic and Facultative	Anaerobic
Gram-negative bacilli	Gram-negative bacilli
<i>Escherichia coli</i>	<i>Bacteroides fragilis</i>
<i>Pseudomonas aeruginosa</i>	Other <i>Bacteroides</i> species
<i>Klebsiella</i> species	<i>Fusobacterium</i> species
Gram-positive cocci	Gram-positive cocci

<i>Streptococcus anginosus</i>	<i>Peptostreptococcus</i> species
Other <i>Streptococcus</i> species	Gram-positive bacilli
<i>Enterococcus</i> species	<i>Clostridium</i> species

The routine culture of intraperitoneal samples in patients with either perforated or nonperforated appendicitis is questionable. As discussed earlier, the flora is known, and therefore broad-spectrum antibiotics are indicated. By the time culture results are available, the patient often has recovered from the illness. In addition, the number of organisms cultured and the ability of a specific laboratory to culture anaerobic organisms vary greatly. Peritoneal culture should be reserved for patients who are immunosuppressed, as a result of either illness or medication, and for patients who develop an abscess after the treatment of appendicitis.^{20–22} Antibiotic prophylaxis is effective in the prevention of postoperative wound infection and intra-abdominal abscess.²³ Antibiotic coverage is limited to 24 to 48 hours in cases of nonperforated appendicitis. For perforated appendicitis, 7 to 10 days of therapy is recommended. IV antibiotics are usually given until the white blood cell count is normal and the patient is afebrile for 24 hours. Antibiotic irrigation of the peritoneal cavity and the use of transperitoneal drainage through the wound are controversial.²⁴

Clinical Manifestations

SYMPTOMS

Abdominal pain is the prime symptom of acute appendicitis. Classically, pain is initially diffusely centered in the lower epigastrium or umbilical area, is moderately severe, and is steady, sometimes with intermittent cramping superimposed. After a period varying from 1 to 12 hours, but usually within 4 to 6 hours, the pain localizes to the right lower quadrant. This classic pain sequence, although usual, is not invariable. In some patients, the pain of appendicitis begins in the right lower quadrant and remains there. Variations in the anatomic location of the appendix account for many of the variations in the principal locus of the somatic phase of the pain. For example, a long appendix with the inflamed tip in the left lower quadrant causes pain in that area. A retrocecal appendix may cause principally flank or back pain; a pelvic appendix, principally suprapubic pain; and a retroileal appendix, testicular pain, presumably from irritation of the spermatic artery and ureter. Intestinal malrotation also is responsible for puzzling pain patterns. The visceral component is in the normal location, but the somatic component is felt in that part of the abdomen where the cecum has been arrested in rotation.

Anorexia nearly always accompanies appendicitis. It is so constant that the diagnosis should be questioned if the patient is not anorectic. Although vomiting occurs in nearly 75% of patients, it is neither prominent nor prolonged, and most patients vomit only once or twice. Vomiting is caused by both neural stimulation and the presence of ileus.

Most patients give a history of obstipation beginning before the onset of abdominal pain, and many feel that defecation would relieve their abdominal pain. Diarrhea occurs in some patients, however, particularly children, so that the pattern of bowel function is of little differential diagnostic value.

The sequence of symptom appearance has great significance for the differential diagnosis. In >95% of patients with acute appendicitis, anorexia is the first symptom, followed by abdominal pain, which is followed, in turn, by vomiting (if vomiting occurs). If vomiting precedes the onset of pain, the diagnosis of appendicitis should be questioned.

SIGNS

Physical findings are determined principally by what the anatomic position of the inflamed appendix is, as well as by whether the organ has already ruptured when the patient is first examined.

Vital signs are minimally changed by uncomplicated appendicitis. Temperature elevation is rarely $>1^{\circ}\text{C}$ (1.8°F) and the pulse rate is normal or slightly elevated. Changes of greater magnitude usually indicate that a complication has occurred or that another diagnosis should be considered.²⁵

Patients with appendicitis usually prefer to lie supine, with the thighs, particularly the right thigh, drawn up, because any motion increases pain. If asked to move, they do so slowly and with caution.

The classic right lower quadrant physical signs are present when the inflamed appendix lies in the anterior position. Tenderness often is maximal at or near the McBurney point.⁸ Direct rebound tenderness usually is present. In addition, referred or indirect rebound tenderness is present. This referred tenderness is felt maximally in the right lower quadrant, which indicates localized peritoneal irritation.²⁵ The Rovsing sign—pain in the right lower quadrant when palpatory pressure is exerted in the left lower quadrant—also indicates the site of peritoneal irritation. Cutaneous hyperesthesia in the area supplied by the spinal nerves on the right at T10, T11, and T12 frequently accompanies acute appendicitis. In patients with obvious appendicitis, this sign is superfluous, but in some early cases, it may be the first positive sign. Hyperesthesia is elicited either by needle prick or by gently picking up the skin between the forefinger and thumb.

Muscular resistance to palpation of the abdominal wall roughly parallels the severity of the inflammatory process. Early in the disease, resistance, if present, consists mainly of voluntary guarding. As peritoneal irritation progresses, muscle spasm increases and becomes largely involuntary, that is, true reflex rigidity due to contraction of muscles directly beneath the inflamed parietal peritoneum.

Anatomic variations in the position of the inflamed appendix lead to deviations in the usual physical findings. With a retrocecal appendix, the anterior abdominal findings are less striking, and tenderness may be most marked in the flank. When the inflamed appendix hangs into the pelvis, abdominal findings may be entirely absent, and the diagnosis may be missed unless the rectum is examined. As the examining finger exerts pressure on the peritoneum of Douglas' cul-de-sac, pain is felt in the suprapubic area as well as locally within the rectum. Signs of localized muscle irritation also may be present. The psoas sign indicates an irritative focus in proximity to that muscle. The test is performed by having the patient lie on the left side as the examiner slowly extends the patient's right thigh, thus stretching the iliopsoas muscle. The test result is positive if extension produces pain. Similarly, a positive obturator sign of hypogastric pain on stretching the obturator internus indicates irritation in the pelvis. The test is performed by passive internal rotation of the flexed right thigh with the patient supine.

LABORATORY FINDINGS

Mild leukocytosis, ranging from 10,000 to 18,000 cells/mm³, usually is present in patients with acute, uncomplicated appendicitis and often is accompanied by a moderate polymorphonuclear predominance. White blood cell counts are variable, however. It is unusual for the white blood cell count to be $>18,000$ cells/mm³ in uncomplicated appendicitis. White blood cell counts above this level raise the possibility of a perforated appendix with or without an abscess. Urinalysis can be useful to rule out the urinary tract as the source of infection. Although several white or red blood cells can be present from ureteral or bladder irritation as a result of an inflamed appendix, bacteriuria in a urine specimen obtained via catheter generally is not seen in acute appendicitis.²⁶

Imaging Studies

Plain films of the abdomen, although frequently obtained as part of the general evaluation of a patient with an acute

abdomen, rarely are helpful in diagnosing acute appendicitis. However, plain radiographs can be of significant benefit in ruling out other pathology. In patients with acute appendicitis, one often sees an abnormal bowel gas pattern, which is a nonspecific finding. The presence of a fecalith is rarely noted on plain films but, if present, is highly suggestive of the diagnosis. A chest radiograph is sometimes indicated to rule out referred pain from a right lower lobe pneumonic process.

Additional radiographic studies include barium enema examination and radioactively labeled leukocyte scans. If the appendix fills on barium enema, appendicitis is excluded. On the other hand, if the appendix does not fill, no determination can be made.²⁷ To date, there has not been enough experience with radionuclide scans to assess their utility.

Graded compression sonography has been suggested as an accurate way to establish the diagnosis of appendicitis. The technique is inexpensive, can be performed rapidly, does not require a contrast medium, and can be used even in pregnant patients. Sonographically, the appendix is identified as a blind-ending, nonperistaltic bowel loop originating from the cecum. With maximal compression, the diameter of the appendix is measured in the anteroposterior dimension. Scan results are considered positive if a noncompressible appendix ≥ 6 mm in the anteroposterior direction is demonstrated (Fig. 30-3). The presence of an appendicolith establishes the diagnosis. Thickening of the appendiceal wall and the presence of periappendiceal fluid is highly suggestive. Sonographic demonstration of a normal appendix, which is an easily compressible, blind-ending tubular structure measuring ≤ 5 mm in diameter, excludes the diagnosis of acute appendicitis. The study results are considered inconclusive if the appendix is not visualized and there is no pericecal fluid or mass. When the diagnosis of acute appendicitis is excluded by sonography, a brief survey of the remainder of the abdominal cavity should be performed to establish an alternative diagnosis. In females of childbearing age, the pelvic organs must be adequately visualized either by transabdominal or endovaginal ultrasonography to exclude gynecologic pathology as a cause of acute abdominal pain. The sonographic diagnosis of acute appendicitis has a reported sensitivity of 55 to 96% and a specificity of 85 to 98%.²⁸⁻³⁰ Sonography is similarly effective in children and pregnant women, although its application is somewhat limited in late pregnancy.

Sonogram of a 10-year-old girl who presented with nausea, vomiting, and abdominal pain. The appendix measured 10.0 mm in maximal anteroposterior diameter in both the noncompression (**A**) and compression (**B**) views.

Although sonography can easily identify abscesses in cases of perforation, the technique has limitations and results are user dependent. A false-positive scan result can occur in the presence of periappendicitis from surrounding inflammation, a dilated fallopian tube can be mistaken for an inflamed appendix, inspissated stool can mimic an appendicolith, and, in obese patients, the appendix may not be compressible because of overlying fat. False-negative sonogram results can occur if appendicitis is confined to the appendiceal tip, the appendix is retrocecal, the appendix is markedly enlarged and mistaken for small bowel, or the appendix is perforated and therefore compressible.³¹

Some studies have reported that graded compression sonography improved the diagnosis of appendicitis over clinical examination, specifically decreasing the percentage of negative explorations for appendectomies from 37 to 13%.³² Sonography also decreases the time before operation. Sonography identified appendicitis in 10% of patients who were believed to have a low likelihood of the disease on physical examination.³³ The positive and negative predictive values of ultrasonography have impressively been reported as 91 and 92%, respectively. However, in a recent prospective multicenter study, routine ultrasonography did not improve diagnostic accuracy or rates of negative appendectomy or perforation compared with clinical assessment.

High-resolution helical CT also has been used to diagnose appendicitis. On CT scan, the inflamed appendix appears dilated (>5 cm) and the wall is thickened. There is usually evidence of inflammation, with "dirty fat," thickened mesoappendix, and even an obvious phlegmon (Fig. 30-4). Fecaliths can be easily visualized, but their presence is not necessarily

pathognomonic of appendicitis. An important suggestive abnormality is the arrowhead sign. This is caused by thickening of the cecum, which funnels contrast agent toward the orifice of the inflamed appendix. CT scanning is also an excellent technique for identifying other inflammatory processes masquerading as appendicitis.

Computed tomographic scans with findings positive for appendicitis. Note the thick-walled and dilated appendix (**A**) and mesenteric streaking and "dirty fat" (**B**).

Several CT techniques have been used, including focused and nonfocused CT scans and enhanced and nonenhanced helical CT scanning. Nonenhanced helical CT scanning is important, because one of the disadvantages of using CT scanning in the evaluation of right lower quadrant pain is dye allergy. Surprisingly, all of these techniques have yielded essentially identical rates of diagnostic accuracy: 92 to 97% sensitivity, 85 to 94% specificity, 90 to 98% accuracy, and 75 to 95% positive and 95 to 99% negative predictive values.^{34–36} The additional use of a rectally administered contrast agent did not improve the results of CT scanning.

A number of studies have documented improvement in diagnostic accuracy with the liberal use of CT scanning in the work-up of suspected appendicitis. CT lowered the rate of negative appendectomies from 19 to 12% in one study,³⁷ and the incidence of negative appendectomies in women from 24 to 5% in another.³⁸ The use of this imaging study altered the care of 24% of patients studied and provided alternative diagnoses in half of the patients with normal appendices on CT scan.³⁹

Despite the potential usefulness of this technique, there are significant disadvantages. CT scanning is expensive, exposes the patient to significant radiation, and cannot be used during pregnancy. Allergy contraindicates the administration of IV contrast agents in some patients, and others cannot tolerate the oral ingestion of luminal dye, particularly in the presence of nausea and vomiting. Finally, not all studies have documented the utility of CT scanning in all patients with right lower quadrant pain.⁴⁰

A number of studies have compared the effectiveness of graded compression sonography and helical CT in establishing the diagnosis of appendicitis. Although the differences are rather small, CT scanning has consistently proven superior. For example, in one study, 600 ultrasounds and 317 CT scans demonstrated sensitivity of 80 and 97%, specificity of 93 and 94%, diagnostic accuracy of 89 and 95%, positive predictive value of 91 and 92%, and negative predictive value of 88 and

98%, respectively.³⁰ In another study, ultrasound positively impacted the management of 19% of patients, compared with 73% of patients for CT. Finally, in a third study, the negative appendix rate was 17% for patients studied by ultrasonography compared with a negative appendix rate of 2% for patients who underwent helical CT scanning.⁴¹ One concern about ultrasonography is the high intraobserver variability.⁴²

One issue that has not been resolved is which patients are candidates for imaging studies.⁴³ This question may be moot, because CT scanning routinely is ordered by emergency physicians before surgeons are even consulted. The concept that all patients with right lower quadrant pain should undergo CT scanning has been strongly supported by two reports by Rao and his colleagues at the Massachusetts General Hospital. In one, this group documented that CT scanning led to a fall in the negative appendectomy rate from 20 to 7% and a decline in the perforation rate from 22 to 14%, as well as establishment of an alternative diagnosis in 50% of patients.⁴⁴ In the second study, published in the *New England Journal of Medicine*, Rao and associates documented that CT scanning prevented 13 unnecessary appendectomies, saved 50 inpatient hospital days, and lowered the per-patient cost by \$447.⁴⁵ In contrast, several other studies failed to prove an advantage of routine CT scanning, documenting that surgeon accuracy approached that of the imaging study and expressing concern that the imaging studies could adversely delay appendectomy in affected patients.^{46,47}

The rational approach is the selective use of CT scanning. This has been documented by several studies in which imaging was performed based on an algorithm or protocol.⁴⁸ The likelihood of appendicitis can be ascertained using the Alvarado scale (Table 30-2).⁴⁹ This scoring system was designed to improve the diagnosis of appendicitis and was devised by giving relative weight to specific clinical manifestation. Table 30-2 lists the eight specific indicators identified. Patients with scores of 9 or 10 are almost certain to have appendicitis; there is little advantage in further work-up, and they should go to the operating room. Patients with scores of 7 or 8 have a high likelihood of appendicitis, whereas scores of 5 or 6 are compatible with, but not diagnostic of, appendicitis. CT scanning is certainly appropriate for patients with Alvarado scores of 5 and 6, and a case can be built for imaging for those with scores of 7 and 8. On the other hand, it is difficult to justify the expense, radiation exposure, and possible complications of CT scanning in patients whose scores of 0 to 4 make it extremely unlikely (but not impossible) that they have appendicitis.

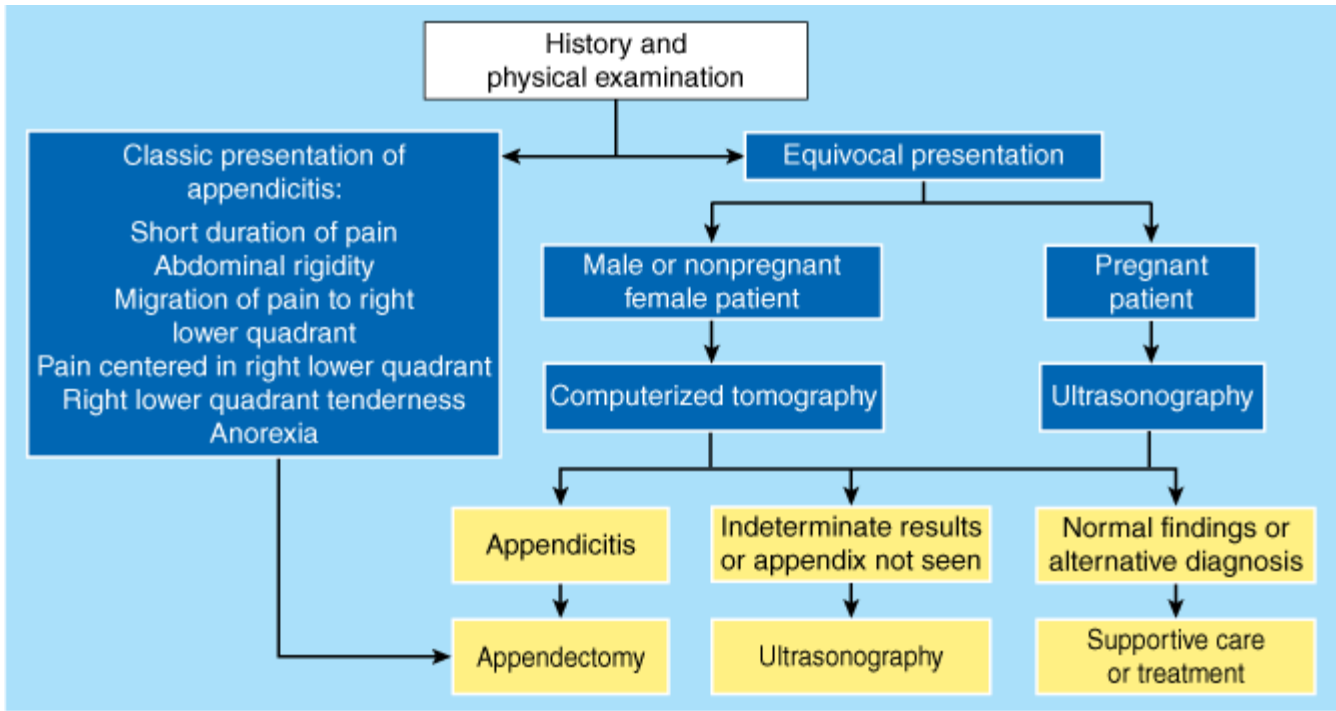

Table 30-2 Alvarado Scale for the Diagnosis of Appendicitis		
	Manifestations	Value
Symptoms	Migration of pain	1
	Anorexia	1
	Nausea and/or vomiting	1
Signs	Right lower quadrant tenderness	2
	Rebound	1
	Elevated temperature	1
Laboratory values	Leukocytosis	2
	Left shift in leukocyte count	1
		Total points 10

Selective CT scanning based on the likelihood of appendicitis takes advantage of the clinical skill of the experienced surgeon

and, when indicated, adds the expertise of the radiologist and his or her imaging study. Figure 30-5 proposes a treatment algorithm addressing the rational use of diagnostic testing.⁵⁰

Laparoscopy can serve as both a diagnostic and therapeutic maneuver for patients with acute abdominal pain and suspected acute appendicitis. Laparoscopy is probably most useful in the evaluation of females with lower abdominal complaints, because appendectomy is performed on a normal appendix in as many as 30 to 40% of these patients. Differentiating acute gynecologic pathology from acute appendicitis can be effectively accomplished using the laparoscope.

Appendiceal Rupture

Immediate appendectomy has long been the recommended treatment for acute appendicitis because of the presumed risk of progression to rupture. The overall rate of perforated appendicitis is 25.8%. Children <5 years of age and patients >65 years of age have the highest rates of perforation (45 and 51%, respectively) (Fig. 30-6).^{14,15,51} It has been suggested that delays in presentation are responsible for the majority of perforated appendices. There is no accurate way of determining when and if an appendix will rupture before resolution of the inflammatory process. Recent studies suggest that, in selected patients, observation and antibiotic therapy alone may be an appropriate treatment for acute appendicitis.^{17,52}

Rate of appendiceal rupture by age group.

(Personal communication from David Flum, MD.)

Appendiceal rupture occurs most frequently distal to the point of luminal obstruction along the antimesenteric border of the appendix. Rupture should be suspected in the presence of fever with a temperature of $>39^{\circ}\text{C}$ (102°F) and a white blood cell count of $>18,000$ cells/ mm^3 . In the majority of cases, rupture is contained and patients display localized rebound tenderness. Generalized peritonitis will be present if the walling-off process is ineffective in containing the rupture.

In 2 to 6% of cases, an ill-defined mass is detected on physical examination. This could represent a phlegmon, which consists of matted loops of bowel adherent to the adjacent inflamed appendix, or a periappendiceal abscess. Patients who present with a mass have experienced symptoms for a longer duration, usually at least 5 to 7 days. Distinguishing acute, uncomplicated appendicitis from acute appendicitis with perforation on the basis of clinical findings is often difficult, but it is important to make the distinction because their treatment differs. CT scan may be beneficial in guiding therapy. Phlegmons and small abscesses can be treated conservatively with IV antibiotics; well-localized abscesses can be managed with percutaneous drainage; complex abscesses should be considered for surgical drainage. If operative drainage is required, it should be performed using an extraperitoneal approach, with appendectomy reserved for cases in which the appendix is easily accessible. Interval appendectomy performed at least 6 weeks after the acute event has classically been recommended for all patients treated either nonoperatively or with simple drainage of an abscess.^{53,54}

Differential Diagnosis

The differential diagnosis of acute appendicitis is essentially the diagnosis of the acute abdomen (see Chap. 35). This is because clinical manifestations are not specific for a given disease but are specific for disturbance of a given physiologic function or functions. Thus, an essentially identical clinical picture can result from a wide variety of acute processes within the peritoneal cavity that produce the same alterations of function as does acute appendicitis.

The accuracy of preoperative diagnosis should be approximately 85%. If it is consistently less, it is likely that some unnecessary operations are being performed, and a more rigorous preoperative differential diagnosis is in order. A diagnostic accuracy rate that is consistently >90% should also cause concern, because this may mean that some patients with atypical, but bona fide, cases of acute appendicitis are being "observed" when they should receive prompt surgical intervention. The Haller group, however, has shown that this is not invariably true.⁵⁵ Before that group's study, the perforation rate at the hospital at which the study took place was 26.7%, and acute appendicitis was found in 80% of the patients undergoing operation. By implementing a policy of intensive in-hospital observation when the diagnosis of appendicitis was unclear, the group raised the rate of acute appendicitis found at operation to 94%, but the perforation rate remained unchanged at 27.5%.⁵⁵ The rate of false-negative appendectomies is highest in young adult females. A normal appendix is found in 32 to 45% of appendectomies performed in women 15 to 45 years of age.¹⁴

A common error is to make a preoperative diagnosis of acute appendicitis only to find some other condition (or nothing) at operation. Much less frequently, acute appendicitis is found after a preoperative diagnosis of another condition. The most common erroneous preoperative diagnoses—together accounting for >75% of cases—are, in descending order of frequency, acute mesenteric lymphadenitis, no organic pathologic condition, acute pelvic inflammatory disease, twisted ovarian cyst or ruptured graafian follicle, and acute gastroenteritis.

The differential diagnosis of acute appendicitis depends on four major factors: the anatomic location of the inflamed appendix; the stage of the process (i.e., simple or ruptured); the patient's age; and the patient's sex.^{56–60}

ACUTE MESENTERIC ADENITIS

Acute mesenteric adenitis is the disease most often confused with acute appendicitis in children. Almost invariably, an upper respiratory tract infection is present or has recently subsided. The pain usually is diffuse, and tenderness is not as sharply localized as in appendicitis. Voluntary guarding is sometimes present, but true rigidity is rare. Generalized lymphadenopathy may be noted. Laboratory procedures are of little help in arriving at the correct diagnosis, although a relative lymphocytosis, when present, suggests mesenteric adenitis. Observation for several hours is in order if the diagnosis of mesenteric adenitis seems likely, because it is a self-limited disease. However, if the differentiation remains in doubt, immediate exploration is the safest course of action.

Human infection with *Yersinia enterocolitica* or *Yersinia pseudotuberculosis*, transmitted through food contaminated by feces or urine, causes mesenteric adenitis as well as ileitis, colitis, and acute appendicitis. Many of the infections are mild and self limited, but they may lead to systemic disease with a high fatality rate if untreated. The organisms are usually sensitive to tetracyclines, streptomycin, ampicillin, and kanamycin. A preoperative suspicion of the diagnosis should not delay operative intervention, because appendicitis caused by *Yersinia* cannot be clinically distinguished from appendicitis due to other causes. Approximately 6% of cases of mesenteric adenitis are caused by *Yersinia* infection.

Salmonella typhimurium infection causes mesenteric adenitis and paralytic ileus with symptoms similar to those of appendicitis. The diagnosis can be established by serologic testing. *Campylobacter jejuni* causes diarrhea and pain that mimics that of appendicitis. The organism can be cultured from stool.

GYNECOLOGIC DISORDERS

Diseases of the female internal reproductive organs that may erroneously be diagnosed as appendicitis are, in approximate descending order of frequency, pelvic inflammatory disease, ruptured graafian follicle, twisted ovarian cyst or tumor, endometriosis, and ruptured ectopic pregnancy.

Pelvic Inflammatory Disease

In pelvic inflammatory disease the infection usually is bilateral but, if confined to the right tube, may mimic acute appendicitis. Nausea and vomiting are present in patients with appendicitis, but in only approximately 50% of those with pelvic inflammatory disease. Pain and tenderness are usually lower, and motion of the cervix is exquisitely painful. Intracellular diplococci may be demonstrable on smear of the purulent vaginal discharge. The ratio of cases of appendicitis to cases of pelvic inflammatory disease is low in females in the early phase of the menstrual cycle and high during the luteal phase. The careful clinical use of these features has reduced the incidence of negative findings on laparoscopy in young women to 15%.

Ruptured Graafian Follicle

Ovulation commonly results in the spillage of sufficient amounts of blood and follicular fluid to produce brief, mild lower abdominal pain. If the amount of fluid is unusually copious and is from the right ovary, appendicitis may be simulated. Pain and tenderness are rather diffuse. Leukocytosis and fever are minimal or absent. Because this pain occurs at the midpoint of the menstrual cycle, it is often called *mittelschmerz*.

Twisted Ovarian Cyst

Serous cysts of the ovary are common and generally remain asymptomatic. When right-sided cysts rupture or undergo torsion, the manifestations are similar to those of appendicitis. Patients develop right lower quadrant pain, tenderness, rebound, fever, and leukocytosis. If the mass is palpable on physical examination, the diagnosis can be made easily. Both transvaginal ultrasonography and CT scanning can be diagnostic if a mass is not palpable.

Torsion requires emergent operative treatment. If the torsion is complete or longstanding, the pedicle undergoes thrombosis, and the ovary and tube become gangrenous and require resection. Leakage of ovarian cysts resolves spontaneously, however, and is best treated nonoperatively.^{24,56–61}

Ruptured Ectopic Pregnancy

Blastocysts may implant in the fallopian tube (usually the ampullary portion) and in the ovary. Rupture of right tubal or ovarian pregnancies can mimic appendicitis. Patients may give a history of abnormal menses, either missing one or two periods or noting only slight vaginal bleeding. Unfortunately, patients do not always realize they are pregnant. The development of right lower quadrant or pelvic pain may be the first symptom. The diagnosis of ruptured ectopic pregnancy should be relatively easy. The presence of a pelvic mass and elevated levels of chorionic gonadotropin are characteristic. Although the leukocyte count rises slightly (to approximately 14,000 cells/mm³), the hematocrit level falls as a consequence of the intra-abdominal hemorrhage. Vaginal examination reveals cervical motion and adnexal tenderness, and a more definitive diagnosis can be established by culdocentesis. The presence of blood and particularly decidual tissue is pathognomonic. The treatment of ruptured ectopic pregnancy is emergency surgery.

ACUTE GASTROENTERITIS

Acute gastroenteritis is common but usually can be easily distinguished from acute appendicitis. Gastroenteritis is characterized by profuse diarrhea, nausea, and vomiting. Hyperperistaltic abdominal cramps precede the watery stools. The abdomen is relaxed between cramps, and there are no localizing signs. Laboratory values vary with the specific cause.

OTHER INTESTINAL DISORDERS

Meckel's Diverticulitis

Meckel's diverticulitis gives rise to a clinical picture similar to that of acute appendicitis. Meckel's diverticulum is located within the distal 2 ft of the ileum. Meckel's diverticulitis is associated with the same complications as appendicitis and requires the same treatment—prompt surgical intervention. Resection of the segment of ileum bearing the diverticulum with end-to-end anastomosis can nearly always be done through a McBurney incision, extended if necessary, or laparoscopically.

Crohn's Enteritis

The manifestations of acute regional enteritis—fever, right lower quadrant pain and tenderness, and leukocytosis—often simulate acute appendicitis. The presence of diarrhea and the absence of anorexia, nausea, and vomiting favor a diagnosis of enteritis, but this is not sufficient to exclude acute appendicitis. In an appreciable percentage of patients with chronic regional enteritis, the diagnosis is first made at the time of operation for presumed acute appendicitis. In cases of an acutely inflamed distal ileum with no cecal involvement and a normal appendix, appendectomy is indicated. Progression to chronic Crohn's ileitis is uncommon.

Colonic Lesions

Diverticulitis or perforating carcinoma of the cecum, or of that portion of the sigmoid that lies in the right side, may be impossible to distinguish from appendicitis. These entities should be considered in older patients. CT scanning is often helpful in making a diagnosis in older patients with right lower quadrant pain and atypical clinical presentations.

Epiploic appendagitis probably results from infarction of the colonic appendage(s) secondary to torsion. Symptoms may be minimal, or there may be continuous abdominal pain in an area corresponding to the contour of the colon, lasting several days. Pain shift is unusual, and there is no diagnostic sequence of symptoms. The patient does not look ill, nausea and vomiting are unusual, and appetite generally is unaffected. Localized tenderness over the site is usual and often is associated with rebound without rigidity. In 25% of reported cases, pain persists or recurs until the infarcted epiploic appendage is removed.

OTHER DISEASES

Diseases or conditions not mentioned in the preceding sections that must be considered in the differential diagnosis include foreign body perforations of the bowel, closed-loop intestinal obstruction, mesenteric vascular infarction, pleuritis of the right lower chest, acute cholecystitis, acute pancreatitis, hematoma of the abdominal wall, epididymitis, testicular torsion, urinary tract infection, ureteral stone, primary peritonitis, and Henoch-Schönlein purpura.

Acute Appendicitis in the Young

The establishment of a diagnosis of acute appendicitis is more difficult in young children than in the adult. The inability of young children to give an accurate history, diagnostic delays by both parents and physicians, and the frequency of GI upset in children are all contributing factors.⁶² In children the physical examination findings of maximal tenderness in the right lower quadrant, the inability to walk or walking with a limp, and pain with percussion, coughing, and hopping were found to have the highest sensitivity for appendicitis.⁶³

The more rapid progression to rupture and the inability of the underdeveloped greater omentum to contain a rupture lead to significant morbidity rates in children. Children <5 years of age have a negative appendectomy rate of 25% and an

appendiceal perforation rate of 45%. These rates may be compared with a negative appendectomy rate of <10% and a perforated appendix rate of 20% for children 5 to 12 years of age.^{13,14} The incidence of major complications after appendectomy in children is correlated with appendiceal rupture. The wound infection rate after the treatment of nonperforated appendicitis in children is 2.8% compared with a rate of 11% after the treatment of perforated appendicitis. The incidence of intra-abdominal abscess also is higher after the treatment of perforated appendicitis than after nonperforated appendicitis (6% vs. 3%).²³ The treatment regimen for perforated appendicitis generally includes immediate appendectomy and irrigation of the peritoneal cavity. Antibiotic coverage is limited to 24 to 48 hours in cases of nonperforated appendicitis. For perforated appendicitis IV antibiotics usually are given until the white blood cell count is normal and the patient is afebrile for 24 hours. The use of antibiotic irrigation of the peritoneal cavity and transperitoneal drainage through the wound are controversial. Laparoscopic appendectomy has been shown to be safe and effective for the treatment of appendicitis in children.⁶⁴

Acute Appendicitis in the Elderly

Compared with younger patients, elderly patients with appendicitis often pose a more difficult diagnostic problem because of the atypical presentation, expanded differential diagnosis, and communication difficulty. These factors may be responsible for the disproportionately high perforation rate seen in the elderly. In the general population, perforation rates range from 20 to 30%, compared with 50 to 70% in the elderly.⁶⁵ In addition, the perforation rate appears to increase with age >80 years.⁶⁶

Elderly patients usually present with lower abdominal pain, but on clinical examination, localized right lower quadrant tenderness is present in only 80 to 90% of patients. A history of periumbilical pain migrating to the right lower quadrant is reported infrequently. The usefulness of the Alvarado score appears to decline in the elderly. Fewer than 50% of the elderly with appendicitis have an Alvarado score of ≥ 7 .⁶⁶ Although currently there are no criteria that definitively identify elderly patients with acute appendicitis who are at risk of rupture, prioritization should be given to patients with a temperature of $>38^{\circ}\text{C}$ (100.4°F) and a shift to the left in leukocyte count of $>76\%$, especially if they are male, are anorectic, or have had pain of long duration before admission.⁶⁵

As a result of increased comorbidities and an increased rate of perforation, postoperative morbidity, mortality, and hospital length of stay are increased in the elderly compared with younger populations with appendicitis. Although no randomized trials have been conducted, it appears that elderly patients benefit from a laparoscopic approach to treatment of appendicitis. The use of laparoscopy in the elderly has significantly increased in recent years. In general, laparoscopic appendectomy offers elderly patients with appendicitis a shorter length of hospital stay, a reduction in complication and mortality rates, and a greater chance of discharge to home (independent of further nursing care or rehabilitation).⁶⁷

Acute Appendicitis during Pregnancy

Appendectomy for presumed appendicitis is the most common surgical emergency during pregnancy. The incidence is approximately 1 in 766 births. Acute appendicitis can occur at any time during pregnancy.⁶⁸ The overall negative appendectomy rate during pregnancy is approximately 25% and appears to be higher than the rate seen in nonpregnant women.^{68,69} A higher rate of negative appendectomy is seen in the second trimester, and the lowest rate is in the third trimester. The diversity of clinical presentations and the difficulty in making the diagnosis of acute appendicitis in pregnant women is well established. This is particularly true in the late second trimester and the third trimester, when many abdominal symptoms may be considered pregnancy related. In addition, during pregnancy there are anatomic changes in the appendix (Fig. 30-7) and increased abdominal laxity that may further complicate clinical evaluation. *There is no association*

between appendectomy and subsequent fertility.

Appendicitis in pregnancy should be suspected when a pregnant woman complains of abdominal pain of new onset. The most consistent sign encountered in acute appendicitis during pregnancy is pain in the right side of the abdomen. Seventy-four percent of patients report pain located in the right lower abdominal quadrant, with no difference between early and late pregnancy. Only 57% of patients present with the classic history of diffuse periumbilical pain migrating to the right lower quadrant. Laboratory evaluation is not helpful in establishing the diagnosis of acute appendicitis during pregnancy. The physiologic leukocytosis of pregnancy has been defined as high as 16,000 cells/mm³. In one series only 38% of patients with appendicitis had a white blood cell count of >16,000 cells/mm³.⁶⁸ Recent data suggest that the incidence of perforated or complex appendicitis is not increased in pregnant patients.⁶⁹

When the diagnosis is in doubt, abdominal ultrasound may be beneficial. Another option is magnetic resonance imaging, which has no known deleterious effects on the fetus. The American College of Radiology recommends the use of nonionizing radiation techniques for front-line imaging in pregnant women.⁷⁰ Laparoscopy has been advocated in equivocal cases, especially early in pregnancy; however laparoscopic appendectomy may be associated with an increase in pregnancy-related

complications. In an analysis of outcomes in California using administrative databases, laparoscopy was found to be associated with a 2.31 increased odds of fetal loss over open surgery.⁶⁹

The overall incidence of fetal loss after appendectomy is 4% and the risk of early delivery is 7%. Rates of fetal loss are considerably higher in women with complex appendicitis than in those with a negative appendectomy and with simple appendicitis. It is important to note that a negative appendectomy is not a benign procedure. Removing a normal appendix is associated with a 4% risk of fetal loss and 10% risk of early delivery. Maternal mortality after appendectomy is extremely rare (0.03%). Because the incidence of ruptured appendix is similar in pregnant and nonpregnant women and because maternal mortality is so low, it appears that the greatest opportunity to improve fetal outcomes is by improving diagnostic accuracy and reducing the rate of negative appendectomy.^{68–71}

Appendicitis in Patients with AIDS or HIV Infection

The incidence of acute appendicitis in HIV-infected patients is reported to be 0.5%. This is higher than the 0.1 to 0.2% incidence reported for the general population.⁷² The presentation of acute appendicitis in HIV-infected patients is similar to that in noninfected patients. The majority of HIV-infected patients with appendicitis have fever, periumbilical pain radiating to the right lower quadrant (91%), right lower quadrant tenderness (91%), and rebound tenderness (74%). HIV-infected patients do not manifest an absolute leukocytosis; however, if a baseline leukocyte count is available, nearly all HIV-infected patients with appendicitis demonstrate a relative leukocytosis.^{72,73}

The risk of appendiceal rupture appears to be increased in HIV-infected patients. In one large series of HIV-infected patients who underwent appendectomy for presumed appendicitis, 43% of patients were found to have perforated appendicitis at laparotomy.⁷⁴ The increased risk of appendiceal rupture may be related to the delay in presentation seen in this patient population.^{72,74} The mean duration of symptoms before arrival in the emergency department has been reported to be increased in HIV-infected patients, with >60% of patients reporting the duration of symptoms to be longer than 24 hours.⁷² In early series, significant hospital delay also may have contributed to high rates of rupture.⁷² However, with increased understanding of abdominal pain in HIV-infected patients, hospital delay has become less prevalent.^{72,75} A low CD4 count is also associated with an increased incidence of appendiceal rupture. In one large series, patients with nonruptured appendices had CD4 counts of 158.75 ± 47 cells/mm³ compared with 94.5 ± 32 cells/mm³ in patients with appendiceal rupture.⁷²

The differential diagnosis of right lower quadrant pain is expanded in HIV-infected patients compared with the general population. In addition to the conditions discussed elsewhere in this chapter, opportunistic infections should be considered as a possible cause of right lower quadrant pain.^{72–75} Such opportunistic infections include cytomegalovirus (CMV) infection, Kaposi's sarcoma, tuberculosis, lymphoma, and other causes of infectious colitis. CMV infection may be seen anywhere in the GI tract. CMV infection causes a vasculitis of blood vessels in the submucosa of the gut, which leads to thrombosis. Mucosal ischemia develops, leading to ulceration, gangrene of the bowel wall, and perforation. Spontaneous peritonitis may be caused by opportunistic pathogens, including CMV, *Mycobacterium avium-intracellulare* complex, *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, and *Strongyloides*. Kaposi's sarcoma and non-Hodgkin's lymphoma may present with pain and a right lower quadrant mass. Viral and bacterial colitis occur with a higher frequency in HIV-infected patients than in the general population. Colitis should always be considered in HIV-infected patients presenting with right lower quadrant pain. Neutropenic enterocolitis (typhlitis) should also be considered in the differential diagnosis of right lower quadrant pain in HIV-infected patients.^{73,75}

A thorough history and physical examination is important when evaluating any patient with right lower quadrant pain. In the

HIV-infected patient with classic signs and symptoms of appendicitis, immediate appendectomy is indicated. In those patients with diarrhea as a prominent symptom, colonoscopy may be warranted. In patients with equivocal findings, CT scan is usually helpful. The majority of pathologic findings identified in HIV-infected patients who undergo appendectomy for presumed appendicitis are typical. The negative appendectomy rate is 5 to 10%. However, in up to 25% of patients AIDS-related entities are found in the operative specimens, including CMV, Kaposi's sarcoma, and *M. avium-intracellulare* complex.^{72,74}

In a retrospective study of 77 HIV-infected patients from 1988 to 1995, the 30-day mortality rate for patients undergoing appendectomy was reported to be 9.1%.⁷² More recent series report 0% mortality in this group of patients.⁷⁵ Morbidity rates for HIV-infected patients with nonperforated appendicitis are similar to those seen in the general population. Postoperative morbidity rates appear to be higher in HIV-infected patients with perforated appendicitis. In addition, the length of hospital stay for HIV-infected patients undergoing appendectomy is twice that for the general population.^{72,75} No series has been reported to date that addresses the role of laparoscopic appendectomy in the HIV-infected population.

Treatment

Despite the advent of more sophisticated diagnostic modalities, the importance of early operative intervention should not be minimized. Once the decision to operate for presumed acute appendicitis has been made, the patient should be prepared for the operating room. Adequate hydration should be ensured, electrolyte abnormalities should be corrected, and pre-existing cardiac, pulmonary, and renal conditions should be addressed. A large meta-analysis has demonstrated the efficacy of preoperative antibiotics in lowering the infectious complications in appendicitis.²³ Most surgeons routinely administer antibiotics to all patients with suspected appendicitis. If simple acute appendicitis is encountered, there is no benefit in extending antibiotic coverage beyond 24 hours. If perforated or gangrenous appendicitis is found, antibiotics are continued until the patient is afebrile and has a normal white blood cell count. For intra-abdominal infections of GI tract origin that are of mild to moderate severity, the Surgical Infection Society has recommended single-agent therapy with cefoxitin, cefotetan, or ticarcillin-clavulanic acid. For more severe infections, single-agent therapy with carbapenems or combination therapy with a third-generation cephalosporin, monobactam, or aminoglycoside plus anaerobic coverage with clindamycin or metronidazole is indicated.²⁴ The recommendations are similar for children.⁷⁶

OPEN APPENDECTOMY

For open appendectomy most surgeons use either a McBurney (oblique) or Rocky-Davis (transverse) right lower quadrant muscle-splitting incision in patients with suspected appendicitis. The incision should be centered over either the point of maximal tenderness or a palpable mass. If an abscess is suspected, a laterally placed incision is imperative to allow retroperitoneal drainage and to avoid generalized contamination of the peritoneal cavity. If the diagnosis is in doubt, a lower midline incision is recommended to allow a more extensive examination of the peritoneal cavity. This is especially relevant in older patients with possible malignancy or diverticulitis.

Several techniques can be used to locate the appendix. Because the cecum usually is visible within the incision, the convergence of the taeniae can be followed to the base of the appendix. A sweeping lateral to medial motion can aid in delivering the appendiceal tip into the operative field. Occasionally, limited mobilization of the cecum is needed to aid in adequate visualization. Once identified, the appendix is mobilized by dividing the mesoappendix, with care taken to ligate the appendiceal artery securely.

The appendiceal stump can be managed by simple ligation or by ligation and inversion with either a purse-string or Z stitch.

As long as the stump is clearly viable and the base of the cecum is not involved with the inflammatory process, the stump can be safely ligated with a nonabsorbable suture. The mucosa is frequently obliterated to avoid the development of mucocoele. The peritoneal cavity is irrigated and the wound closed in layers. If perforation or gangrene is found in adults, the skin and subcutaneous tissue should be left open and allowed to heal by secondary intent or closed in 4 to 5 days as a delayed primary closure. In children, who generally have little subcutaneous fat, primary wound closure has not led to an increased incidence of wound infection.

If appendicitis is not found, a methodical search must be made for an alternative diagnosis. The cecum and mesentery should first be inspected. Next, the small bowel should be examined in a retrograde fashion beginning at the ileocecal valve and extending at least 2 ft. In females, special attention should be paid to the pelvic organs. An attempt also should be made to examine the upper abdominal contents. Peritoneal fluid should be sent for Gram's staining and culture. If purulent fluid is encountered, it is imperative that the source be identified. A medial extension of the incision (Fowler-Weir), with division of the anterior and posterior rectus sheath, is acceptable if further evaluation of the lower abdomen is indicated. If upper abdominal pathology is encountered, the right lower quadrant incision is closed and an appropriate upper midline incision is made.⁹

LAPAROSCOPIC APPENDECTOMY

Semm first reported successful laparoscopic appendectomy several years before the first laparoscopic cholecystectomy.¹⁰ However, the laparoscopic approach to appendectomy did not come into widespread use until after the success of laparoscopic cholecystectomy. This may be due to the fact that appendectomy, by virtue of its small incision, is already a form of minimal-access surgery.⁷⁷

Laparoscopic appendectomy is performed under general anesthesia. A nasogastric tube and a urinary catheter are placed before obtaining a pneumoperitoneum. Laparoscopic appendectomy usually requires the use of three ports. Four ports may occasionally be necessary to mobilize a retrocecal appendix. The surgeon usually stands to the patient's left. One assistant is required to operate the camera. One trocar is placed in the umbilicus (10 mm), and a second trocar is placed in the suprapubic position. Some surgeons place this second port in the left lower quadrant. The suprapubic trocar is either 10 or 12 mm, depending on whether or not a linear stapler will be used. The placement of the third trocar (5 mm) is variable and usually is either in the left lower quadrant, epigastrium, or right upper quadrant. Placement is based on location of the appendix and surgeon preference. Initially, the abdomen is thoroughly explored to exclude other pathology. The appendix is identified by following the anterior taeniae to its base. Dissection at the base of the appendix enables the surgeon to create a window between the mesentery and the base of the appendix (Fig. 30-8A). The mesentery and base of the appendix are then secured and divided separately. When the mesoappendix is involved with the inflammatory process, it is often best to divide the appendix first with a linear stapler and then to divide the mesoappendix immediately adjacent to the appendix with clips, electrocautery, Harmonic Scalpel, or staples (Fig. 30-8B and 30-8C). The base of the appendix is not inverted. The appendix is removed from the abdominal cavity through a trocar site or within a retrieval bag. The base of the appendix and the mesoappendix should be evaluated for hemostasis. The right lower quadrant should be irrigated. Trocars are removed under direct vision.^{78,79}

The utility of laparoscopic appendectomy in the management of acute appendicitis remains controversial. Surgeons may be hesitant to implement a new technique because the conventional open approach already has proved to be simple and effective. A number of articles in peer-reviewed journals have compared laparoscopic and open appendectomy, including >20 randomized, controlled trials and 6 meta-analyses.^{64,77,80–84} The overall quality of these randomized, controlled trials has

been limited by the failure to blind patients and providers as to the treatment modality used. Furthermore, investigators have failed to perform prestudy sample size analysis for the outcomes studied.⁶⁴ The largest meta-analysis comparing open to laparoscopic appendectomy included 47 studies, 39 of which were studies of adult patients. This analysis demonstrated that the duration of surgery and costs of operation were higher for laparoscopic appendectomy than for open appendectomy. Wound infections were approximately half as likely after laparoscopic appendectomy as after open appendectomy. However, the rate of intra-abdominal abscess was three times higher after laparoscopic appendectomy than after open appendectomy.⁶⁴

A principal proposed benefit of laparoscopic appendectomy has been decreased postoperative pain. Patient-reported pain on the first postoperative day is significantly less after laparoscopic appendectomy. However, the difference has been calculated to be only 8 points on a 100-point visual analogue scale. This difference is below the level of pain that an average patient is able to perceive.⁶² Hospital length of stay also is statistically significantly less after laparoscopic appendectomy. However, in most studies this difference is <1 day.^{64,77} It appears that a more important determinant of length of stay after appendectomy is the pathology found at operation—specifically, whether a patient has perforated or nonperforated appendicitis. In nearly all studies, laparoscopic appendectomy is associated with a shorter period before return to normal activity, return to work, and return to sports.^{64,77,80–84} However, treatment and subject bias may have a significant impact on the data. Although the majority of studies have been performed in adults, similar data have been obtained in children.⁶⁴

There appears to be little benefit to laparoscopic appendectomy over open appendectomy in thin males between the ages of 15 and 45 years. In these patients, the diagnosis usually is straightforward. Open appendectomy has been associated with outstanding results for several decades. Laparoscopic appendectomy should be considered an option in these patients, based on surgeon and patient preference. Laparoscopic appendectomy may be beneficial in obese patients, in whom it may be difficult to gain adequate access through a small right lower quadrant incision. In a retrospective study of 116 patients with a mean body mass index of 35, postoperative length of stay was significantly shorter in the group undergoing laparoscopic appendectomy, and there were fewer open wounds. In all obese patients in whom the procedure was completed laparoscopically the incisions closed primarily, whereas the wounds closed primarily in only 58% of obese patients who underwent open appendectomy. There was no difference in rates of wound infection; intra-abdominal abscess rates were not reported.⁸⁵

Diagnostic laparoscopy has been advocated as a potential tool to decrease the number of negative appendectomies performed. However, the morbidity associated with laparoscopy and general anesthesia is acceptable only if pathology requiring surgical treatment is present and is amenable to treatment using laparoscopic techniques. The question of leaving a normal appendix in situ is a controversial one. Seventeen to 26% of appendices that appear normal at exploration are found to have pathologic features on histologic analysis.⁸⁰ The availability of diagnostic laparoscopy may actually lower the threshold for exploration and thus adversely impact the negative appendectomy rate.⁸⁶ Fertile women with presumed appendicitis constitute the group of patients most likely to benefit from diagnostic laparoscopy. Up to one third of these patients do not have appendicitis at exploration. In most of the patients without appendicitis, gynecologic pathology is identified.⁸⁷ A large meta-analysis demonstrated that in fertile women in whom appendectomy was deemed necessary, diagnostic laparoscopy reduced the number of unnecessary appendectomies.⁶⁴ In addition, the number of women without a final diagnosis was smaller. It appears that leaving a normal-appearing appendix in fertile women with identifiable gynecologic pathology is safe.⁸⁷

In summary, it has not been resolved whether laparoscopic appendectomy is more effective in treating acute appendicitis

than the time-proven method of open appendectomy. It does appear that laparoscopic appendectomy is effective in the management of acute appendicitis. Laparoscopic appendectomy should be considered part of the surgical armamentarium available to treat acute appendicitis. The decision on how to treat a specific patient with appendicitis should be based on surgical skill, patient characteristics, clinical scenario, and patient preference. Additional well-controlled, prospective, blinded studies are needed to determine which subsets of patients may benefit from any given approach to the treatment of appendicitis.

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY

Natural orifice transluminal endoscopic surgery (NOTES) is a new surgical procedure using flexible endoscopes in the abdominal cavity. In this procedure, access is gained by way of organs that are reached through a natural, already-existing external orifice. The hoped-for advantages associated with this method include the reduction of postoperative wound pain, shorter convalescence, avoidance of wound infection and abdominal-wall hernias, and the absence of scars. The first case of transvaginal removal of a normal appendix has recently been reported.⁸⁸ Much work remains to determine if NOTES provides any additional advantages over the laparoscopic approach to appendectomy.

ANTIBIOTICS AS DEFINITIVE THERAPY

Traditional management of acute appendicitis has emphasized emergent surgical management. This approach has been based on the theory that, over time, simple appendicitis will progress to perforation, with resulting increases in morbidity and mortality. As a result, a relatively high negative appendectomy rate has been accepted to avoid the possibility of progression to perforation. Recent data suggest that acute appendicitis and acute appendicitis with perforation may be separate disease entities with distinct pathophysiology. A time series analysis performed on a 25-year data set did not find a significant negative relationship between the rates of negative appendectomy and perforation.¹⁷ A study analyzing time to surgery and perforation demonstrated that risk of rupture is minimal within 36 hours of symptom onset. Beyond this point, there is about a 5% risk of rupture in each ensuing 12-hour period. However, in many patients the disease will have an indolent course. In one study 10 of the 18 patients who did not undergo operation for ≥ 6 days after their symptoms began did not experience rupture.⁸⁹

Many acute abdominal conditions such as acute diverticulitis and acute cholecystitis are managed with urgent but not emergent surgery. Moreover, evidence from submarine personnel who develop appendicitis suggests that nonoperative management of appendicitis may be a viable treatment option. Sailors who develop appendicitis while stationed on submarines do not have access to prompt surgical care. They are successfully treated with antibiotics and fluids days to weeks after the initial attack until the ship can surface and they can be transferred to a hospital for care.⁹⁰

A randomized study comparing antibiotic treatment with immediate appendectomy has been completed. Two hundred and fifty-two men 18 to 50 years of age with the presumptive diagnosis of appendicitis were enrolled in the study between March 1996 and June 1999. For patients randomly assigned to antibiotic therapy, if symptoms did not improve within the first 24 hours, an appendectomy was performed. Participants were evaluated after 1 week, 6 weeks, and 1 year. Acute appendicitis was found in 97% of the 124 patients randomly assigned to surgery. Six patients (5%) had perforated appendices. The complication rate in the surgery group was 14% (17 of 124). Of the 128 patients enrolled in the antibiotic group, 15 patients (12%) underwent operation within the first 24 hours due to lack of improvement in symptoms and apparent local peritonitis. At operation seven patients (5%) had perforation. The rate of recurrence within 1 year was 15% (16 patients) in the group treated with antibiotics. In five of these patients a perforated appendix was found at operation.⁵² Although it initially appears

from these data that the use of antibiotics alone may be reasonable therapy for acute appendicitis, there are several issues to take into account. First, this study included only men between the ages of 18 and 50 and may not have broad applicability to all patients with appendicitis, especially those populations known to have higher perforation rates. Second, the incidence of perforation was 9% in the antibiotic group when patients requiring operation in both the acute and delayed settings are considered. This compares unfavorably with the perforation rate of 5% for those patients operated on immediately. In addition, the study follow-up was only 1 year, which suggests that patients receiving only antibiotic therapy may still be at risk for the development of appendicitis. Finally, when patients are treated with antibiotics alone it is possible that diagnoses of significant pathology such as carcinoid or carcinoma may be delayed.¹⁶ Because no laboratory test or clinical investigation can reliably distinguish patients whose appendicitis is potentially amenable to conservative treatment, surgery still remains the gold standard of care for patients with acute appendicitis.

INTERVAL APPENDECTOMY

The accepted approach for the treatment of appendicitis associated with a palpable or radiographically documented mass (abscess or phlegmon) is conservative therapy with interval appendectomy 6 to 10 weeks later. This technique has been quite successful and produces much lower morbidity and mortality rates than immediate appendectomy. Unfortunately, this treatment is associated with greater expense and longer hospitalization time (8 to 13 days vs. 3 to 5 days).⁹¹

The initial treatment consists of IV antibiotics and bowel rest. Although this therapy is generally effective, there is a 9 to 15% failure rate, with operative intervention required at 3 to 5 days after presentation. Percutaneous or operative drainage of abscesses is not considered a failure of conservative therapy.

Although the second stage of this treatment plan, interval appendectomy, has usually been carried out, the need for subsequent operation has been questioned. The major argument against interval appendectomy is that approximately 50% of patients treated conservatively never develop manifestations of appendicitis, and those who do generally can be treated nonoperatively. In addition, pathologic examination of the resected appendix shows normal findings in 20 to 50% of cases.

On the other hand, the data clearly support the need for interval appendectomy. In a prospective series, 19 of 48 patients (40%) who were successfully treated conservatively needed appendectomy at an earlier time (mean of 4.3 weeks) than the 10 weeks planned because of bouts of appendicitis.⁹¹ Overall, the rate of late failure as a consequence of acute disease averages 20%. An additional 14% of patients either continue to have, or redevelop, right lower quadrant pain. Although the appendix may occasionally be pathologically normal, persistent periappendiceal abscesses and adhesions are found in 80% of patients. In addition, almost 50% have histologic evidence of inflammation in the organ itself. Several neoplasms also have been detected in the resected appendices, even in those of children.¹⁶

The timing of interval appendectomy is somewhat controversial. Appendectomy may be required as early as 3 weeks after conservative therapy. Two thirds of the cases of recurrent appendicitis occur within 2 years, and this is the outside limit. Interval appendectomy is associated with a morbidity rate of $\leq 3\%$ and a hospitalization time of 1 to 3 days. The laparoscopic approach has been used and has been successful in 68% of procedures.⁹² In a more recent study in children, interval appendectomy was performed successfully using the laparoscopic approach in all 35 patients.⁹³

Prognosis

The mortality from appendicitis in the United States has steadily decreased from a rate of 9.9 per 100,000 in 1939 to 0.2 per 100,000 today. Among the factors responsible are advances in anesthesia, antibiotics, IV fluids, and blood products. Principal factors influencing mortality are whether rupture occurs before surgical treatment and the age of the patient. The overall

mortality rate in acute appendicitis with rupture is approximately 1%. The mortality rate of appendicitis with rupture in the elderly is approximately 5%—a fivefold increase from the overall rate. Death is usually attributable to uncontrolled sepsis—peritonitis, intra-abdominal abscesses, or gram-negative septicemia. Pulmonary embolism continues to account for some deaths.

Morbidity rates parallel mortality rates and are significantly increased by rupture of the appendix and, to a lesser extent, by old age. In one report, complications occurred in 3% of patients with nonperforated appendicitis and in 47% of patients with perforations. Most of the serious early complications are septic and include abscess and wound infection. Wound infection is common but is nearly always confined to the subcutaneous tissues and responds promptly to wound drainage, which is accomplished by reopening the skin incision. Wound infection predisposes the patient to wound dehiscence. The type of incision is relevant; complete dehiscence rarely occurs in a McBurney incision.

The incidence of intra-abdominal abscess secondary to peritoneal contamination from gangrenous or perforated appendicitis has decreased markedly since the introduction of potent antibiotics. The sites of predilection for abscesses are the appendiceal fossa, pouch of Douglas, the subhepatic space, and between loops of intestine. In the latter site abscesses are usually multiple. Transrectal drainage is preferred for an abscess that bulges into the rectum.

Fecal fistula is an annoying, but not particularly dangerous, complication of appendectomy that may be caused by sloughing of the portion of the cecum inside a constricting purse-string suture; by slipping of the ligature off a tied, but not inverted, appendiceal stump; or by necrosis from an abscess encroaching on the cecum.

Intestinal obstruction, initially paralytic but sometimes progressing to mechanical obstruction, may occur with slowly resolving peritonitis with loculated abscesses and exuberant adhesion formation. Late complications are quite uncommon. Adhesive band intestinal obstruction after appendectomy does occur, but much less frequently than after pelvic surgical therapy. The incidence of inguinal hernia is three times higher in patients who have had an appendectomy. Incisional hernia is like wound dehiscence in that infection predisposes to it, it rarely occurs in a McBurney incision, and it is not uncommon in a lower right paramedian incision.⁹⁴

CHRONIC APPENDICITIS

Whether chronic appendicitis is a true clinical entity has been questioned for many years. However, clinical data document the existence of this uncommon disease.⁹⁵ Histologic criteria have been established. Characteristically, the pain lasts longer and is less intense than that of acute appendicitis but is in the same location. There is a much lower incidence of vomiting, but anorexia and occasionally nausea, pain with motion, and malaise are characteristic. Leukocyte counts are predictably normal and CT scans are generally nondiagnostic.

At operation, surgeons can establish the diagnosis with 94% specificity and 78% sensitivity. There is an excellent correlation between clinical symptomatology, intraoperative findings, and histologic abnormalities. Laparoscopy can be used effectively in the management of this clinical entity. Appendectomy is curative. Symptoms resolve postoperatively in 82 to 93% of patients. Many of those whose symptoms are not cured or recur are ultimately diagnosed with Crohn's disease.⁹⁵

APPENDICEAL PARASITES

A number of intestinal parasites cause appendicitis. Although *Ascaris lumbricoides* is the most common, a wide spectrum of helminths have been implicated, including *Enterobius vermicularis*, *Strongyloides stercoralis*, and *Echinococcus granulosus*. The live parasites occlude the appendiceal lumen, causing obstruction. The presence of parasites in the appendix at operation

makes ligation and stapling of the appendix technically difficult. Once appendectomy has been performed and the patient has recovered, therapy with helminthicide is necessary to clear the remainder of the GI tract.

Amebiasis also can cause appendicitis. Invasion of the mucosa by trophozoites of *Entamoeba histolytica* incites a marked inflammatory process. Appendiceal involvement is a component of more generalized intestinal amebiasis. Appendectomy must be followed by appropriate antiamebic therapy (metronidazole).

INCIDENTAL APPENDECTOMY

Decisions regarding the efficacy of incidental appendectomy should be based on the epidemiology of appendicitis. The best data were published by the Centers for Disease Control and Prevention based on the period from 1979 to 1984.¹¹ During this period, an average of 250,000 cases of appendicitis occurred annually in the United States. The highest annual incidence of appendicitis was in patients 9 to 19 years of age (23.3 per 10,000 population). Males were more likely to develop appendicitis than females. Accordingly, the incidence during teenage years was 27.6 in males and 20.5 in females per 10,000 population per year. Beyond age 19 years, the annual incidence fell. Among those >45 years of age, the annual incidence was 6 in 10,000 males and 4 in 10,000 females. When the life table technique was used, the data identified a lifetime risk of appendicitis of 8.6% in men and 6.7% in women. Although men were more likely to develop appendicitis, the preoperative diagnosis was correct in 91.2% of men and 78.6% of women. Similarly, perforation occurred more commonly in men than in women (19.2 vs. 17.8%). In contrast to the number of cases of appendicitis, 310,000 incidental appendectomies were performed between 1979 and 1984, 62% of the total appendectomies in men and 17.7% of those in women. Based on these data, 36 incidental appendectomies had to be performed to prevent one patient from developing appendicitis.⁹⁶

The financial aspects of the decision to perform incidental appendectomy were assessed.⁹⁷ For open appendectomy, there was a financial disincentive to perform incidental appendectomy. On an annual basis, \$20,000,000 had to be spent to save the \$6,000,000 cost of appendicitis. With the laparoscopic approach, it was cost effective to perform incidental appendectomy only in patients <25 years of age and only if the reimbursement for surgeons was 10% of the usual and customary charges. At a higher rate of reimbursement, incidental appendectomy was not cost effective in any age group.

Although incidental appendectomy is generally neither clinically nor economically appropriate, there are some special patient groups in whom it should be performed during laparotomy or laparoscopy for other indications. These include children about to undergo chemotherapy, the disabled who cannot describe symptoms or react normally to abdominal pain, patients with Crohn's disease in whom the cecum is free of macroscopic disease, and individuals who are about to travel to remote places where there is no access to medical or surgical care.⁹⁸

Appendectomy is routinely carried out during performance of Ladd's procedure for malrotation, because displacement of the cecum into the left upper quadrant would complicate the diagnosis of subsequent appendicitis.

TUMORS

Appendiceal malignancies are extremely rare. Primary appendiceal cancer is diagnosed in 0.9 to 1.4% of appendectomy specimens.¹⁶ These tumors are only rarely suspected preoperatively. Fewer than 50% of cases are diagnosed at operation.⁹⁹ Most series report that carcinoid is the most common appendiceal malignancy, representing >50% of the primary lesions of the appendix.^{16,98,99} A review from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program found the age-adjusted incidence of appendiceal malignancies to be 0.12 cases per 1,000,000 people per year.⁹⁹ Data from the SEER program identified mucinous adenocarcinoma as the most frequent histologic diagnosis (38% of total

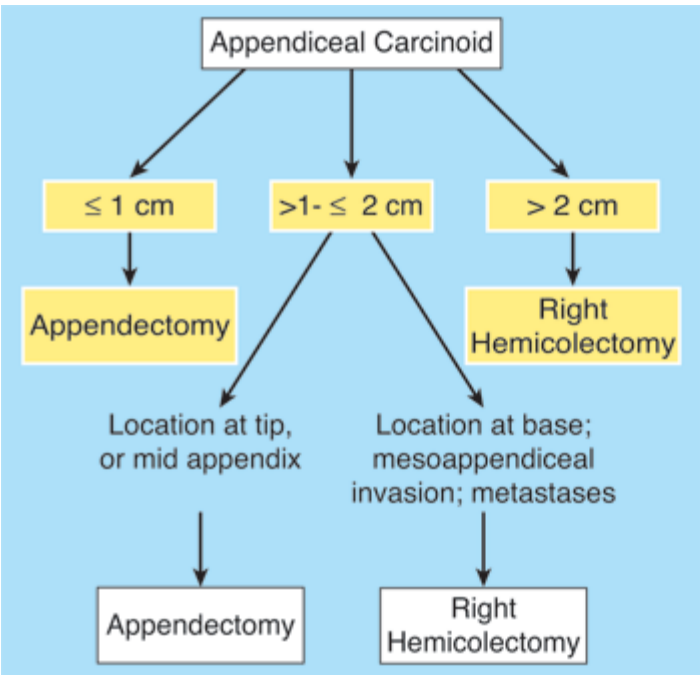

reported cases), followed by adenocarcinoma (26%), carcinoid (17%), goblet cell carcinoma (15%), and signet-ring cell carcinoma (4%).⁹⁹ Five-year survival for appendiceal malignancies varies by tumor type. Patients with carcinoid tumors have the best 5-year survival (83%), whereas those with signet-ring cell cancers have the lowest (18%).^{99,100}

Carcinoid

The finding of a firm, yellow, bulbar mass in the appendix should raise the suspicion of an appendiceal carcinoid. The appendix is the most common site of GI carcinoid, followed by the small bowel and then the rectum. Carcinoid syndrome is rarely associated with appendiceal carcinoid unless widespread metastases are present, which occur in 2.9% of cases. Symptoms attributable directly to the carcinoid are rare, although the tumor can occasionally obstruct the appendiceal lumen much like a fecalith and result in acute appendicitis.^{16,100,101}

The majority of carcinoids are located in the tip of the appendix. Malignant potential is related to size, with tumors <1 cm rarely resulting in extension outside of the appendix or adjacent to the mass. The mean tumor size for carcinoids is 2.5 cm.¹⁰⁰ Carcinoid tumors usually present with localized disease (64%). Treatment for tumors ≤1 cm is appendectomy. For tumors larger than 1 to 2 cm located at the base or with lymph node metastases, right hemicolectomy is indicated (Fig. 30-9). Despite these recommendations, SEER data indicate that proper surgery for carcinoids is not performed at least 28% of the time.¹⁰⁰

Fig. 30-9.

Algorithm for the management of patients with appendiceal carcinoid.

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm with three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid.⁹⁹ The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients also may present with ascites or a palpable mass, or the neoplasm may be discovered during an

operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas have a propensity for early perforation, although they are not clearly associated with a worsened prognosis.¹⁰¹ Overall 5-year survival is 55% and varies with stage and grade. Patients with appendiceal adenocarcinoma are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the GI tract.⁹⁹

Mucocele

A mucocele of the appendix is an obstructive dilatation by intraluminal accumulation of mucoid material. Mucoceles may be caused by one of four processes: retention cysts, mucosal hyperplasia, cystadenomas, and cystadenocarcinomas. The clinical presentation of a mucocele is nonspecific, and often it is an incidental finding at operation for acute appendicitis. An intact mucocele presents no future risk for the patient; however, the opposite is true if the mucocele has ruptured and epithelial cells have escaped into the peritoneal cavity. As a result, when a mucocele is visualized at the time of laparoscopic examination, conversion to open laparotomy is recommended. Conversion from a laparoscopic approach to a laparotomy ensures that a benign process will not be converted to a malignant one through mucocele rupture. In addition, laparotomy allows for thorough abdominal exploration to rule out the presence of mucoid fluid accumulations.⁹⁹

The presence of a mucocele of the appendix does not mandate performance of a right hemicolectomy. The principles of surgery include resection of the appendix, wide resection of the mesoappendix to include all the appendiceal lymph nodes, collection and cytologic examination of all intraperitoneal mucus, and careful inspection of the base of the appendix. Right hemicolectomy, or preferably cecectomy, is reserved for patients with a positive margin at the base of the appendix or positive periappendiceal lymph nodes. Recently, a more aggressive approach to ruptured appendiceal neoplasms has been advocated. This approach includes a thorough but minimally aggressive approach at initial laparotomy, as described earlier, with subsequent referral to a specialized center for consideration of re-exploration and hyperthermic intraperitoneal chemotherapy.¹⁰¹

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a rare condition in which diffuse collections of gelatinous fluid are associated with mucinous implants on peritoneal surfaces and omentum. Pseudomyxoma is two to three times more common in females than in males. Recent immunocytologic and molecular studies suggest that the appendix is the site of origin for the overwhelming majority of cases of pseudomyxoma. Pseudomyxoma is invariably caused by neoplastic mucus-secreting cells within the peritoneum. These cells may be difficult to classify as malignant because they may be sparse, widely scattered, and have a low-grade cytologic appearance. Patients with pseudomyxoma usually present with abdominal pain, distention, or a mass. Primary pseudomyxoma usually does not cause abdominal organ dysfunction. However, ureteral obstruction and obstruction of venous return can be seen.¹⁰² Pseudomyxoma is a disease that progresses slowly and in which recurrences may take years to develop or become symptomatic.¹⁰² In a series from the Mayo Clinic, 76% of patients developed recurrences within the abdomen.¹⁰³ Lymph node metastasis and distant metastasis are uncommon.

The use of imaging before surgery is advantageous to plan surgery. CT scanning is the preferred imaging modality. At surgery a variable volume of mucinous ascites is found together with tumor deposits involving the right hemidiaphragm, right retrohepatic space, left paracolic gutter, ligament of Treitz, and the ovaries in women. Peritoneal surfaces of the bowel are usually free of tumor. Thorough surgical debulking is the mainstay of treatment. All gross disease and the omentum should be removed. If not done previously, appendectomy is routinely performed. Hysterectomy with bilateral salpingo-

oophorectomy is performed in women. Survival is better in patients who undergo R0 or R1 resection than in patients who undergo R2 resection (visible gross disease remaining).¹⁰⁴ *Because 5-year survival of mucinous appendiceal neoplasms is only 30%,* adjuvant intraperitoneal hyperthermic chemotherapy is advocated as a standard adjunct to radical cytoreductive surgery.¹⁰⁵ Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is a long, tedious procedure with operative times of 300 to 1020 minutes reported. In addition, morbidity (38%) and mortality (6%) are high. Cytoreductive surgery with intraperitoneal hyperthermic chemotherapy is associated with a 5-year survival of between 53 and 78%. Survival is associated with initial patient performance status.^{104–106}

Any recurrence should be investigated completely. Recurrences are usually treated by additional surgery. It is important to note that surgery for recurrent disease is usually difficult and is associated with an increased incidence of unintentional enterotomies, anastomotic leaks, and fistulas.^{102,103}

Lymphoma

Lymphoma of the appendix is extremely uncommon. The GI tract is the most frequently involved extranodal site for non-Hodgkin's lymphoma.¹⁰⁷ Other types of appendiceal lymphoma, such as Burkitt's, as well as leukemia, have also been reported.¹⁰⁸ Primary lymphoma of the appendix accounts for 1 to 3% of GI lymphomas. Appendiceal lymphoma usually presents as acute appendicitis and is rarely suspected preoperatively. Findings on CT scan of an appendiceal diameter ≥ 2.5 cm or surrounding soft tissue thickening should prompt suspicion of an appendiceal lymphoma. The management of appendiceal lymphoma confined to the appendix is appendectomy. Right hemicolectomy is indicated if tumor extends beyond the appendix onto the cecum or mesentery. A postoperative staging work-up is indicated before initiating adjuvant therapy. Adjuvant therapy is not indicated for lymphoma confined to the appendix.^{108,109}

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 31. Liver >

KEY POINTS

1. Understand extrahepatic and intrahepatic liver anatomy and physiology.
2. Understand hepatic molecular signaling pathways.
3. Know the features of acute liver failure and cirrhosis, along with treatment options.
4. Formulate a plan for the work-up of an incidental liver lesion.
5. Understand the current treatment options for primary and metastatic liver cancer.
6. Describe the nomenclature and steps in performing an anatomic right or left hepatic resection.

HISTORY OF LIVER SURGERY

The ancient Greek myth of Prometheus reminds us that the liver is the only organ that regenerates. According to Greek mythology, Zeus was furious with the titan Prometheus because he gave fire to the mortals. In return, Zeus chained Prometheus to Mount Caucasus and sent his giant eagle to eat his liver during the day, only to have it regenerate at night. Although this is an exaggeration, the principles are correct that after hepatic resection, the remnant liver will hypertrophy over weeks to months to regain most of its original liver mass. It is interesting to note that the ancient Greeks seem to have been aware of this fact, because the Greek word for the liver, *hēpar*, derives from the verb *hēpaomai*, which means "mend" or "repair." Hence *hēpar* roughly translates as "repairable."¹ The importance of the liver dates back to even biblical times, for the Babylonians (c. 2000 B.C.) considered the liver to be the seat of the soul. There are scattered reports of liver surgery for battlefield injuries, but the first recorded elective hepatic resection was done in 1888 in Germany by Langenbuch. There followed reports of liver resections in the United States (Tiffany, 1890) and Europe (Lucke, 1891), as well as the first large series of hepatic resections by Keen in 1899.^{2,3} In 1908, Pringle described in *Annals of Surgery* the "arrest of hepatic hemorrhage due to trauma" by compression of the porta hepatis, a maneuver that now bears his name.⁴ Possibly due to the potential for massive hemorrhage during liver surgery, very little progress in surgical techniques was recorded for the next half-century. Work by Rex, Cantlie, and others laid the groundwork for experimental and clinical reports in the 1950s by Couinaud, Hjortsjo, Healey, Lortat-Jacob, and Starzl.^{5,6} These seminal contributions paved the way for the modern era of hepatic resection surgery.

LIVER ANATOMY

The liver is the largest organ in the body, weighing approximately 1500 g. It sits in the right upper abdominal cavity beneath the diaphragm and is protected by the rib cage. It is reddish brown and is surrounded by a fibrous sheath known as *Glisson's capsule*. The liver is held in place by several ligaments (Fig. 31-1). The round ligament is the remnant of the obliterated umbilical vein and enters the left liver hilum at the front edge of the falciform ligament. The falciform ligament separates the left lateral and left medial segments along the umbilical fissure and anchors the liver to the anterior abdominal wall. Deep in the plane between the caudate lobe and the left lateral segment is the fibrous ligamentum venosum, which is the obliterated ductus venosus and is covered by the plate of Arantius. The left and right triangular ligaments secure the two sides of the liver to the diaphragm. Extending from the triangular ligaments anteriorly on the liver are the coronary ligaments. The right coronary ligament also extends from the right undersurface of the liver to the peritoneum overlying the right kidney, thereby anchoring the liver to the right retroperitoneum. These ligaments (round, falciform, triangular, and coronary) can be divided in a bloodless plane to fully mobilize the liver to facilitate hepatic resection. Centrally and just to the left of the gallbladder fossa, the liver attaches via the hepatoduodenal and the gastrohepatic ligaments (Fig. 31-2). The hepatoduodenal ligament is known as the *porta hepatis*

and contains the common bile duct, the hepatic artery, and the portal vein. From the right side and deep (dorsal) to the porta hepatis is the foramen of Winslow, also known as the *epiploic foramen* (see Fig. 31-2). This passage connects directly to the lesser sac and allows complete vascular inflow control to the liver when the hepatoduodenal ligament is clamped using the Pringle maneuver.

In situ liver hilar anatomy with hepatoduodenal and gastrohepatic ligaments. Foramen of Winslow is depicted.

Segmental Anatomy

The liver is grossly separated into the right and left lobes by the plane from the gallbladder fossa to the inferior vena cava (IVC), known as *Cantlie's line*.⁵ The right lobe typically accounts for 60 to 70% of the liver mass, with the left lobe (and caudate lobe) making up the

remainder. The caudate lobe lies to the left and anterior of the IVC and contains three subsegments: the Spiegel lobe, the paracaval portion, and the caudate process.⁷ The falciform ligament does not separate the right and left lobes, but rather it divides the left lateral segment from the left medial segment. The left lateral and left medial segments also are referred to as *sections* as defined in the Brisbane 2000 terminology, which is outlined later in the section "Hepatic Resection Techniques." A significant advance in our understanding of liver anatomy came from the cast work studies of the French surgeon and anatomist Couinaud in the early 1950s. Couinaud divided the liver into eight segments, numbering them in a clockwise direction beginning with the caudate lobe as segment I.⁶ Segments II and III comprise the left lateral segment, and segment IV is the left medial segment (Fig. 31-3). Thus, the left lobe is made up of the left lateral segment (Couinaud's segments II and III) and the left medial segment (segment IV). Segment IV can be subdivided into segment IVB and segment IVA. Segment IVA is cephalad and just below the diaphragm, spanning from segment VIII to the falciform ligament adjacent to segment II. Segment IVB is caudad and adjacent to the gallbladder fossa. Many anatomy textbooks also refer to segment IV as the *quadrate lobe*. *Quadrate lobe* is an outdated term, and the preferred term is *segment IV* or *left medial segment*. Most surgeons still refer to segment I as the *caudate lobe*, rather than segment I. The right lobe is comprised of segments V, VI, VII, and VIII, with segments V and VIII making up the right anterior lobe, and segments VI and VII the right posterior lobe.

Couinaud's liver segments (I through VIII) numbered in a clockwise manner. The left lobe includes segments II to IV, the right lobe includes segments V to VIII, and the caudate lobe is segment I. IVC = inferior vena cava.

Additional functional anatomy was highlighted by Bismuth based on the distribution of the hepatic veins. The three hepatic veins run in corresponding scissura (fissures) and divide the liver into four sectors.⁸ The right hepatic vein runs along the right scissura and separates the right posterolateral sector from the right anterolateral sector. The main scissura contains the middle hepatic vein and separates the right and left livers. The left scissura contains the course of the left hepatic vein and separates the left posterior and left anterior sectors. Although many other investigators contributed to the description of liver anatomy, it was clearly the work of Couinaud that provided the most detailed understanding of segmental liver anatomy. Couinaud devoted decades to understanding the anatomy of the liver—a PubMed search of "Couinaud C" and "liver" yields 72 publications.

Hepatic Artery

The liver has a dual blood supply consisting of the hepatic artery and the portal vein. The hepatic artery delivers approximately 25% of the blood supply, and the portal vein approximately 75%. The hepatic artery arises from the celiac axis (trunk), which gives off the left gastric, splenic, and common hepatic arteries (Fig. 31-4). The common hepatic artery then divides into the gastroduodenal artery and the hepatic artery proper. The right gastric artery typically originates off of the hepatic artery proper, but this is variable. The hepatic artery proper divides into the right and left hepatic arteries. This "classic" or standard arterial anatomy is present in only approximately 75% of cases, with the remaining 25% having variable anatomy. It is critical to understand the arterial (and biliary) anatomic variants to avoid surgical complications when operating on the liver, gallbladder, pancreas, or adjacent organs.

Arterial anatomy of the upper abdomen and liver, including the celiac trunk and hepatic artery branches. a. = artery; LHA = left hepatic artery; RHA = right hepatic artery.

The most common hepatic arterial variants are shown (Fig. 31-5). The right hepatic artery is replaced coming off the superior mesenteric artery (SMA) 18 to 22% of the time. When there is a replacement or accessory right hepatic artery, it traverses posterior to the portal vein and then takes up a right lateral position before diving into the liver parenchyma. This can be recognized visually on a preoperative computed tomographic (CT) or magnetic resonance imaging (MRI) scan, and confirmed by palpation in the hilum where a separate right posterior pulsation is felt distinct from that of the hepatic artery proper that lies anteriorly in the hepatoduodenal ligament to the left of the common bile duct. A replacement (or accessory) left hepatic artery comes off of the left gastric artery in 12 to 15% of cases and runs obliquely in the gastrohepatic ligament anterior to the caudate lobe before entering the hilar plate at the base of the umbilical fissure. Other less common variants (approximately 2% each) are an early bifurcation of the left and right hepatic arteries, as well as a completely replaced common hepatic artery coming off the SMA (see Fig. 31-5). Although not well demonstrated in the illustration, the clue for a completely replaced common hepatic artery coming off the SMA is the presence of a strong arterial pulsation to the right of the common bile duct, rather than the left side, in the porta hepatis. Another important point is that the right hepatic artery passes deep and posterior to the common bile duct approximately 88% of the time but crosses anterior to the common bile duct in approximately 12% of cases. The cystic artery feeding the gallbladder usually arises from the right hepatic artery in Calot's triangle.

Common hepatic artery anatomic variants. SMA = superior mesenteric artery.

Portal Vein

The portal vein is formed by the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein usually drains into the splenic vein upstream from the confluence (Fig. 31-6). The main portal vein traverses the porta hepatis before dividing into the left and right portal vein branches. The left portal vein typically branches from the main portal vein outside of the liver with a sharp bend to the left and consists of the transverse portion followed by a 90-degree turn at the base of the umbilical fissure to become the umbilical portion before entering the liver parenchyma (Fig. 31-7). The left portal vein then divides to give off the segment III and II branches to the left lateral segment, as well as the segment IV feedback branches that supply the left medial segment. The left portal vein also provides the dominant inflow branch to the caudate lobe (although branches can arise from the main and right portal veins also), usually close to the bend between the transverse and umbilical portions. The division of the right portal vein is usually higher in the hilum and may be close to (or inside) the liver parenchyma at the hilar plate.

Anatomy of the left portal vein (LPV). Cadaver cast shows the transverse and umbilical portions of the LPV. LIG. VEN = ligamentum venosum; RD LIG. = round ligament.

(Reproduced with permission from Botero AC, Strasberg SM: Division of the left hemiliver in man—segments, sectors, or sections. *Liver Transpl Surg* 4:226, 1998.)

The portal vein drains the splanchnic blood from the stomach, pancreas, spleen, small intestine, and majority of the colon to the liver before

returning to the systemic circulation. The portal vein pressure in an individual with normal physiology is low at 3 to 5 mmHg. The portal vein is valveless, however, and in the setting of portal hypertension, the pressure can be quite high (20 to 30 mmHg). This results in decompression of the systemic circulation through portocaval anastomoses, most commonly via the coronary (left gastric) vein, which produces esophageal and gastric varices with the propensity for major hemorrhage. Another branch of the main portal vein is the superior pancreaticoduodenal vein (which comes off low in an anterior lateral position and is divided during pancreaticoduodenectomy). Closer to the liver, the main portal vein typically gives off a short branch (posterior lateral) to the caudate process on the right side. It is important to identify this branch and ligate it during hilar dissection for anatomic right hemihepatectomy to avoid avulsion.

Hepatic Veins and Inferior Vena Cava

There are three hepatic veins (right, middle, and left) that pass obliquely through the liver to drain the blood to the suprahepatic IVC and eventually the right atrium (Fig. 31-8). The right hepatic vein drains segments V to VIII; the middle hepatic vein drains segment IV as well as segments V and VIII; and the left hepatic vein drains segments II and III. The caudate lobe is unique because its venous drainage feeds directly into the IVC. In addition, the liver usually has a few small, variable short hepatic veins that directly enter the IVC from the undersurface of the liver. The left and middle hepatic veins form a common trunk approximately 95% of the time before entering the IVC, whereas the right hepatic vein inserts separately (in an oblique orientation) into the IVC. There is a large inferior accessory right hepatic vein in 15 to 20% of cases that runs in the hepatocaval ligament. This can be a source of torrential bleeding if control is lost during right hepatectomy. The hepatic vein branches bisect the portal branches inside the liver parenchyma (i.e., the right hepatic vein runs between the right anterior and posterior portal veins; the middle hepatic vein passes between the right anterior and left portal vein; and the left hepatic vein crosses between the segment III and II branches of the left portal vein).

Bile Duct and Hepatic Ducts

Within the hepatoduodenal ligament, the common bile duct lies anteriorly and to the right. It gives off the cystic duct to the gallbladder and becomes the common hepatic duct before dividing into the right and left hepatic ducts. In general, the hepatic ducts follow the arterial branching pattern inside the liver. The bifurcation of the right anterior hepatic duct usually enters the liver above the hilar plate, whereas the right posterior duct dives behind the right portal vein and can be found on the surface of the caudate process before entering the liver. The left hepatic duct typically has a longer extrahepatic course before giving off segmental branches behind the left portal vein at the base of the umbilical fissure. Considerable variation exists, and in 30 to 40% of cases there is a nonstandard hepatic duct confluence with accessory or aberrant ducts (Fig. 31-9). The cystic duct itself also has a variable pattern of drainage into the common bile duct. This can lead to potential injury or postoperative bile leakage during cholecystectomy or hepatic resection, and the surgeon needs to expect these variants. The gallbladder sits adherent to hepatic segments IVB (left lobe) and V (right lobe) (see Chap. 32).

Fig. 31-9.

A: Normal bifurcation 57%
B: Trifurcation of 3 ducts 12%

C: R anterior (C1, 16%) or R posterior (C2, 4%) duct draining into CHD

D: R posterior (D1, 5%) or R anterior duct (D2, 1%) draining into the left hepatic duct

E: Absence of hepatic duct confluence 3%

F: Drainage of R posterior duct into cystic duct 2%

Neural Innervation and Lymphatic Drainage

The parasympathetic innervation of the liver comes from the left vagus, which gives off the anterior hepatic branch, and the right vagus,

which gives off the posterior hepatic branch. The sympathetic innervation involves the greater thoracic splanchnic nerves and the celiac ganglia, although the function of these nerves is poorly understood. The denervated liver after hepatic transplantation seems to function with normal capacity. A common source of referred pain to the right shoulder and scapula as well as the right side or back is the right phrenic nerve, which is stimulated by tumors that stretch Glisson's capsule or by diaphragmatic irritation.

Lymph is produced within the liver and drains via the perisinusoidal space of Disse and periportal clefts of Mall to larger lymphatics that drain to the hilar cystic duct lymph node (Calot's triangle node), as well as the common bile duct, hepatic artery, and retropancreatic and celiac lymph nodes. This is particularly important for resection of hilar cholangiocarcinoma, which has a high incidence of lymph node metastases. The hepatic lymph also drains cephalad to the cardiophrenic lymph nodes and the latter can be pathologically identified on a staging CT or MRI scan.

LIVER PHYSIOLOGY

The liver is the largest gland in the body and has an extraordinary spectrum of functions. These many functions comprise processes such as storage, metabolism, production, and secretion. One crucial role is the processing of absorbed nutrients through the metabolism of glucose, lipids, and proteins. The liver maintains glucose concentrations in a normal range over both short and long periods by performing several important roles in carbohydrate metabolism. In the fasting state, the liver ensures a sufficient supply of glucose to the central nervous system. The liver can produce glucose by breaking down glycogen through glycogenolysis and by de novo synthesis of glucose through gluconeogenesis from noncarbohydrate precursors such as lactate, amino acids, and glycerol. In the postprandial state, excess circulating glucose is removed by glycogen synthesis or glycolysis and lipogenesis. The liver also plays a central role in lipid metabolism through the formation of bile and the production of cholesterol and fatty acids. Protein metabolism occurs in the liver through amino acid deamination resulting in the production of ammonia as well as the production of a variety of proteins. In addition to metabolism, the liver is also responsible for the synthesis of most circulating plasma proteins. Among these proteins are albumin, factors of the coagulation and fibrinolytic systems, and compounds of the complement cascade. Furthermore, the detoxification of many substances through drug metabolism occurs in the liver, as do immunologic responses through the many immune cells found in its reticuloendothelial system.⁹

Bilirubin Metabolism

Bilirubin is the breakdown product of normal heme catabolism. The bilirubin is bound to albumin in the circulation and sent to the liver. In the liver, it is conjugated to glucuronic acid in a reaction catalyzed by the enzyme glucuronyl transferase, which makes it soluble in water. Each bilirubin molecule reacts with two uridine diphosphoglucuronic acid molecules to form bilirubin diglucuronide. This glucuronide is then excreted into the bile canaliculi. A small amount of bilirubin glucuronide escapes into the blood and is then excreted in the urine. The majority of conjugated bilirubin is excreted in the intestine as waste, because the intestinal mucosa is relatively impermeable to conjugated bilirubin. However, it is permeable to unconjugated bilirubin and urobilinogens, a series of bilirubin derivatives formed by the action of bacteria. Thus, some of the bilirubin and urobilinogens are reabsorbed in the portal circulation; they are again excreted by the liver or enter the circulation and are excreted in the urine.¹⁰

Formation of Bile

Bile is a complex fluid containing organic and inorganic substances dissolved in an alkaline solution that flows from the liver through the biliary system and into the small intestine. The main components of bile are water, electrolytes, and a variety of organic molecules including bile pigments, bile salts, phospholipids (lecithin), and cholesterol. The two fundamental roles of bile are to aid in the digestion and absorption of lipids and lipid-soluble vitamins and to eliminate waste products (bilirubin and cholesterol) through secretion into bile and elimination in feces. Bile is produced by hepatocytes and secreted through the biliary system. In between meals, bile is stored in the gallbladder and concentrated through the absorption of water and electrolytes. Upon entry of food into the duodenum, bile is released from the gallbladder to aid in digestion. About 1 L of bile can be produced by the human liver daily. However, >95% of the bile salts secreted in bile are reabsorbed in the intestine and then excreted again by the liver (enterohepatic circulation).

Bile salts, in conjunction with phospholipids, are responsible for the digestion and absorption of lipids in the small intestine. Bile salts are sodium and potassium salts of bile acids conjugated to amino acids. The bile acids are derivatives of cholesterol synthesized in the

hepatocyte. Cholesterol, ingested from the diet or derived from hepatic synthesis, is converted into the bile acids cholic acid and chenodeoxycholic acid. These bile acids are conjugated to either glycine or taurine before secretion into the biliary system. Bacteria in the intestine can remove glycine and taurine from bile salts. They can also convert some of the primary bile acids into secondary bile acids by removing a hydroxyl group, producing deoxycholic from cholic acid, and lithocholic from chenodeoxycholic acid.

Bile salts are amphipathic, containing both hydrophobic and hydrophilic domains. The amphipathic nature of bile salts allows for the emulsification of lipids, which results in the breakdown of fat globules into microscopic droplets. This greatly increases the surface area of lipids, which permits their digestion by lipases. Bile salts are also able to carry and solubilize lipids by forming micelles. Lipids collect in the micelles, with cholesterol in the hydrophobic center and amphipathic phospholipids with their hydrophilic heads on the outside and their hydrophobic tails in the center. The micelles play an important role in keeping lipids in solution and transporting them to the brush border of the intestinal epithelial cells, where they are absorbed.

Bile salts secreted into the intestine are efficiently reabsorbed and reused. Approximately 90 to 95% of the bile salts are absorbed from the small intestine at the terminal ileum. The remaining 5 to 10% enters the colon and is converted to the secondary salts of deoxycholic acid and lithocholic acid. The mixture of primary and secondary bile salts and bile acids is absorbed primarily by active transport in the terminal ileum. The absorbed bile salts are transported back to the liver in the portal vein and re-excreted in the bile. Those lost in the stool are replaced by synthesis in the liver. The continuous process of secretion of bile salts in the bile, their passage through the intestine, and their subsequent return to the liver is termed the *enterohepatic circulation*.¹⁰

Drug Metabolism

The liver plays an important role in providing mechanisms for ridding the body of foreign molecules (xenobiotics) that are absorbed from the environment. In most cases, a drug is relatively lipophilic to ensure good absorption. The liver participates in the elimination of these lipid-soluble drugs by transforming them into more readily excreted hydrophilic products. There are two main reactions that can occur in the liver important for drug metabolism. Phase I reactions include oxidation, reduction, and hydrolysis of molecules that result in metabolites that are more hydrophilic than the original chemicals. The cytochrome P-450 system is a family of hemoproteins important for oxidative reactions involving drug and toxic substances. Phase II reactions, also known as *conjugation reactions*, are synthetic reactions that involve addition of subgroups to the drug molecule. These subgroups include glucuronate, acetate, glutathione, glycine, sulfate, and methyl groups. These drug reactions occur mainly in the smooth endoplasmic reticulum of the hepatocyte.

Many factors can affect drug metabolism in the liver. When the rate of metabolism of a pharmacologically active metabolite is increased (i.e., enzyme induction), the duration of the drug action will decrease. However, when the metabolism of a drug is decreased (i.e., enzyme inhibition), then the drug will be metabolically active for a longer period of time. It is important to note that some drugs may be converted to active products by metabolism in the liver. An example is acetaminophen when taken in larger doses. Normally, acetaminophen is conjugated by the liver to harmless glucuronide and sulfate metabolites that are water soluble and eliminated in the urine. During an overdose, the normal metabolic pathways are overwhelmed, and some of the drug is converted to a reactive and toxic intermediate by the cytochrome P-450 system. Glutathione can normally bind to this intermediate and lead to the excretion of a harmless product. However, as glutathione stores are diminished, the reactive intermediate cannot be detoxified and it combines with lipid bilayers of hepatocytes, which results in cellular necrosis. Thus, treatment of acetaminophen overdoses consists of replacing glutathione with sulfhydryl compounds such as acetylcysteine.

Liver Function Tests

Liver function tests is a term frequently used to refer to measurement of the levels of a group of serum markers for evaluation of liver dysfunction. Most commonly, levels of aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase (AP), γ -glutamyltranspeptidase (GGTP), and bilirubin are included in this panel. This term is a misnomer, however, because most of these tests measure not liver function but rather cell damage. More accurate measurement of the liver's synthetic function is provided by serum albumin levels and prothrombin time. Although measuring liver enzyme levels is important in the assessment of a patient's liver disease, these test results can be nonspecific. Thus, evaluation of patients with suspected liver disease should always involve careful interpretation of

abnormalities in these liver test results in the context of a thorough history and physical examination. The approach to evaluating abnormal laboratory values can also be simplified by categorizing the type of abnormality that predominates (hepatocellular damage, abnormal synthetic function, or cholestasis).

Hepatocellular Injury

Hepatocellular injury of the liver is usually indicated by abnormalities in levels of the liver aminotransferases AST and ALT. These enzymes participate in gluconeogenesis by catalyzing the transfer of amino groups from aspartic acid or alanine to ketoglutaric acid to produce oxaloacetic acid and pyruvic acid, respectively (these enzymes were formerly referred to as *glutamic-oxaloacetic transaminase* and *glutamic-pyruvic transaminase*). AST is found in the liver, cardiac muscle, skeletal muscle, kidney, brain, pancreas, lungs, and red blood cells and thus is less specific for disorders of the liver. ALT is predominately found in the liver and thus is more specific for liver disease. Hepatocellular injury is the trigger for release of these enzymes into the circulation. Common causes of elevated aminotransferase levels include viral hepatitis, alcohol abuse, medications, genetic disorders (Wilson's disease, hemochromatosis, alpha1-antitrypsin deficiency), and autoimmune diseases.

The extent of serum aminotransferase elevations can suggest certain etiologies of the liver injury. However, the levels of the enzymes in these tests correlate poorly with the severity of hepatocellular necrosis, because they may not be significantly elevated in conditions of hepatic fibrosis or cirrhosis. In alcoholic liver disease, an AST:ALT ratio of >2:1 is common. Mild elevations of transaminase levels can be found in nonalcoholic fatty liver disease, chronic viral infection, or medication-induced injury. Moderate increases in the levels of these enzymes are common in acute viral hepatitis. In conditions of ischemic insults, toxin ingestions (i.e., acetaminophen), and fulminant hepatitis, AST and ALT levels can be elevated to the thousands.

Abnormal Synthetic Function

Albumin synthesis is an important function of the liver and thus can be measured to evaluate the liver's synthetic function. The liver produces approximately 10 g of albumin per day. However, albumin levels are dependent on a number of factors such as nutritional status, renal dysfunction, protein-losing enteropathies, and hormonal disturbances. In addition, level of albumin is not a marker of acute hepatic dysfunction due to albumin's long half-life of 15 to 20 days.

Most clotting factors (except factor VIII) are synthesized exclusively in the liver, and thus their levels can also be used as a measure of hepatic synthetic function. Measurements of the prothrombin time and international normalized ratio (INR) are one of the best tests of hepatic synthetic function. The prothrombin time measures the rate of conversion of prothrombin to thrombin. To standardize the reporting of prothrombin time and avoid interlaboratory variability, the INR was developed. The INR is the ratio of the patient's prothrombin time to the mean control prothrombin time. Because vitamin K is involved in the γ -carboxylation of factors used to measure prothrombin time (factors II, VII, IX, and X), values may be prolonged in other conditions such as vitamin K deficiency and warfarin therapy.

Cholestasis

Cholestasis is a condition in which bile flow from the liver to the duodenum is impaired. Disturbances in bile flow may be due to intrahepatic causes (hepatocellular dysfunction) or extrahepatic causes (biliary tree obstruction). Cholestasis often results in the release of certain enzymes and thus can be detected by measuring the serum levels of bilirubin, AP, and GGTP, which will be abnormal. Bilirubin is a breakdown product of hemoglobin metabolism. Unconjugated bilirubin is insoluble and thus is transported to the liver bound to albumin. In the liver, it is conjugated to allow excretion in bile. Measured total bilirubin levels can be low, normal, or high in patients with significant liver disease because of the liver's reserve ability to conjugate significant amounts of bilirubin. Thus, to help aid in the diagnosis of hyperbilirubinemia, fractionation of the total bilirubin is usually performed to distinguish between conjugated (direct) and unconjugated (indirect) bilirubin. *Indirect bilirubin* is a term frequently used to refer to unconjugated bilirubin in the circulation because the addition of another chemical is necessary to differentiate this fraction from the whole. Normally, >90% of serum bilirubin is unconjugated. The testing process for conjugated bilirubin, in contrast, is direct without the addition of other agents. The direct bilirubin test measures the levels of conjugated bilirubin and delta bilirubin (conjugated bilirubin bound to albumin).

The patterns of elevation of the different fractions of bilirubin provide important diagnostic clues as to the cause of cholestasis. In general,

an elevated indirect bilirubin level suggests intrahepatic cholestasis and an elevated direct bilirubin level suggests extrahepatic obstruction. Mechanisms that can result in increases in unconjugated bilirubin levels include increased bilirubin production (hemolytic disorders and resorption of hematomas) or defects (inherited or acquired) in hepatic uptake or conjugation. The rate-limiting step in bilirubin metabolism is the excretion of bilirubin from hepatocytes, so conjugated hyperbilirubinemia can be seen in inherited or acquired disorders of intrahepatic excretion or extrahepatic obstruction. Conjugated bilirubin cannot be excreted and accumulates in the hepatocytes, which results in its secretion into the circulation. Because conjugated bilirubin is water soluble, it can be found in the urine of patients with jaundice.

AP is an enzyme with a wide tissue distribution but is found primarily in the liver and bones. In the liver, it is expressed by the bile duct epithelium. In conditions of biliary obstruction, levels rise as a result of increased synthesis and release into the serum. Because the half-life of serum AP is approximately 7 days, it may take several days for levels to normalize even after resolution of the biliary obstruction.

GGTP is another enzyme found in hepatocytes and released from the bile duct epithelium. Elevation of GGTP is an early marker and also a sensitive test for hepatobiliary disease. Like AP elevation, however, it is nonspecific and can be produced by a variety of disorders in the absence of liver disease. Increased levels of GGTP can be induced by certain medications, alcohol abuse, pancreatic disease, myocardial infarction, renal failure, and obstructive pulmonary disease. For this reason, elevated GGTP levels are often interpreted in conjunction with other enzyme abnormalities. For example, a raised GGTP level with increased AP level supports a liver source.

Jaundice

Jaundice refers to the yellowish staining of the skin, sclera, and mucous membranes with the pigment bilirubin. Hyperbilirubinemia is usually detectable as jaundice when blood levels rise above 2.5 to 3 mg/dL. Jaundice can be caused by a wide range of benign and malignant disorders. However, when present, it may indicate a serious condition, and thus knowledge of the differential diagnosis of jaundice and a systematic approach to the work-up of the patient is necessary. Work-up of a patient with jaundice is simplified by organizing the possible causes of the disorder into groups based on the location of bilirubin metabolism. As mentioned previously, bilirubin metabolism can take place in three phases: prehepatic, intrahepatic, and posthepatic. The prehepatic phase includes the production of bilirubin from the breakdown of heme products and its transport to the liver. The majority of the heme results from red blood cell metabolism and the rest from other heme-containing organic compounds such as myoglobin and cytochromes. In the liver, the insoluble unconjugated bilirubin is then conjugated to glucuronic acid to allow for solubility in bile and excretion. The posthepatic phase of bilirubin metabolism consists of excretion of soluble bilirubin through the biliary system into the duodenum. Dysfunction in any of these phases can lead to jaundice.¹⁰

PREHEPATIC

Jaundice as a result of elevated levels of unconjugated bilirubin occurs from faulty prehepatic metabolism and usually arises from conditions that interfere with proper conjugation of bilirubin in the hepatocyte. Insufficient conjugation is often seen in processes that result in excessive heme metabolism. Subsequently, the conjugation system is overwhelmed, which results in unconjugated hyperbilirubinemia. Causes of hemolysis include inherited and acquired hemolytic anemias. Inherited hemolytic anemias include genetic disorders of the red blood cell membrane (hereditary spherocytosis), enzyme defects (glucose-6-phosphate dehydrogenase deficiency), and defects in hemoglobin structure (sickle cell anemia and thalassemias). Hemolytic anemias can also be acquired, and these can be further divided into those with immune-mediated and those with non-immune-mediated causes. Immune-mediated hemolytic anemias result in a positive finding on a direct Coombs' test and have a variety of autoimmune and drug-induced causes. In contrast, direct Coombs' test results are negative in nonimmune hemolytic anemias. The causes in this latter category are varied and include drugs and toxins that directly damage red blood cells, mechanical trauma (heart valves), microangiopathy, and infections. Prehepatic dysfunction of bilirubin metabolism can also result from failure in the transport of unconjugated bilirubin to the liver by albumin in any condition that leads to plasma protein loss. A poor nutritional state or excess protein loss as seen in burn patients can lead to elevated levels of unconjugated bilirubin in the circulation and jaundice.

INTRAHEPATIC

Intrahepatic causes of jaundice involve the intracellular mechanisms for conjugation and excretion of bile from the hepatocyte. The enzymatic processes in the hepatocytes can be affected by any condition that impairs hepatic blood flow and subsequent function of the liver (ischemic or hypoxic events). Furthermore, there are multiple inherited disorders of enzyme metabolism that can result in either unconjugated or conjugated hyperbilirubinemia. Gilbert syndrome is a genetic variant characterized by diminished activity of the enzyme glucuronyltransferase, which results in decreased conjugation of bilirubin to glucuronide. It is a benign condition that affects approximately 4 to 7% of the population. Typically, the disease results in transient mild increases in unconjugated bilirubin levels and jaundice during episodes of fasting, stress, or illness. These episodes are self limited and usually do not require further treatment. Another inherited disorder of bilirubin conjugation is Crigler-Najjar syndrome. It is a rare disease found in neonates and can result in neurotoxic sequelae from bilirubin encephalopathy.

In addition to defects in conjugation, disorders in bilirubin excretion in the hepatocyte can also lead to jaundice. Rotor's syndrome and Dubin-Johnson syndrome are two uncommon genetic disorders that disrupt transport of conjugated bilirubin from the hepatocyte and result in conjugated hyperbilirubinemia. There are also multiple acquired conditions that result in inflammation and intrahepatic cholestasis by affecting hepatocyte mechanisms for conjugation and excretion of bile. Viruses, alcohol abuse, sepsis, and autoimmune disorders can all result in inflammation in the liver with subsequent disruption of bilirubin transport in the liver. In addition, jaundice can also occur from the cytotoxic effects of many medications, including acetaminophen, oral contraceptives, and anabolic steroids.

POSTHEPATIC

Posthepatic causes of jaundice are usually the result of intrinsic or extrinsic obstruction of the biliary duct system that prevents the flow of bile into the duodenum. There is a wide spectrum of pathologies that may present with obstructive jaundice. Intrinsic obstruction can occur from biliary diseases, including cholelithiasis, choledocholithiasis, benign and malignant biliary strictures, cholangiocarcinoma, cholangitis, and papillary disorders. Extrinsic compression of the biliary tree is commonly due to pancreatic disorders. Patients with pancreatitis, pseudocysts, and malignancies can present with jaundice due to external compression of the biliary system. Finally, with the growing armamentarium of endoscopic tools and minimally invasive surgical approaches, surgical complications are becoming more frequent causes of extrahepatic cholestasis. Misadventures with surgical clips, retained stones, and inadvertent ischemic insults to the biliary system can result in obstructive jaundice recognized immediately postoperatively or many years later.

MOLECULAR SIGNALING PATHWAYS IN THE LIVER

Acute Phase Reaction

The liver is the site of synthesis of acute phase proteins that consist of a group of plasma proteins that are rapidly released in response to inflammatory conditions elsewhere in the body. The synthesis of these proteins in the liver is influenced by a number of inflammatory mediators. Cytokines such as tumor necrosis factor alpha (TNF- α), interferon- γ , interleukin-1 (IL-1), interleukin-6 (IL-6), and interleukin-8 (IL-8) are released by inflammatory cells into the circulation at sites of injury and modulate the acute phase response. In response to these cytokines, the liver increases synthesis and release of a wide variety of proteins, including ceruloplasmin, complement factors, C-reactive protein, D-dimer protein, α_1 -antitrypsin, and serum amyloid A. There are proteins such as serum albumin and transferrin whose levels also decrease (negative acute phase proteins) in response to inflammation.

The acute phase response of the liver can be initiated in reaction to infection, trauma, or malignancy. The purpose of the release of these proteins from the liver is to contain infectious processes, prevent further tissue damage, and begin reparative and regeneration processes to restore body homeostasis. For example, products of the complement pathways can attach to microbes to allow for phagocytosis and act as chemoattractants to the areas of inflammation. C-reactive protein is an important acute phase protein that is also involved in the clearance of microorganisms by binding to their membranes and functioning as an opsonin to facilitate phagocytosis. Other proteins such as α_1 -antitrypsin are protease inhibitors and restrict the protease activity of enzymes of inflammatory cells. Thus, the secretion of acute phase proteins from the liver during the acute phase response is an early defense measure against harmful stimuli before the full activation of the immune response.¹¹

Lipopolysaccharide Signaling

The liver is a complex organ with an important function in immune surveillance and clearance of bacteria and their products. This function is facilitated by the fact that the liver receives all of the drainage of the GI tract via the portal blood flow, which makes it the last barrier preventing bacteria and their toxins from reaching the systemic circulation. The importance of preventing bacteria and their products from reaching the systemic bloodstream is evident in patients who are infected with gram-negative bacteria. Gram-negative bacterial infection produces an acute inflammatory reaction that can lead to septic shock and multiple organ failure. The complications of gram-negative sepsis are initiated by endotoxin (lipopolysaccharide, or LPS). LPS is a glycolipid constituent of the outer membranes of gram-negative bacteria composed of a hydrophilic polysaccharide portion and a hydrophobic domain called *lipid A*. The lipid A structure is the LPS component responsible for the biologic effects of LPS. Mere nanogram amounts of LPS injected into humans can result in the manifestations of septic shock. The profound effects of LPS are caused not only by the direct effect of LPS itself but also by activation of LPS-sensitive cells, which results in the excessive release of cytokines and other inflammatory mediators.

Because sepsis from gram-negative bacterial infection continues to be a major cause of morbidity and mortality, significant efforts have been made to identify the molecules involved in LPS binding and signaling (Fig. 31-10). Lipopolysaccharide-binding protein (LBP), CD14, myeloid differentiation-2 (MD-2), and toll-like receptors all have been identified as important mediators in the pathway of LPS stimulation. LBP is an acute phase protein synthesized by hepatocytes that binds the lipid A moiety of LPS and forms a soluble LBP-LPS complex. This LBP-LPS complex then interacts with CD14, a receptor identified as important in LPS recognition, which results in the release of inflammatory cytokines and mediators.¹² Studies have shown that although LBP is important, it is not required for LPS to interact with CD14; however, its presence markedly decreases the concentration of LPS necessary for cellular activation. This may be important especially at the low concentrations of LPS found under physiologic conditions. CD14 exists in two forms: membrane form and soluble form. The interaction of LPS with membrane CD14 or soluble CD14 is important in host clearance of LPS. This interaction is also responsible for the toxic effects of LPS seen in the liver and systemic circulation after the release of inflammatory cytokines and mediators. Although membrane CD14 is a membrane protein found on the surface of cells of myeloid lineage and mediates the activation of these cells by LPS, soluble CD14 is found in the serum and enables responses to LPS by cells that do not express CD14. In addition to playing an important role in the release of LBP as an acute phase reactant during LPS-mediated inflammatory insults, the liver is also one of the major sources of release of soluble CD14 into the circulation.

Lipopolysaccharide (LPS) and toll-like receptor 4 (TLR4) signaling in the liver. Circulating LPS-binding protein (LBP) binds to LPS in the plasma and is recognized by CD14. LPS signaling requires the formation of a complex consisting of dimerized TLR4 receptors and the adaptor MD-2. Subsequent signals activated by TLR4 can be subdivided into those dependent on MyD88 and MAL and those independent of MyD88, which require the adaptors TRIF and TRAM. LPS signaling leads to the activation of multiple inflammatory pathways, including nuclear factor κ B (NF- κ B), interferon regulatory factor 3 (IRF-3), and mitogen-activated protein kinase (MKK). IKK = inhibitor of κ B kinase; JNK = c-Jun N-terminal kinase; MAL = MyD88-adaptor-like; MD-2 = myeloid differentiation-2; MyD88 = myeloid differentiation factor 88; TBK1 = TANK-binding kinase 1; TIR = toll/interleukin-1 receptor; TRAF6 = tumor necrosis factor receptor-associated factor 6; TRAM = TRIF-related adaptor molecule; TRIF = TIR domain-containing adaptor-inducing interferon- β .

The binding of the LBP-LPS complex to CD14 is not enough to transduce an intracellular LPS signal.¹² Membrane CD14 is a glycosylphosphatidylinositol-anchored protein without a membrane-spanning domain. Thus, signaling further downstream of LPS requires additional elements. In studies using chemically modified, radiolabeled LPS capable of cross-linking to nearby proteins, LPS has been shown to cross-link specifically to two other molecules, TLR4 and MD-2. TLR4 is a member of the family of proteins called *toll-like receptors* and has been identified as the transmembrane coreceptor to CD14. TLR4 was originally identified as the molecular sensor for bacterial LPS when studies demonstrated that mutations in the *tlr4* gene were responsible for defective LPS signaling in mutant mice. Thus, initiation of the LPS signaling cascade requires the interaction of LPS directly with the heteromeric receptor complex of CD14, TLR4, and MD-2. Activation of this complex senses the presence of bacterial LPS at the cell surface and then transmits a signal into the cytoplasm through two distinct pathways. One pathway is dependent on an adaptor known as *myeloid differentiation factor 88 (MyD88)*. The other pathway is MyD88 independent and relies on an adaptor known as *toll/IL-1 receptor domain-containing adaptor-inducing interferon- β (TRIF)*.

The liver is the main organ involved in the clearance of LPS from the bloodstream and so plays a critical role in the identification and processing of LPS.¹³ Kupffer cells are the resident macrophages of the liver and have been shown to participate in LPS clearance. Studies have demonstrated that the majority of radiolabeled LPS injected IV is quickly cleared from the circulation and found in the liver, primarily localized to the Kupffer cells.¹³ Kupffer cells also contribute to the inflammatory cascade by producing cytokines in response to LPS. Interestingly, hepatocytes, the parenchymal cells of the liver, also have all the components required for LPS recognition and signaling and can participate in the response to LPS and process LPS for clearance.

Although the liver is essential in the host response to gram-negative bacterial infection by contributing to LPS clearance and to the LPS-induced inflammatory reaction, evidence reveals that LPS may actually have a reciprocal role in the pathogenesis of liver disorders. A relationship between LPS and liver disease is not a novel concept. Early studies showed a correlation between the presence or absence of

gut-derived LPS and the development of liver injury.¹² Attempts to eliminate gut-derived LPS have had protective effects in various animal models of liver injury, including models of alcohol-induced liver disease.¹² Other studies have shown the synergism between LPS and hepatotoxins in worsening liver injury. Strategies of endotoxin antagonism have been examined in animal models and clinical trials.¹⁴

In summary, the liver is essential in the clearance of LPS, but it can also contribute to the negative systemic effects seen in gram-negative bacterial sepsis by excessive activation of the LPS signaling pathway. In addition, there is evidence that this signaling pathway may participate in the pathogenesis of a variety of liver diseases. An understanding and characterization of the LPS pathway within the liver is an important step to understanding the molecular basis for the lethal effect of LPS during sepsis and liver disorders.

Nitric Oxide

Nitric oxide (NO) is a diffusible, free-radical gas that was first identified in 1980 as endothelium-derived relaxing factor. Its physiologic and pathophysiologic importance in the cardiovascular system was discovered with the identification of its vital role as a vasodilator. However, its mediation of a variety of other diverse biologic activities has since been recognized. In the liver, the influence of NO in normal physiology as well as in states of disease has been extensively studied. The activation of inflammatory cascades in the liver almost universally includes the upregulation of the inducible or inflammatory isoform of nitric oxide synthase (iNOS) and subsequent NO production. The functions of iNOS and NO in the liver are complex, and a clear dichotomy in their roles in liver dysfunction, whether being protective or detrimental, has been demonstrated.

NO can be produced by one of three nitric oxide synthases (NOSs): neuronal NOS (nNOS), iNOS, and endothelial NOS (eNOS)¹⁵ (Fig. 31-11). These enzymes catalyze the conversion of L-arginine to NO and L-citrulline. The enzymes nNOS and eNOS are constitutively expressed in a wide range of tissues. The activity of iNOS and eNOS is primarily controlled by calcium-mediated signaling that results in transient activation of these enzymes to produce small amounts of NO. As its name implies, iNOS is not normally expressed in resting states in most tissues but is upregulated by gene transcription under conditions of stress. In contrast to nNOS and eNOS, iNOS produces a large and sustained amount of NO. Although iNOS was first identified in macrophages, it has been shown to be expressed in most cell types if appropriately stimulated. Interestingly, studies of the liver with hepatocytes provided the first evidence that parenchymal cells could express iNOS. It is now known that iNOS can be expressed in all cell types of the liver, but hepatocyte expression appears to be the most prominent. Studies have shown that many inflammatory mediators, including cytokines, microbial products, and oxidative stress, are all capable of stimulating iNOS expression in the liver.¹⁶

The L-arginine/nitric oxide synthase (NOS)/nitric oxide (NO) pathway. NO is implicated in a wide range of regulatory mechanisms as well as inflammatory processes. L-Arginine is converted to NO by the enzyme NOS. NO has been found to have a dichotomous action in various inflammatory settings, mediating both protective and deleterious effects.

The chemical action of NO in biologic systems has been difficult to study due to its short-lived nature. NO is highly reactive with other molecules due to its one unpaired electron. These interactions can result in either nitrosation or oxidation with subsequent varied effects on cellular processes. NO also can signal through cyclic nucleotides by activating the soluble isoform of guanylyl cyclase, which increases levels of cyclic guanosine monophosphate (cGMP). The functions of cGMP include acting as a second messenger that transmits signals by activating downstream kinases or cyclic nucleotide-gated channels. In addition to affecting cGMP signaling, NO also has been found to modulate the expression of many genes.

The role of NO in inflammatory states of the liver is complex and is at times conflicting.¹⁶ Under physiologic conditions, NO is important in maintaining hepatic perfusion. However, under inflammatory conditions, such as ischemia/reperfusion (I/R), NO can play either a protective or harmful role depending on the enzymatic source (iNOS vs. eNOS) and the type of ischemia reperfusion (cold vs. warm). It appears that the low level of constitutively expressed eNOS-derived NO is primarily beneficial in models of I/R injury, with vasodilation and subsequent improvement in hepatic microcirculation as the proposed mechanism of protection. Interestingly, activation of iNOS in similar models suggests a potentially harmful role for iNOS. NO, through its reaction with reactive nitrogen and oxygen intermediates generated in the course of reperfusion injury, can contribute to much of the hepatocellular damage, depending on the intracellular ratio of these intermediates to NO. The production of iNOS and NO are also closely tied to multiple other inflammatory mediators in the liver, and activation of these downstream signals may explain some of the detrimental effects of NO in I/R injury of the liver. Thus, given its diverse biologic effects as a signaling molecule, it is not surprising that NO plays both a protective and potentially harmful role in the setting of hepatic I/R injury. The final effect of NO varies in different liver diseases and depends on the overall hepatic environment. The potential use of NO pharmacologic manipulation to treat hepatic disease will require careful balance of the risks and benefits of this simple yet extremely complicated molecule.

Heme Oxygenase System

Heme oxygenase (HO) is the rate-limiting enzyme in the degradation of heme to yield biliverdin, carbon monoxide (CO), and free iron (Fig. 31-12). The HO system, which is activated in response to multiple cellular stresses, has been shown to be an endogenous cytoprotectant in

a variety of inflammatory conditions. Currently three HO isozymes have been identified. HO-1 is the inducible form of HO, whereas HO-2 and HO-3 are constitutively expressed. The function of HO in heme degradation is essential due to the potentially toxic effects of heme. An excess of heme can cause cellular damage from oxidative stress due to its production of reactive oxygen species. Thus, the HO system is an important defense mechanism against free heme-mediated oxidative stress.

Fig. 31-12.

Heme oxygenase 1 (HO-1) and carbon monoxide (CO) signaling. HO-1 is an enzyme involved in the degradation of heme. Its protective effects in settings of hepatic stress are mediated by the catalytic products of heme degradation: ferritin, bilirubin, and CO.

HO-1 has been shown to be induced in a variety of organs during diverse conditions such as hypoxia, endotoxemia, I/R, hyperthermia, and radiation exposure.¹⁷ HO-1 is involved in maintaining redox homeostasis during cellular stress. In the liver, HO-1 is thought normally to modulate hepatic microvasculature tone through its generation of CO and, like NO, its activation of guanylyl cyclase. This important role is demonstrated in animal models of portal hypertension in which inhibition of HO-1 exacerbates hypertension. Because HO-1 is induced as a protective mechanism in response to various stimuli, targeted induction of HO-1 has been studied as a therapeutic strategy for protection against inflammatory processes. HO-1 overexpression exerts hepatoprotective effects in models of I/R injury, hemorrhagic shock and resuscitation, acetaminophen-induced hepatonecrosis, and sepsis-mediated liver injury.¹⁷

Although HO-1 has been shown to provide protective effects in a variety of inflammatory states, the specific mechanisms by which HO-1 mediates its protective effects remains to be fully elucidated.¹⁷ Originally thought to be only potentially toxic waste, the by-products generated during heme catabolism now appear to play important roles in protecting against cellular stress. The well-known hazardous effects of high doses of CO are attributable to its ability to bind hemoglobin and myoglobin, which prevents the release of oxygen to tissues. However, only recently have the physiologic and beneficial roles of CO been identified. CO is produced in injured tissues via induction of HO-1 and contributes to the attenuation of proinflammatory processes. Similar to NO, CO plays an important role in maintaining the microcirculation through its activation of soluble guanylyl cyclase and subsequent elevation of intracellular cGMP. The signaling activities of cGMP lead to smooth muscle relaxation and inhibition and platelet aggregation. In addition, CO also has been shown to inhibit proinflammatory cytokines (TNF- α , IL-1) and chemokines while simultaneously inducing anti-inflammatory cytokines (IL-10). Exogenous low-dose CO has been shown to protect the liver from I/R injury and endotoxemia.

Biliverdin and bilirubin are other metabolites of heme that also are recognized as possible mediators of HO-1's protective function (see Fig. 31-12). The cytosolic enzyme biliverdin reductase catalyzes the reduction of biliverdin to bilirubin. Both biliverdin and bilirubin have important endogenous antioxidant properties. Free iron, the third by-product of heme oxidation, is known to be cytotoxic by catalyzing the production of hydroxyl radicals. However, HO-1 induction is associated with increased levels of ferritin, the free iron-sequestering protein. Thus, the increase in ferritin levels with the subsequent decrease in intracellular concentrations of free iron results in a net antioxidant

effect. Importantly, both bilirubin and ferritin have been shown to protect against liver injury in a variety of I/R models.¹⁷

In summary, HO-1 is upregulated and protective in multiple conditions of hepatic stress. Until recently, the degradation products of the HO system were thought to be only potentially toxic waste. It now appears that CO, biliverdin and bilirubin, and ferritin are important in the maintenance of cellular redox homeostasis and may play a role in the mechanism of hepatoprotection in disease. Studies involving induction of HO-1 expression and use of its metabolic products hold therapeutic promise for novel agents to protect against disorders of hepatic inflammation.

Toll-Like Receptors

The liver is a central regulator of the systemic immune response after acute insults to the body. Not only does it play a crucial role in modulating the systemic inflammatory response to infection or injury, it is also subject to injury and dysfunction from these same processes. Recent advances in the study of mechanisms for the activation of the innate immune system have pointed to the TLRs as a common pathway for immune recognition of microbial invasion and tissue injury.¹⁸ By recognizing either microbial products or endogenous molecules released from damaged sites, the TLR system is capable of alerting the host to danger by activating the innate immune system. Initially, this is manifested by the production of inflammatory mediators and the rapid uptake of invading microbes and their products. When excessive, this inflammatory response can contribute to organ damage and dysfunction.

To date, 13 TLRs have been described in mice and 10 in humans.¹⁸ TLRs are a family of proteins that are mammalian homologues to the *Drosophila* Toll, a protein that functions in development and immunity. The cytoplasmic portion of TLRs is similar to that of the IL-1 receptor (IL-1R) family and is called the *toll/IL-1 receptor (TIR) domain*. Unlike the IL-1R extracellular portion that consists of an immunoglobulin-like domain, the TLRs have leucine-rich repeats in their extracellular portion. The TLRs have many structural similarities, both extracellularly and intracellularly, but they differ from each other in ligand specificities and expression patterns, and show some variability in the signaling pathways they activate.

The TLRs were initially identified as components of the innate immune system that acted as a front-line defense mechanism against infections. Their recognition of patterns on pathogens, such as microbial peptides, LPS, lipoteichoic acids, bacterial DNA, and single-stranded RNA, resulted in the activation of an inflammatory response meant for controlling the invading organisms. In situations of noninfectious inflammation such as seen in trauma, clinicians have long recognized similar activation of the same inflammatory pathways and systemic manifestations. This observation, among others, led to the hypothesis that the immune system is designed to recognize any threats, whether from pathogens or tissue damage, that may lead to disruption of homeostasis. Under conditions of sterile inflammation, the activation of immune cells is through the release of endogenous danger molecules, normal cell constituents released by damaged or dying cells, or components of the extracellular matrix, released by the action of proteases at the site of tissue damage. Recent observations show that both microbial products and endogenous danger molecules can be recognized through the TLR system.

Perhaps more than any of the other TLR family members, TLR4 sits at the interface of microbial and sterile inflammation. Whereas the role of TLR4 in the recognition of LPS is well established, only recently has it become apparent that TLR4 also participates in the recognition of endogenous danger molecules¹⁸ (see Fig. 31-10). In vivo evidence for TLR4-mediated danger signaling comes from studies of acute tissue injury in hemorrhagic shock, trauma, and I/R models.¹⁹ In each case, TLR4-mutant animals exhibited reduced injury or inflammation compared with wild-type controls. In efforts to identify the ligands responsible for TLR4-dependent signaling in noninfectious insults, multiple molecules have been suggested. These include heat shock proteins, fibrinogen, hyaluronic acid, heparin sulfate, and high mobility group box 1 (HMGB1). Although a central role for TLR4 in recognizing tissue injury is building, studies are beginning to suggest that other TLR family members may also participate in the recognition of endogenous molecules released by tissue injury.¹⁹ The very recent realization that certain TLR family members also respond to endogenous molecules released from stressed or damaged tissues points to a molecular basis for a shared mechanism of innate immune activation by infection and injury.

RADIOLOGIC EVALUATION OF THE LIVER

Ultrasound

Abdominal ultrasound is a commonly applied imaging modality used to evaluate abdominal symptoms. Ultrasound technology is based on the pulse-echo principle. The ultrasound transducer converts electrical energy to high-frequency sound energy that is transmitted into tissue. Although some of the ultrasound waves are transmitted through the tissue, some are reflected back, and the ultrasound image is produced when the ultrasound receiver detects those reflected waves. This real-time gray scale (B-mode) imaging is augmented by Doppler flow imaging. Doppler ultrasound not only can detect the presence of blood vessels but also can determine the direction and velocity of blood flow. Ultrasonography is a useful initial imaging test of the liver because it is inexpensive, is widely available, involves no radiation exposure, and is well tolerated by patients. It is excellent for diagnosing biliary pathology and focal liver lesions. In addition, liver injury can be evaluated in trauma patients using the focused abdominal sonography for trauma examination. Limitations of ultrasound include incomplete imaging of the liver, most often at the dome or beneath ribs on the surface, and incomplete visualization of lesion boundaries. Moreover, obesity and overlying bowel gas also can interfere with image quality. Thus, ultrasonographically detected masses usually require further evaluation by other imaging modalities due to the lower sensitivity and specificity of ultrasound compared with CT and MRI.

The advent of contrast-enhanced ultrasound has improved the ability of this modality to differentiate among benign and malignant lesions. The injection of gas microbubble agents can increase the sensitivity and specificity of ultrasound in detecting and diagnosing liver lesions. Microbubbles are <10 μ m and, when given IV, allow for more effective echo enhancement. Contrast-enhanced ultrasound imaging of the liver improves delineation of liver lesions through identification of dynamic enhancement patterns and the vascular morphology of the lesion. In addition, some agents exhibit a late liver-specific phase in which the bubbles are taken up by cells in the reticuloendothelial system and accumulate in normal liver parenchyma after the vascular enhancement has faded.

The use of intraoperative ultrasound of the liver has rapidly expanded over the years with the increasing number and complexity of hepatic resections being performed.²⁰ It has the ability to provide the surgeon with real-time accurate information useful for surgical planning. Intraoperative ultrasound is considered the gold standard for detecting liver lesions, and studies have shown that it can identify 20 to 30% more lesions than other preoperative imaging modalities. Importantly, it has been shown to influence surgical management in almost 50% of planned liver resections for malignancies. Applications for intraoperative ultrasound of the liver include tumor staging, visualization of intrahepatic vascular structures (Fig. 31-13), and guidance of resection plane by assessment of the relationship of a mass to the vessels. In addition, biopsy of lesions and ablation of tumors can be guided by intraoperative ultrasound.

Intraoperative liver ultrasound images of the portal veins, hepatic veins, and inferior vena cava (IVC). *Upper panel* shows the portal vein bifurcation with echogenic Glissonian sheath. The confluence of the three hepatic veins [right hepatic vein (RHV), middle hepatic vein (MHV), and left hepatic vein (LHV)] and the IVC is shown in the *middle panel*. An accessory LHV is present in this patient. *Lower panel* is a color Doppler image showing flow.

Computed Tomography

Computed tomography (CT) produces a digitally processed cross-sectional image of the body from a large series of x-ray images. The introduction of helical (spiral) CT has tremendously improved the imaging capabilities of this technique compared to earlier conventional axial CT. This is especially true with regard to the liver. Helical CT scanners combine a continuous patient-table motion with continuous rotation of the CT gantry, which allows rapid acquisition of a volume of data within a single breath hold. This increased scan speed eliminates artifacts due to variations in inspiration and facilitates optimal contrast delivery.

Contrast medium is routinely used in CT evaluation of the liver because of the similar densities of most pathologic liver masses and normal hepatic parenchyma. A CT scan with a dual- or triple-phase bolus of IV contrast agent is performed to achieve the greatest enhancement of contrast between normal and pathologic tissues.²¹ Ideally, contrast media should be selectively delivered to either the tumor or the liver, but not both. Radiologists use the dual blood supply of the liver and the hemodynamics of hepatic tumors to achieve this goal. The liver is unique in that it has a dual blood supply. The portal vein supplies approximately 75% of the blood flow and the hepatic artery the remaining 25%. However, many liver tumors receive the majority of their blood supply from the hepatic artery. After injection of the contrast agent, the rapid scan time of helical CT allows for CT sections through the liver in both the arterial dominant phase (20 to 30 seconds after the beginning of contrast delivery) and venous or portal dominant phase (60 to 70 seconds after contrast injection) (Fig. 31-14). Thus, many hepatic tumors that derive the majority of their blood supply from the hepatic artery as well as other hypervascular lesions are well delineated in the arterial phase. On the other hand, the portal phase provides optimal enhancement of the normal liver parenchyma because the majority of its blood supply is derived from the portal vein. This allows for detection of hypovascular lesions because they will appear hypoattenuated in relation to the brighter normal liver parenchyma.²¹

Computed tomographic (CT) images of hepatic veins and Couinaud's liver segments. The images show the three hepatic veins and inferior vena cava (IVC) (*upper panel*), as well as Couinaud's liver segments (*lower panels*). LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a technique that produces images based on magnetic fields and radio waves. The MRI scanner creates a powerful magnetic field that aligns the hydrogen atoms in the body, and radio waves are used to alter the alignment of this magnetization. Different tissues absorb and release radio wave energy at different rates, and this information is used to construct an image of the body. Most tissues can be differentiated by differences in their characteristic T1 and T2 relaxation times. T1 is a measure of how quickly a tissue can become magnetized, and T2 measures how quickly it loses its magnetization. As with CT technology, advances in MRI now provide the opportunity to perform single-breath T1-weighted imaging and respiration-triggered T2-weighted imaging. The development of breath-hold imaging techniques has eliminated many of the motion artifacts that previously limited the sensitivity and application of MRI for imaging of the liver. As with the iodinated contrast media use in CT scanning, multiple contrast agents have been developed for MRI to increase the difference in signal intensity between normal liver and pathologic lesion. Gadopentetate dimeglumine (salt of the gadolinium complex of diethylenetriamine pentaacetic acid) is an MRI contrast agent that behaves in a manner very similar to iodine in CT. Liver-specific MRI contrast agents also have been developed that rely on excretion by Kupffer cells (ferumoxides) or secretion in bile by hepatocytes (iminodiacetic acid-derivative radionuclides) to further improve the sensitivity and specificity of MRI.²²

Positron Emission Tomography

Positron emission tomography (PET) is a nuclear medicine test that produces images of metabolic activity in tissues by detecting gamma rays emitted by a radioisotope incorporated into a metabolically active molecule. Fluorodeoxyglucose is the most common metabolic molecule used in PET imaging. Although traditional imaging such as CT, ultrasound, and MRI provide anatomic information, PET offers functional imaging of tissues with high metabolic activity, including most types of metastatic tumors. PET has emerged as another modality useful for detection of recurrent colorectal cancers. More than 20% of patients with colorectal cancer initially present with hepatic

metastasis, and a large percentage of patients undergoing resection for their primary colorectal cancer eventually experience disease recurrence in the liver. Although hepatic resection of colorectal metastases provides survival rates nearing 50%, the presence of extrahepatic disease is a poor prognosticator and usually precludes aggressive surgical intervention. Thus, accurate information regarding the extent of the disease is necessary for management of patients with colorectal metastases. PET imaging is increasingly used as a tool in the diagnostic work-up of a patient with potentially resectable hepatic disease. In nonrandomized trials, PET demonstrated better sensitivity and specificity than CT scanning for both hepatic disease and extrahepatic disease.²³ Importantly, the information provided by PET resulted in changes to clinical management in up to 25% of cases. However, a disadvantage of images obtained from PET is the lack of exact localization of lesions due to poor resolution. For this reason, integrated PET and CT are increasingly available to potentially improve diagnostic accuracy over standard PET or CT alone. Although the benefit of a synergistic combination of PET and CT has yet to be fully established, this combined modality is rapidly becoming a valuable tool with its increasing availability and use for detection of recurrent colorectal cancer (Fig. 31-15).²³

Computed tomography–positron emission tomography (CT-PET) scans before and after resection of liver metastasis from colorectal cancer in a 54-year-old patient. CT scan shows large 10-cm right lobe liver metastasis (*left panel*), and PET scan findings are strongly positive (*middle panel*). Two years after right hepatectomy, the patient has no evidence of recurrence and significant hypertrophy of the left lobe (*right panel*).

ACUTE LIVER FAILURE

Acute liver failure (ALF) occurs when the rate and extent of hepatocyte death exceeds the liver's regenerative capabilities. It was initially described as a specific disease entity in the 1950s. It also has been referred to as *fulminant hepatic failure*. ALF is a rare disorder affecting approximately 2000 patients annually in the United States. ALF has devastating consequences and is defined by the presence of hepatic encephalopathy occurring as the consequence of severe liver damage in a patient without a history of previous liver disease or portal hypertension.²⁴ The manifestations of ALF may include cerebral edema, hemodynamic instability, increased susceptibility to bacterial and fungal infections, renal failure, coagulopathy, and metabolic disturbances. Even with current medical care, ALF can progress rapidly to hepatic coma and death. The most common cause of death is intracranial hypertension due to cerebral edema, followed by sepsis and multisystem organ failure. The causes of ALF, which are the most important variables in determining outcome, are numerous and can include viral infection as well as drug overdose, reaction, and toxicity. It has been determined that the etiologic factor leading to ALF varies according to geographic location.²⁵ Before the introduction of orthotopic liver transplantation (OLT), the chance for survival was <20%. Currently, most series report survival rates of >65% for affected patients.^{25,26}

Etiology

Differences in etiology, management, and patient outcomes have been described for various regions of the globe. In the East and developing portions of the world, the most common causes of ALF are viral infections, primarily hepatitis B, A, and E.²⁴ In these areas there are a relatively small number of drug-induced cases. In contrast, 65% of cases of ALF in the West are thought to be due to drugs and toxins, with acetaminophen (paracetamol) being the most common etiologic agent in the United States, Australia, United Kingdom, and most of Europe. It is interesting that in France and Spain, where acetaminophen sales are restricted, the rate of acetaminophen-induced

ALF is quite low. Acetaminophen-induced ALF is also uncommon in South America. The U.S. Acute Liver Failure Study Group identified several other causes of ALF, including autoimmune hepatitis, hypoperfusion of the liver (in cardiomyopathy or cardiogenic shock), pregnancy-related conditions, and Wilson's disease.²⁸ Even with exhaustive efforts to identify a cause, approximately 20% of all cases of ALF remain indeterminate in origin.

Clinical Presentation

In a multicenter study involving 17 tertiary care centers and 308 patients in the United States, 73% of all patients with ALF were female, with a median age of 38 years.²⁶ The most common ethnic group affected was whites (74%), followed by Hispanics (9%) and African Americans (3%). Patients were ill for a median of 6 days before the onset of encephalopathy and had a median of 2 days between the onset of jaundice and the development of encephalopathy. Hepatic coma grade at presentation was approximately equally distributed across grades I to IV. Eighty-four percent of the patients in the study were referred from outside hospitals, 40% had a serum creatinine level exceeding 2.0 mg/dL, and 14% had an arterial pH of <7.30. In addition, 44% of the patients acquired a culture-proven infection.

Diagnosis and Clinical Management

When the medical history is obtained, it is important to address the possibility of exposure to viral infections, medications, and other possible toxins. The possibility of previous liver disease needs to be explored. The physical examination must assess and document the patient's mental status as well as attempt to identify findings of chronic liver disease. The initial laboratory examination must evaluate the severity of the ALF as well as attempt to identify the cause (Table 31-1). A liver biopsy should be performed if certain disease entities such as autoimmune hepatitis or lymphoma are a possibility. Because of the associated coagulopathy, if a liver biopsy is needed, it is usually safest to obtain the tissue via a transjugular approach. Patients with ALF should be admitted to the hospital and monitored frequently. Due to the rapidity with which this disease process may progress, a liver transplant center should be contacted and the affected patient transferred to the center early in the evaluation period.

Table 31-1 Acute Liver Failure Laboratory Evaluation

ABO typing
Acute hepatitis panel
Autoimmune marker levels
Ceruloplasmin level
Toxicology screening
Acetaminophen level
HIV screening
Pregnancy test (females)

If acetaminophen overdose is suspected to have occurred within a few hours of presentation, administration of activated charcoal may be useful to reduce the volume of acetaminophen present in the GI tract. *N*-acetylcysteine (NAC), the clinically effective antidote for acetaminophen overdose, should be administered as early as possible to any patient with suspected acetaminophen-associated ALF.²⁹ NAC also should be administered to patients with ALF of unclear etiology, because glutathione stabilization may be beneficial in this patient

population as well. NAC can be administered either orally (140 mg/kg initial dose, followed by 70 mg/kg every 4 hours x 17 doses) or via the intravenous route (loading dose of 150 mg/kg, followed by a maintenance dose of 50 mg/kg). For patients who are suspected of having drug-induced hepatotoxicity, it is important to obtain details regarding all prescription and nonprescription drugs, herbs, and dietary supplements that may have been taken in the previous year. Most instances of drug-induced hepatotoxicity occur in the first 6 months after drug initiation. Any suspected offending agent must be discontinued and an attempt should be made to administer only essential medications.

The majority of patients with ALF need to be monitored in the intensive care unit (ICU) setting, and specific attention needs to be given to fluid management, ulcer prophylaxis, hemodynamic monitoring, electrolyte management, and surveillance for and treatment of infection. Surveillance cultures should be performed to identify bacterial and fungal infections as early as possible. Serum phosphorus levels need to be monitored. Hypophosphatemia, which may indicate a higher likelihood of spontaneous recovery, needs to be corrected via IV administration of phosphorus. Sedation should be avoided, and the head of the bed should be elevated at least 30 degrees. Neurologic examinations should be performed frequently. Intracranial pressure monitoring is reserved for patients in whom a neurologic examination is no longer reliable. CT scans of the head should be performed only to rule out mass lesion or hemorrhage, because they provide limited information regarding increased intracranial pressure. The administration of blood products for thrombocytopenia and prolonged prothrombin time is recommended only in the setting of hemorrhage or before invasive procedures. Acute renal failure is a frequent complication in patients with ALF, and efforts should be made to protect renal function by maintaining sufficient perfusion and avoiding nephrotoxic medications. Should renal replacement therapy become necessary, continuous venovenous hemodialysis should be used rather than intermittent hemodialysis, because continuous venovenous hemodialysis provides better hemodynamic and intracranial stability. The most severely affected patients have a poor prognosis with medical management alone and require liver transplantation. To identify these patients early in the clinical course is important both to maximize the time available to obtain a donor liver allograft for those in need and to avoid transplant in those who will recover without it.

Prognosis

Accurate identification of those ALF patient who will recover spontaneously is important because of the severe shortage of donor liver allografts and the potential complications of lifelong nonspecific immunosuppression. The most widely applied prognostic scoring system is the King's College Hospital ALF criteria.²⁹ This scoring system has separate criteria predicting a poor medical management outcome for acetaminophen-related and non-acetaminophen-related forms of ALF (Table 31-2). Additional prognostic information may be gained from the Acute Physiology and Chronic Health Evaluation II (APACHE II) scores as well as the actin-free Gc-globulin serum concentration. Overall, prognostic scoring systems have proven to have acceptable specificity but low sensitivity in determining patient outcome and therefore should not replace the judgment of an experienced clinician.

Table 31-2 King's College Selection Criteria for Liver Transplantation in Acute Liver Failure	
Cause	Selection Criteria
Acetaminophen	Arterial pH <7.30 irrespective of hepatic coma grade
	<i>Or</i>
	Prothrombin time >100 s + serum creatinine level >3.4 mg/dL + grade III or IV hepatic coma
Not acetaminophen	Prothrombin time >100 s irrespective of hepatic coma grade
	<i>Or</i>
	Any three of the following, irrespective of hepatic coma grade:
	Cryptogenic or drug-induced hepatitis
	Jaundice to coma interval >7 d
	Prothrombin time >50 s
	Serum bilirubin level >17.5 mg/dL
	Age <10 y or >40 y

Liver Transplantation

Despite advances in medical management, OLT remains the only definitive therapy for patients unable to regenerate sufficient hepatocyte mass in a timely manner. The advent of OLT has coincided with a rise in overall ALF survival rates from approximately 20% in the pretransplantation era to >65% at the present time. One-year posttransplantation survival for patients with ALF has been reported to be as high as 80 to 90%.²⁵ Although these improvements in survival rates are impressive, it must be noted that 10% of patients still die while awaiting OLT, which confirms that the potential for improved patient outcome still has not been realized because of the ongoing liver allograft shortage.

Extracorporeal Liver Support

As mentioned earlier, patient survival could be improved if additional time could be gained for the patient while awaiting liver replacement or hepatocyte regeneration. The development of a support device to replace the acutely failing liver has been a highly sought after (and elusive) goal. Several systems have been tested without definitive evidence of efficacy. Transient improvement in hepatic encephalopathy has been observed in several trials, but improvement in hepatocyte function and long-term benefit have not been realized with or without OLT. Liver support trials are difficult to perform due to access to liver replacement, the rarity of affected patients, and the heterogeneous causes and varying levels of disease severity. Therefore, additional data are necessary, and liver support systems should be used only as part of an approved clinical trial.

CIRRHOSIS AND PORTAL HYPERTENSION

Cirrhosis

Cirrhosis, the final sequela of chronic hepatic insult, is characterized by the presence of fibrous septa throughout the liver subdividing the parenchyma into hepatocellular nodules (Fig. 31-16).³⁰ Cirrhosis is the consequence of sustained wound healing in response to chronic liver injury. The etiology of liver injury includes viral, autoimmune, drug-induced, cholestatic, and metabolic diseases. The clinical manifestations of cirrhosis vary from no symptoms to liver failure. Approximately 40% of cirrhotic patients are asymptomatic, but progressive deterioration leading to the need for OLT or death is typical after the development of end-stage liver disease (ESLD). The complications of ESLD include progressive hyperbilirubinemia, malnutrition, decreased synthetic function of the liver, portal hypertension (i.e., ascites and varix-related GI bleeding), hepatic encephalopathy, and life-limiting fatigue. ESLD carries a 5-year mortality of 50%, with 70% of deaths due to liver failure.³¹ In the United States, cirrhosis accounts for 30,000 deaths per year and is the most common non-neoplastic cause of death among patients with hepatobiliary and digestive diseases. An additional 10,000 to 12,000 deaths occur annually due to hepatocellular carcinoma (HCC), the most rapidly increasing neoplasm in the United States.³¹

Histology of cirrhotic liver with regenerating macronodules. *Upper panel:* Grossly cirrhotic liver. *Lower panel:* Regenerative nodules and bridging fibrosis representative of cirrhosis seen on standard light microscopy (hematoxylin and eosin stain).

An understanding of the fibrous septa that cause cirrhosis is essential, because fibrosis is felt to be the disease process leading to cirrhosis. Hepatic fibrosis is the accumulation of extracellular matrix or scar tissue in response to acute or chronic liver injury. It is postulated that the stellate cell is activated by hepatic necrosis; the production of cytokines, including IL-1, IL-6, and TNF- α ; and the growth factors transforming growth factor beta1 and epidermal growth factor. Activation of the stellate cell is associated with pathologic matrix degeneration due to increased production of membrane-type matrix metalloproteinase-1, matrix metalloproteinase-2, and tissue inhibitors of metalloproteinases. The activated stellate cells undergo phenotypic changes, including proliferation, contraction, chemotaxis, retinoid loss, and proinflammatory responses that lead to the accumulation of extracellular matrix and cirrhosis. Activated stellate cells impede portal vein blood flow and increase portal resistance by constricting individual sinusoids and by contracting the cirrhotic liver. Endothelin-1, arginine vasopressin, adrenomedullin, and eicosanoids are all mediators of stellate cell contraction and appear to play a significant role in portal hypertension, as does a diminished production of NO by the endothelial cell.³²

CLASSIFICATION OF CIRRHOSIS

Morphologically, cirrhosis can be described as micronodular, macronodular, or mixed. Micronodular cirrhosis is characterized by thick regular septa, small uniform regenerative nodules, and involvement of virtually every hepatic lobule. Macronodular cirrhosis frequently has septa and regenerative nodules of varying sizes. The regenerative nodules consist of irregularly sized hepatocytes with large nuclei and cell plates of varying thickness. Mixed cirrhosis is present when regeneration is occurring in a micronodular liver and over time converts to a macronodular pattern. This morphologic categorization is limited, and cirrhosis is a dynamic process in which nodule size varies over time. The three patterns correlate poorly with etiology, and the same pattern can result from a variety of disease processes. Conversely, a single disease process can demonstrate several morphologic patterns. Irrespective of etiology and morphologic pattern, the cirrhotic liver frequently demonstrates right hepatic lobe atrophy, caudate lobe and left lateral segment hypertrophy, recanalization of the umbilical vein, a nodular surface contour, dilatation of the portal vein, gastroesophageal varices, and splenomegaly on radiographic evaluation.

ETIOLOGY AND CLINICAL MANIFESTATIONS OF CIRRHOSIS

Cirrhosis can result from a wide range of disease processes (Table 31-3). Regardless of cause, cirrhosis leads to two consequences: hepatocellular failure and portal hypertension. Patients are then evaluated to determine if the cirrhosis is "compensated" (lacking manifestations of ESLD) or "decompensated" (with evidence of ESLD and certain clinicopathologic associations). Medical history and physical examination findings of cirrhosis are outlined (Table 31-4). Fat stores and muscle mass are reduced, and resting energy expenditure is increased. Muscle cramps occur frequently in the cirrhotic patient and are felt to correlate with ascites, low mean arterial pressure, and plasma renin activity. Cramps usually respond to administration of quinine sulfate and human albumin. Abdominal hernias are common with ascites and should be electively repaired only in patients with well-compensated cirrhosis; otherwise the hernia should be repaired at the time of or after the patient's OLT. HCC can occur in all forms of cirrhosis, and every cirrhotic patient should undergo screening for the development of HCC every 6 months via cross-sectional imaging and measurement of serum alpha-fetoprotein (AFP) level. It must be kept in mind that only 60 to 75% of HCCs produce AFP; therefore, a normal serum AFP level does not rule out HCC. Cirrhosis is associated with increased cardiac output and heart rate as well as decreased systemic vascular resistance and blood pressure. Cirrhotic patients are more prone to infections due to impaired phagocytic activity of the reticuloendothelial system. Bacterial infections, often of intestinal origin, are common and must be suspected in a patient with unexplained pyrexia or clinical deterioration. Spontaneous bacterial peritonitis also is seen in cases of cirrhosis with ascites. Intrinsic drug metabolism is reduced in the cirrhotic liver, and this fact needs to be recognized when prescribing medications.

Table 31-3 Etiology of Cirrhosis
Viral hepatitis (hepatitis B, C, and D)
Cryptogenic
Alcohol abuse
Metabolic abnormalities
Iron overload (hemochromatosis)
Copper overload (Wilson's disease)
Alpha1-antitrypsin deficiency
Glycogen storage disease (types IA, III, and IV)
Tyrosinemia
Galactosemia
Cholestatic liver disease
Hepatic vein outflow abnormalities
Budd-Chiari syndrome
Cardiac failure
Autoimmune hepatitis
Toxins and drugs

Table 31-4 Clinical History and Physical Examination Findings Associated with Cirrhosis
History
Life-limiting fatigue or weight loss
Jaundice (icterus; skin, urine, and stool color)
Anorexia and cachexia
Abdominal pain
Peripheral edema
Ascites
GI bleeding, hemorrhoids

Loss of libido
Loss of menstrual cycle
Hepatic encephalopathy
Physical examination
Malnutrition
Fetor hepaticus
Jaundiced skin, icteric sclera
Spider angiomata
Finger clubbing, white nail beds, palmar erythema, Dupuytren's contracture
Gynecomastia, testicular atrophy
Hyperdynamic cardiovascular status
Parotid enlargement
Ascites, pleural effusion
Abdominal hernia
Caput medusa
Abnormal liver size
Splenomegaly
Temporal muscle wasting
Asterixis

LABORATORY FINDINGS ASSOCIATED WITH CIRRHOSIS

Laboratory findings vary in the cirrhotic patient depending on the degree of compensation; however, in general a number of trends are seen. The cirrhotic patient usually has a mild normocytic normochromic anemia. The white blood cell and platelet counts are reduced, and the bone marrow is macronormoblastic. The prothrombin time is prolonged and does not respond to vitamin K therapy, and the serum albumin level is depressed. Urobilinogen is present and urinary sodium excretion is diminished in the presence of ascites. The serum levels of bilirubin, transaminases, and alkaline phosphatase may all be elevated. However, normal liver function test results do not eliminate the possibility of cirrhosis.

LIVER BIOPSY

Cirrhosis is identified by histopathologic examination of the liver; however, the diagnosis can be made in many cases from a constellation of clinical features, laboratory values, and radiographic findings. Liver biopsy, usually performed via a percutaneous approach, may be useful in determining the cause of the disease, disease activity, and disease progress. If there are contraindications to percutaneous liver biopsy, such as ascites or a coagulation defect, the transjugular approach should be used. If needed, ultrasound or CT guidance can be helpful in obtaining an adequate sample and avoiding other viscera.

Hepatic Reserve and Assessment of Surgical Risk in the Cirrhotic Patient

Assessing the hepatic reserve of the cirrhotic patient is important, because cirrhosis and portal hypertension can have a negative impact on the outcome of nontransplant surgical procedures. A number of laboratory tests have been used to assess hepatic reserve in patients with cirrhosis. Tests of indocyanine green, sorbitol, and galactose elimination capacity as well as the carbon 13 galactose breath test and carbon 13 aminopyrine breath test have all been disappointing clinically due to their dependence on flow to the liver as well as the unavailability and complexity of the tests. The monoethylglycinexylidide (MEGX) test, which measures MEGX formation after the administration of lidocaine, depends on the hepatic cytochrome P-450 3A4 isoenzyme and although approximately 80% sensitive and specific in determining cirrhosis, loses both sensitivity and specificity as the serum bilirubin level rises secondary to interference with the fluorescent readout system.

Child-Turcotte-Pugh Score

The Child-Turcotte-Pugh (CTP) score was originally developed to evaluate the risk of portocaval shunt procedures secondary to portal hypertension and subsequently has been shown to be useful in predicting surgical risks of other intra-abdominal operations performed on cirrhotic patients (Table 31-5). Numerous studies have demonstrated overall surgical mortality rates of 10% for patients with class A cirrhosis, 30% for those with class B cirrhosis, and 75 to 80% for those with class C cirrhosis.³³ The CTP score is derived from five variables as shown in Table 31-5. The problems with the CTP score are the presence of subjective variables (encephalopathy and ascites), its narrow range (5 to 15 points), and the equal weighting given to each variable.

Table 31-5 Child-Turcotte-Pugh (CTP) Score			
Variable	1 Point	2 Points	3 Points
Bilirubin level	<2 mg/dL	2–3 mg/dL	>3 mg/dL
Albumin level	>3.5 g/dL	2.8–3.5 g/dL	<2.8 g/dL
International normalized ratio	<1.7	1.7–2.2	>2.2
Encephalopathy	None	Controlled	Uncontrolled
Ascites	None	Controlled	Uncontrolled
Child-Turcotte-Pugh class			
Class A = 5–6 points			
Class B = 7–9 points			
Class C = 10–15 points			

Model for End-Stage Liver Disease Scoring System

The Model for End-Stage Liver Disease (MELD) is a linear regression model based on objective laboratory values (INR, bilirubin level, and creatinine level). It was originally developed as a tool to predict mortality after transjugular intrahepatic portosystemic shunt (TIPS) but has been validated and has been used as the sole method of liver transplant allocation in the United States since 2002. The MELD formula is as follows:

where SCr is serum creatinine level (in milligrams per deciliter) and Tbil is serum bilirubin level (in milligrams per deciliter).

A number of recent studies have examined the relative values of MELD and CTP scores in predicting postoperative mortality in cirrhotic patients undergoing nontransplant surgical procedures. Northup and colleagues demonstrated that MELD score was the only statistically significant predictor of 30-day mortality.³⁴ In this study, mortality increased by approximately 1% for each MELD point up to a score of 20 and by 2% for each MELD point above 20. It also has been demonstrated that cirrhotic patients who undergo emergent surgery or major surgical procedures have a greater risk of mortality.³⁵ In these studies, the relative risk of mortality increased by 14% for each 1-point increase in MELD score. The American Society of Anesthesiologists scoring system also has been shown to be useful in predicting 7-day mortality rates after surgery in cirrhotic patients.

Portal Hypertension

The portal venous system contributes approximately 75% of the blood and 72% of the oxygen supplied to the liver. The portal vein is formed by the confluence of the superior mesenteric vein and the splenic vein. In the average adult 1000 to 1500 mL/min of portal venous blood is supplied to the liver. However, this amount can be significantly increased in the cirrhotic patient. The portal venous system is without valves and drains blood from the spleen, pancreas, gallbladder, and abdominal portion of the alimentary tract into the liver. Tributaries of the portal vein communicate with veins draining directly into the systemic circulation. These communications occur at the gastroesophageal junction, anal canal, falciform ligament, splenic venous bed and left renal vein, and retroperitoneum (Fig. 31-17). The normal portal venous pressure is 5 to 10 mmHg, and at this pressure very little blood is shunted from the portal venous system into the systemic circulation. As portal venous pressure increases, however, the communications with the systemic circulation dilate, and a large amount of blood may be shunted around the liver and into the systemic circulation. NO is believed to be an important mediator of this venous dilatation.

IMAGING OF THE PORTAL VENOUS SYSTEM AND MEASUREMENT OF PORTAL VENOUS PRESSURE

The patency of the portal vein and the nature of the collateral circulation should be established. An understanding of portal vein patency and anatomy is crucial before undertaking portosystemic shunts, hepatic resection, or hepatic transplantation. The simplest initial investigation is abdominal ultrasonography. A large portal vein suggests portal hypertension but is not diagnostic. Doppler ultrasound is capable of outlining the anatomy of the portal vein, ruling out thrombosis, and indicating portal venous flow direction. Doppler ultrasound also is useful in evaluating surgical shunt and TIPS flow. Abdominal CT arteriography and magnetic resonance angiography both are capable of revealing portal vein anatomy as well as patency. Visceral angiography and portal venography are reserved for cases that cannot be evaluated satisfactorily by noninvasive methods and require further clarification of portal patency or anatomy.

The most accurate method of determining portal hypertension is hepatic venography. The most commonly used procedure involves placing a balloon catheter directly into the hepatic vein and measuring the free hepatic venous pressure (FHVP) with the balloon deflated and the wedged hepatic venous pressure (WHVP) with the balloon inflated to occlude the hepatic vein. The hepatic venous pressure gradient (HVPG) is then calculated by subtracting the free from the wedged venous pressure ($HVPG = WHVP - FHVP$). The HVPG represents the pressure in the hepatic sinusoids and portal vein and is a measure of portal venous pressure.

DEFINITION OF PORTAL HYPERTENSION

A WHVP or direct portal venous pressure that is >5 mmHg greater than the inferior vena cava (IVC) pressure, a splenic pressure of >15 mmHg, or a portal venous pressure measured at surgery of >20 mmHg is abnormal and indicates portal hypertension.³⁶ A portal pressure of >12 mmHg is necessary for varices to form and subsequently bleed.

ETIOLOGY AND CLINICAL FEATURES OF PORTAL HYPERTENSION

The causes of portal hypertension can be divided into three major groups: presinusoidal, sinusoidal, and postsinusoidal.³⁶ Although multiple disease processes can result in portal hypertension (Table 31-6), in the United States the most common cause of portal hypertension is usually an intrahepatic one, namely, cirrhosis. The most significant clinical finding associated with portal hypertension is the development of gastroesophageal varices. The major blood supply to gastroesophageal varices is the anterior branch of the left gastric or coronary vein. Portal hypertension also results in splenomegaly with enlarged, tortuous, and even aneurysmal splenic vessels. Splenomegaly frequently is associated with hypersplenism, causing leukopenia, thrombocytopenia, and anemia. The umbilical vein may recannulate and dilate, which leads to visible collaterals on the abdominal wall. If flow in the umbilical vein becomes great enough, a caput medusa will form and there may be an audible venous hum (Cruveilhier-Baumgarten murmur). Large spontaneous venous shunts may form between the portal venous system and the left renal vein. These shunts, however, are ineffective in reducing portal venous pressure and preventing upper GI bleeding from esophageal varices. Ascites occurs when portal hypertension is particularly high and when hepatic dysfunction is present. Anorectal varices are present in approximately 45% of cirrhotic patients, and incidence is increased in patients with bleeding from esophageal varices. Anorectal varices must be distinguished from hemorrhoids, which do not communicate with the portal system and are not present at increased incidence in patients with portal hypertension.

Constrictive pericarditis

Portal hypertension is the consequence of both increased portal vascular resistance and increased portal flow. Increased portal resistance may be due to the abnormal architecture and nodularity of cirrhosis or an obstructed portal vein. Myofibroblasts, Ito cells, and sinusoidal endothelium all play a role in portal venous contraction. As portal venous collaterals develop, diverting blood into the systemic circulation, portal hypertension is maintained by increasing portal flow and splanchnic vasodilatation. This leads to a hyperdynamic portal venous circulation that seems to be related to the severity of the liver failure. Cardiac output increases, and there is a generalized vasodilation. Arterial blood pressure is normal to mildly depressed with a low systemic vascular resistance. The factors maintaining the hyperdynamic circulation are complex and only partially understood. There appears to be a complex interaction between vasodilators and vasoconstrictors that might be formed or fail to be inactivated by the hepatocyte or may be of gut origin. NO, endothelin-1, prostacyclin, and glucagon are all postulated to play a role in the hyperdynamic splanchnic circulation.

MANAGEMENT OF ESOPHAGEAL VARICES

The most significant manifestation of portal hypertension and the leading cause of morbidity and mortality associated with portal hypertension is variceal bleeding. Approximately 30% of patients with compensated cirrhosis and 60% of patients with decompensated cirrhosis have esophageal varices. One third of all patients with varices experience variceal bleeding. Each episode of bleeding is associated with a 20 to 30% risk of mortality. Seventy percent of patients who survive the initial bleed will experience recurrent variceal hemorrhage within 1 year if left untreated.

Prevention of Variceal Bleeding

Current measures aimed at preventing variceal bleeding include improvement of liver function (i.e., abstention from alcohol), avoidance of aspirin and NSAIDs, and administration of propranolol or nadolol, both of which are nonselective beta blockers. Meta-analyses have demonstrated that beta blockade reduces the index variceal bleed by approximately 45% and reduces bleeding mortality by 50%.³⁷ Approximately 20% of patients do not respond to beta blockade and another 20% cannot tolerate beta blockade due to medication side effects. It has recently been demonstrated that prophylactic endoscopic variceal ligation (EVL) is associated with a lower incidence of first variceal bleed.³⁸ EVL is recommended for patients with medium to large varices, performed every 1 to 2 weeks until obliteration, followed by esophagogastroduodenoscopy (EGD) 1 to 3 months later and surveillance EGD every 6 months to monitor for recurrence of varices.

Management of Acute Variceal Bleeding

Patients with acute variceal hemorrhage should be admitted to an ICU for resuscitation and management. Blood resuscitation should be performed carefully to a hemoglobin level of approximately 8 g/dL. Overreplacment of packed red blood cells and the overzealous administration of saline can lead to both rebleeding and increased mortality. Administration of fresh-frozen plasma and platelets can be considered in patients with severe coagulopathy. Use of recombinant factor VIIa has not been shown to be more beneficial than standard therapy and therefore is not recommended at this time. Cirrhotic patients with variceal bleeding have a high risk of developing bacterial infections, which are associated with rebleeding and a higher mortality rate. The use of short-term prophylactic antibiotics has been shown

both to decrease the rate of bacterial infections and to increase survival. Therefore, their use is recommended, and ceftriaxone 1 g/day IV is often given. Pharmacologic therapy for the variceal hemorrhage can be initiated as soon as the diagnosis of variceal bleeding is made. Vasopressin, administered IV at a dose of 0.2 to 0.8 units/min, is the most potent vasoconstrictor. However, its use is limited by its large number of side effects, and it should be administered for only a short period of time at high doses to prevent ischemic complications. Somatostatin and its analogue octreotide (initial bolus of 50 µg IV followed by continuous infusion of 50 µg/h) also cause splanchnic vasoconstriction. Octreotide has the advantage that it can be administered for 5 days or longer, and it is currently the preferred pharmacologic agent for initial management of acute variceal bleeding. In addition to pharmacologic therapy EGD should be carried out as soon as possible and EVL should be performed. This combination of pharmacologic and EVL therapy has been shown both to improve the initial control of bleeding and to increase the 5-day hemostasis rate.³⁸

Even when aggressive pharmacologic and endoscopic therapies are initiated and these treatment options are maximized, 10 to 20% of patients with variceal bleeding will continue to bleed. Shunt therapy, with either surgical shunts or TIPS, has been shown to control refractory variceal bleeding in >90% of treated individuals. Shunt surgery usually is considered only in patients with preserved hepatic function (i.e., CTP class A); TIPS is used in patients with decompensated liver disease (i.e., CTP class B or C). However, the use of these treatment options is dependent on local expertise.

Balloon tamponade using a Sengstaken-Blakemore tube will control refractory variceal bleeding in >80% of patients. However, its application is limited due to the potential for complications, which include aspiration and esophageal perforation. Therefore, use of a Sengstaken-Blakemore tube should be limited to short-term therapy (<24 hours) in those patients awaiting definitive care.

MANAGEMENT OF GASTRIC VARICES

Gastric varices that occur along the lesser curvature of the stomach should be considered an extension of the patient's esophageal varices and treated in a manner similar to esophageal varices. Gastric varices along the greater curvature, however, require the evaluation of the splenic vein to assure patency. In the presence of cirrhosis and a patent splenic vein, greater curvature gastric varices can be managed with gastric variceal obturation using N-butyl-cyanoacrylate if available. If gastric variceal obturation is unavailable or if endoscopic therapy fails, the patient should be considered for TIPS, which will control variceal bleeding in >90% of cases.

SURGICAL SHUNT

The need for surgical shunts has been reduced since the introduction of the TIPS procedure and hepatic transplantation. At this time the recommendation is that surgical shunts be considered only in patients who have MELD scores of <15, who are not candidates for hepatic transplantation, or who have limited access to TIPS therapy and the necessary follow-up. The aim of the surgical shunt is to reduce portal venous pressure, maintain total hepatic and portal blood flow, and avoid a high incidence of complicating hepatic encephalopathy. Patient survival is determined by hepatic reserve. The portacaval shunt, as first described by Eck in 1877, either joins the portal vein to the IVC in an end-to-side fashion and completely disrupts portal vein flow to the liver, or joins it in a side-to-side fashion and thereby maintains partial portal venous flow to the liver. Currently this shunt is rarely performed due to the high incidence of hepatic encephalopathy and decreased liver function resulting from the reduction of portal perfusion. The Eck fistula also makes subsequent hepatic transplantation much more technically difficult. The mesocaval shunt uses a Dacron graft of 8 to 10 mm in diameter and connects the superior mesenteric vein to the IVC. This procedure is technically easier and does not adversely affect subsequent hepatic transplantation. The shortcomings of this shunt include a higher incidence of shunt thrombosis and rebleeding. The surgical shunt currently used most often is the distal splenorenal or Warren shunt (Fig. 31-18). This shunt is technically the most difficult to perform. It requires division of the gastroesophageal collaterals and allows venous drainage of the stomach and lower esophagus through the short gastrosplenic veins into the spleen, and ultimately decompresses the left upper quadrant by allowing the splenic vein to drain directly into the left renal vein via an end-to-side splenic to left renal vein anastomosis. This shunt has the advantages of being associated with a lower rate of hepatic encephalopathy and decompensation, and not interfering with subsequent hepatic transplantation.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The TIPS procedure involves implantation of a metallic stent between an intrahepatic branch of the portal vein and a hepatic vein radicle. The needle track is dilated until a portal pressure gradient of ≥ 12 mmHg is achieved. TIPS can be performed in 95% of patients by an experienced interventional radiologist, can control variceal bleeding in >90% of cases refractory to medical treatment, and should not affect subsequent hepatic transplantation. Possible complications include bleeding either intra-abdominally or via the biliary tree, infections, renal failure, decreased hepatic function, and hepatic encephalopathy, which occur in 25 to 30% of patients undergoing the TIPS procedure. After the TIPS procedure the hyperdynamic circulation of cirrhosis also can be worsened, and a patient with underlying cardiac problems can experience cardiac failure.

NONSHUNT SURGICAL MANAGEMENT OF REFRACTORY VARICEAL BLEEDING

In the patient with extrahepatic portal vein thrombosis and refractory variceal bleeding, the Sugiura procedure may be considered. The Sugiura procedure consists of extensive devascularization of the stomach and distal esophagus along with transection of the esophagus, splenectomy, truncal vagotomy, and pyloroplasty. As with performance of surgical shunts, patient survival is dependent on hepatic reserve at the time of the surgical procedure. Experience in Western countries is somewhat limited, and a number of modifications have been made to the original Sugiura procedure over time.

Hepatic Transplantation

Patients with cirrhosis, portal hypertension, and variceal bleeding usually die as a result of hepatic failure and not acute blood loss. Therefore, hepatic transplantation must be considered in the patient with ESLD, because it represents the patient's only chance for definitive therapy and long-term survival. Hepatic transplantation also can be considered for the patient with variceal bleeding refractory to all other forms of management. Survival after hepatic transplantation is not affected adversely by the previous performance of EVL, TIPS, or splenorenal or mesocaval shunts. Previous creation of an Eck fistula, however, does make hepatic transplantation much more technically difficult, and therefore this procedure should be avoided in the transplantation candidate. In addition to saving the patient's life, hepatic transplantation reverses most of the hemodynamic and humoral changes associated with cirrhosis.

Budd-Chiari Syndrome

Budd-Chiari syndrome (BCS) is an uncommon congestive hepatopathy characterized by the obstruction of hepatic venous outflow. Patients may present with acute signs and symptoms of abdominal pain, ascites, and hepatomegaly or more chronic symptoms related to long-standing portal hypertension. The obstruction may be thrombotic or nonthrombotic anywhere along the venous outflow system from the hepatic venules to the right atrium. Variations in the level of obstruction is one of the factors explaining the heterogeneity of the disease.

The incidence of BCS is 1 in 100,000 of the general population worldwide.

BCS is defined as primary when the obstructive process involves an endoluminal venous thrombosis. BCS is considered as a secondary process when the veins are compressed or invaded by a neighboring lesion originating outside the vein. A thorough evaluation demonstrates one or more thrombotic risk factors in approximately 75 to 90% of patients with primary BCS. Twenty-five percent of primary BCS patients have two or more risk factors.³⁹ BCS remains poorly understood, however, and primary myeloproliferative disorders account for approximately 35 to 50% of the primary cases of BCS. In most cases the myeloproliferative disorder can be classified as essential thrombocythemia or polycythemia rubra, but forms that are more difficult to classify also occur. In >90% of affected patients the myeloproliferative disorder was not diagnosed before the development of BCS. Most patients (80%) are women of a relatively young age (mean age is 30 years). The diagnosis of myeloproliferative disorder is made by demonstrating clusters of dystrophic megakaryocytes in a bone marrow biopsy specimen or by demonstrating formation of spontaneous colonies in cultures of erythroid progenitors on erythropoietin-poor media.

All known inherited thrombophilias have been implicated in the development of BCS. Activated protein C resistance, generally related to heterozygous or homozygous factor V Leiden mutation, is seen in approximately 25% of patients with BCS. Factor V Leiden mutation is present in the majority of cases related to pregnancy or oral contraceptive use. Anticardiolipin antibodies and hyperhomocysteinemia are also risk factors for BCS. Protein S, protein C, and antithrombin III are all produced in the liver, and their levels are affected by liver dysfunction. Therefore, although levels of these proteins may be found to be low in patients with BCS, it is difficult to prove this as the causative factor. Oral contraceptive use has also been shown to be a risk factor for BCS.³⁹

Clinically significant BCS is usually the result of obstruction of two or more of the major hepatic veins. The obstruction results in increased sinusoidal pressure and decreased sinusoidal blood flow. Therefore, liver congestion, right upper quadrant pain, and ascites may occur. In addition, liver perfusion via the portal vein is decreased, and 70% of affected patients have noninflammatory centrilobular necrosis on biopsy. Acute liver failure is rare, and most patients go on to develop chronic portal hypertension and ascites. Within a few weeks of obstruction centrilobular fibrosis begins and is followed by progressive fibrosis, nodular regeneration, and cirrhosis. Caudate lobe hypertrophy occurs in approximately 50% of cases and is due to the fact that the caudate lobe has direct venous drainage into the IVC. This caudate lobe hypertrophy can result in obstruction of the IVC.

Abdominal ultrasonography is the initial investigation of choice and can demonstrate absence of hepatic vein flow, spiderweb hepatic veins, and collateral hepatic veins.⁴⁰ Abdominal ultrasonography has a sensitivity and specificity of approximately 85%. MRI of the abdomen also is capable of demonstrating hepatic vein thrombosis and evaluating the IVC but is limited in that it cannot show direction of blood flow. The definitive radiographic study to evaluate BCS is hepatic venography to determine the presence and extent of hepatic vein thrombus as well as IVC pressures. Hepatic venography with measurement of IVC pressures should be performed before undertaking TIPS or a surgical shunt. Liver biopsy specimens demonstrate congestion, hepatocyte loss, and centrilobular fibrosis. Liver biopsy is necessary to differentiate BCS from veno-occlusive disease that is due to nonthrombotic obstruction of the hepatic venules by subendothelial swelling.

Initial treatment consists of diagnosing and medically managing the underlying disease process and preventing extension of the hepatic vein thrombosis through systemic anticoagulation. The BCS-associated portal hypertension and ascites are medically managed in a manner similar to that in most cirrhotic patients. Thrombolytic therapy alone for acute thrombosis may be attempted. However, the risk:benefit ratio is still unknown. Hepatic decompression aims to decrease sinusoidal pressure by restoring the outflow of blood from the liver via either medical therapy, recanalization of the obstructed hepatic veins, or side-to-side portacaval shunt. Radiographic and surgical intervention should be reserved for those patients whose condition is nonresponsive to medical therapy. Percutaneous angioplasty and TIPS, in combination with thrombolytic therapy, are currently preferred to surgical shunt because the procedural mortality is low and caudate lobe hypertrophy does not affect the outcome of these procedures. Side-to-side portacaval shunt attempts to turn the portal vein into a hepatic outflow tract. Usually a venous or prosthetic interposition graft is necessary. Patients with a hemodynamically significant IVC stricture due to caudate lobe hypertrophy require preshunt IVC stenting. Most patients with portacaval shunt show improvement in hepatic function and fibrosis at 1 year without significant hepatic encephalopathy.⁴⁰ However, the enthusiasm for this procedure has been curbed due to the relatively high rate of operative mortality and shunt dysfunction. Hepatic transplantation should be considered for patients with

manifestations of ESLD and can be expected to produce a 10-year survival rate of 75%. Whether hepatic transplantation should be a primary treatment for BCS, should replace other hepatic decompressive treatment options, or should be used only as a rescue operation remains unclear and somewhat controversial. It must be noted that, irrespective of the nontransplantation treatment modality initially used, the manifestations of BCS may progress and ultimately require hepatic transplantation.

INFECTIONS OF THE LIVER

The liver contains the largest portion of the reticuloendothelial system in the human body and is therefore able to handle the continuous low-level exposure to enteric bacteria that it receives through the portal venous system. Due to the high level of reticuloendothelial cells in the liver, nonviral infections are unusual.

Pyogenic Liver Abscess

Pyogenic liver abscesses are the most common liver abscesses seen in the United States. Previously they were felt to be due to portal infection, often occurring in young patients secondary to acute appendicitis. However, with earlier diagnosis this cause of abscesses has decreased. Pyogenic liver abscesses also occur as a result of impaired biliary drainage, hematogenous infection arising from sources such as IV drug abuse and teeth cleaning, and local spread of infection (diverticulitis or Crohn's disease). Patients may also develop pyogenic abscess as a complication of subacute bacterial endocarditis and infected indwelling catheters. There appears to be an increasing incidence due to infection by opportunistic organisms among immunosuppressed patients, including transplant and chemotherapy recipients and the AIDS population. Pyogenic hepatic abscesses may be single or multiple and are more frequently found in the right lobe of the liver.⁴¹ The abscess cavities are variable in size and, when multiple, may coalesce to give a honeycomb appearance. Approximately 40% of abscesses are monomicrobial, an additional 40% are polymicrobial, and 20% are culture negative. The most common infecting agents are gram-negative organisms. *Escherichia coli* is found in two thirds, and *Streptococcus faecalis*, *Klebsiella*, and *Proteus vulgaris* are also common. Anaerobic organisms such as *Bacteroides fragilis* are also seen frequently. *Staphylococcus* and *Streptococcus* are more common in patients with endocarditis and infected indwelling catheters.

Patients usually are symptomatic with right upper quadrant pain and fever. Jaundice occurs in up to one third of affected patients. A thorough history and physical examination are necessary to attempt to localize the primary causative site. Leucocytosis, an elevated sedimentation rate, and an elevated alkaline phosphatase (AP) level are the most common laboratory findings. Significant abnormalities in the results of the remaining liver function tests are unusual. Blood cultures reveal the causative organism in approximately 50% of cases. Ultrasound examination of the liver reveals pyogenic abscesses as round or oval hypoechoic lesions with well-defined borders and a variable number of internal echoes. CT scan is highly sensitive in the localization of pyogenic liver abscesses. The abscesses are hypodense and may contain air-fluid levels indicating a gas-producing infectious organism as well as peripheral enhancement (Fig. 31-19). MRI of the abdomen also can detect pyogenic abscesses with a high level of sensitivity but plays a limited role because of its inability to be used for image-guided diagnosis and therapy.

Computed tomographic scan of pyogenic liver abscesses. Multiple hepatic abscesses are seen in a patient after an episode of diverticulitis. Note the loculated large central abscess as well as the left lateral segment abscess.

The current cornerstones of treatment include correction of the underlying cause, needle aspiration, and IV antibiotic therapy. On presentation, percutaneous aspiration and culture of the aspirate may be beneficial to guide subsequent antibiotic therapy. Initial antibiotic therapy needs to cover gram-negative as well as anaerobic organisms. Aspiration and placement of a drainage catheter is beneficial for only a minority of pyogenic abscesses, because most are quite viscous and drainage is ineffective. Antibiotic therapy must be continued for at least 8 weeks. Aspiration and IV antibiotic therapy can be expected to be effective in 80 to 90% of patients. If this initial mode of therapy fails, the patients should undergo surgical therapy, including laparoscopic or open drainage. Anatomic surgical resection can be performed in patients with recalcitrant abscesses. It must be kept in mind throughout the evaluation and treatment of the presumed pyogenic abscess that a necrotic hepatic malignancy must not be mistaken for a hepatic abscess. Therefore, early diagnosis and progression to surgical resection should be advocated for patients who do not respond to initial antibiotic therapy.

Amebic Abscess

Entamoeba histolytica is a parasite that is endemic worldwide, infecting approximately 10% of the world's population. Amebiasis is most common in subtropical climates, especially in areas with poor sanitation. *E. histolytica* exists in a vegetative form and as cysts capable of surviving outside the human body. The cystic form passes through the stomach and small bowel unharmed and then transforms into a trophozoite in the colon. Here it invades the colonic mucosa forming typical flask-shaped ulcers, enters the portal venous system, and is carried to the liver. Occasionally, the trophozoite will pass through the hepatic sinusoid and into the systemic circulation, which results in lung and brain abscesses.

Amebae multiply and block small intrahepatic portal radicles with consequent focal infarction of hepatocytes. They contain a proteolytic enzyme that also destroys liver parenchyma. The abscesses formed are variable in size and can be single or multiple. The amebic abscess is most commonly located in the superior-anterior aspect of the right lobe of the liver near the diaphragm and has a necrotic central portion that contains a thick, reddish brown, pus-like material. This material has been likened to anchovy paste or chocolate sauce. Amebic abscesses are the most common type of liver abscesses worldwide.

Amebiasis should be considered in patients who have traveled to an endemic area and present with right upper quadrant pain, fever, hepatomegaly, and hepatic abscess.⁴¹ Leukocytosis is common, whereas elevated transaminase levels and jaundice are unusual. The most common biochemical abnormality is a mildly elevated AP level. Even though this disease process is secondary to a colonic infection, the

presence of diarrhea is unusual. For most patients findings of the fluorescent antibody test for *E. histolytica* are positive, and results can remain positive for some time after a clinical cure. Amebiasis is unlikely to be present if the serologic test results are negative.

Ultrasound and CT scanning of the abdomen are both very sensitive but nonspecific for the detection of amebic abscesses.⁴¹ CT scanning also is useful in detecting extrahepatic involvement. Amebic abscesses usually appear as well-defined low-density round lesions that have enhancement of the wall. They also usually appear somewhat ragged in appearance with a peripheral zone of edema. The central cavity may have septations as well as fluid levels.

Metronidazole 750 mg tid for 7 to 10 days is the treatment of choice and is successful in 95% of cases. Defervescence usually occurs in 3 to 5 days. The time necessary for the abscess to resolve depends on the initial size at presentation and varies from 30 to 300 days.⁴¹ Both ultrasound and CT of the liver can be used as follow-up after the initiation of medical therapy. Aspiration of the abscess is rarely needed and should be reserved for patients with large abscesses, abscesses that do not respond to medical therapy, abscesses that appear to be superinfected, and abscesses of the left lobe of the liver that may rupture into the pericardium.

Hydatid Disease

Hydatid disease is due to the larval or cyst stage of infection by the tapeworm *Echinococcus granulosus*, which lives in the dog.⁴² Humans, sheep, and cattle are intermediate hosts. The dog is infected by eating the viscera of sheep that contain hydatid cysts. Scolices, contained in the cysts, adhere to the small intestine of the dog and become adult taenia, which attach to the intestinal wall. Each worm sheds approximately 500 ova into the bowel. The infected ova-containing feces of the dog contaminate grass and farmland, and the ova are ingested by sheep, pigs, and humans. The ova have chitinous envelopes that are dissolved by gastric juice. The liberated ovum burrows through the intestinal mucosa and is carried by the portal vein to the liver, where it develops into an adult cyst. Most cysts are caught in the hepatic sinusoids, and 70% of hydatid cysts form in the liver. A few ova pass through the liver and are held up in the pulmonary capillary bed or enter the systemic circulation, forming cysts in the lung, spleen, brain, or bones.

Hydatid disease is most common in sheep-raising areas, where dogs have access to infected offal. These include South Australia, New Zealand, Africa, Greece, Spain, and the Middle East. The disease is uncommon in Britain. Hydatid cysts commonly involve the right lobe of the liver, usually the anterior-inferior or posterior-inferior segments. The uncomplicated cyst may be silent and found only at autopsy or incidentally. Occasionally, the affected patient presents with dull right upper quadrant pain or abdominal distention. Cysts may become secondarily infected, involve other organs, or even rupture, which leads to an allergic or anaphylactic reaction.

The diagnosis of hydatid disease is based on the findings of an enzyme-linked immunosorbent assay (ELISA) for echinococcal antigens, and results are positive in approximately 85% of infected patients.⁴² The ELISA results may be negative in an infected patient if the cyst has not leaked or does not contain scolices, or if the parasite is no longer viable. Eosinophilia of >7% is found in approximately 30% of infected patients. Ultrasonography and CT scanning of the abdomen are both quite sensitive for detecting hydatid cysts. The appearance of the cysts on images depends on the stage of cyst development. Typically, hydatid cysts are well-defined hypodense lesions with a distinct wall. Ring-like calcifications of the pericysts are present in 20 to 30% of cases. As healing occurs, the entire cyst calcifies densely, and a lesion with this appearance is usually dead or inactive. Daughter cysts generally occur in a peripheral location and are typically slightly hypodense compared with the mother cyst. MRI of the abdomen may be useful to evaluate the pericyst, cyst matrix, and daughter cyst characteristics.

Unless the cysts are small or the patient is not a suitable candidate for surgical resection, the treatment of hydatid disease is surgically based because of the high risk of secondary infection and rupture. Medical treatment with albendazole relies on drug diffusion through the cyst membrane. The concentration of drug achieved in the cyst is uncertain but is better than that of mebendazole, and albendazole can be used as initial treatment for small, asymptomatic cysts. For most cysts surgical resection involving laparoscopic or open complete cyst removal with instillation of a scolicidal agent is preferred and usually is curative. If complete cystectomy is not possible, then formal anatomic liver resection can be used. During surgical resection caution must be exercised to avoid rupture of the cyst with release of protoscolices into the peritoneal cavity. Peritoneal contamination can result in an acute anaphylactic reaction or peritoneal implantation of scolices with daughter cyst formation and inevitable recurrence.

Alveolar echinococcosis (caused by *Echinococcus multilocularis*) occurs in the Northern Hemisphere, produces a more generalized

granulomatous reaction, and can present in a manner similar to that of a malignancy. Resection is the treatment of choice.

Ascariasis

Ascaris infection is particularly common in the Far East, India, and South Africa. Ova of the roundworm *Ascaris lumbricoides* arrive in the liver by retrograde flow in the bile ducts. The adult worm is 10 to 20 cm long and may lodge in the common bile duct, producing partial bile duct obstruction and secondary cholangitic abscesses. The ascaris may be a nucleus for the development of intrahepatic gallstones. The clinical presentation in an affected patient may include any of the following: biliary colic, acute cholecystitis, acute pancreatitis, or hepatic abscess.⁴³ Plain abdominal radiographs, abdominal ultrasound, and endoscopic retrograde cholangiography (ERCP) all can demonstrate the ascaris as linear filling defects in the bile ducts. Occasionally worms can be seen moving into and out of the biliary tree from the duodenum. Treatment consists of administration of piperazine citrate, mebendazole, or albendazole in combination with ERCP extraction of the worms. Failure of endoscopic extraction warrants surgical removal of the ascaris.

Schistosomiasis

Schistosomiasis affects >200 million people in 74 countries. Hepatic schistosomiasis is usually a complication of the intestinal disease, because emboli of schistosomiasis ova reach the liver via the mesenteric venous system. Eggs excreted in the feces hatch in water to release free-swimming embryos, which enter snails and develop into fork-tailed cercariae. They then re-enter human skin during contact within infected water. They burrow down to the capillary bed, and at that point there is widespread hematogenous dissemination. Those entering the intrahepatic portal system grow rapidly, and a granulomatous reaction occurs. The degree of resultant portal fibrosis is related to the adult worm load.

Schistosomiasis has three stages of clinical symptomatology: the first includes itching after the entry of cercariae through the skin; the second includes fever, urticaria, and eosinophilia; and the third involves hepatic fibrosis followed by presinusoidal portal hypertension. During this third phase the liver shrinks, the spleen enlarges, and the patient may develop complications of portal hypertension while hepatic function is maintained. Active infection is detected by stool examination. Serologic tests indicate past exposure without specifics regarding timing. A negative serologic test result rules out schistosomal infection. Serum levels of transaminases are usually normal, but the AP level may be mildly elevated. A decreased serum albumin level is usually the result of frequent GI bleeds and decreased nutrition.

Medical treatment of schistosomiasis includes education regarding hygiene and the avoidance of infected water. Treatment with praziquantel 40 to 75 mg/kg as a single dose is the treatment of choice for all forms of schistosomiasis and produces few side effects. GI bleeding usually is controlled by endoscopic variceal ligation. However, in a patient with refractory GI portal hypertensive bleeding, distal splenorenal shunt or gastric devascularization and splenectomy need to be considered.

Viral Hepatitis

The role of the surgeon in the management of viral hepatitis is somewhat limited. However, the disease entities of hepatitis A, B, and C need to be kept in mind during any evaluation for liver disease. The findings of hepatitis A in many cases will be acute, nonspecific, and similar to those associated with hepatic metastases, biliary obstruction, and cirrhosis. Hepatitis B and C can both lead to chronic liver disease, cirrhosis, and hepatocellular carcinoma (HCC). Current hepatitis B vaccination programs as well as treatment protocols involving nucleoside analogues and hepatitis B immunoglobulin have dramatically improved the treatment options for affected patients. The incidence of ESLD and HCC are both diminished by these protocols. Currently, the same therapeutic options are not available for hepatitis C, and although some patients do maintain a sustained viral response after interferon-based therapy, many either do not respond or have recurrences of their disease. The unraveling of the crystal structures of all three major hepatitis C viral enzymes involved in replication has led to the development of several novel drugs, including protease inhibitors, polymerase inhibitors, and hepatitis C vaccines. Although early results are encouraging, longer-term data are required to determine the effectiveness of these new treatment options.

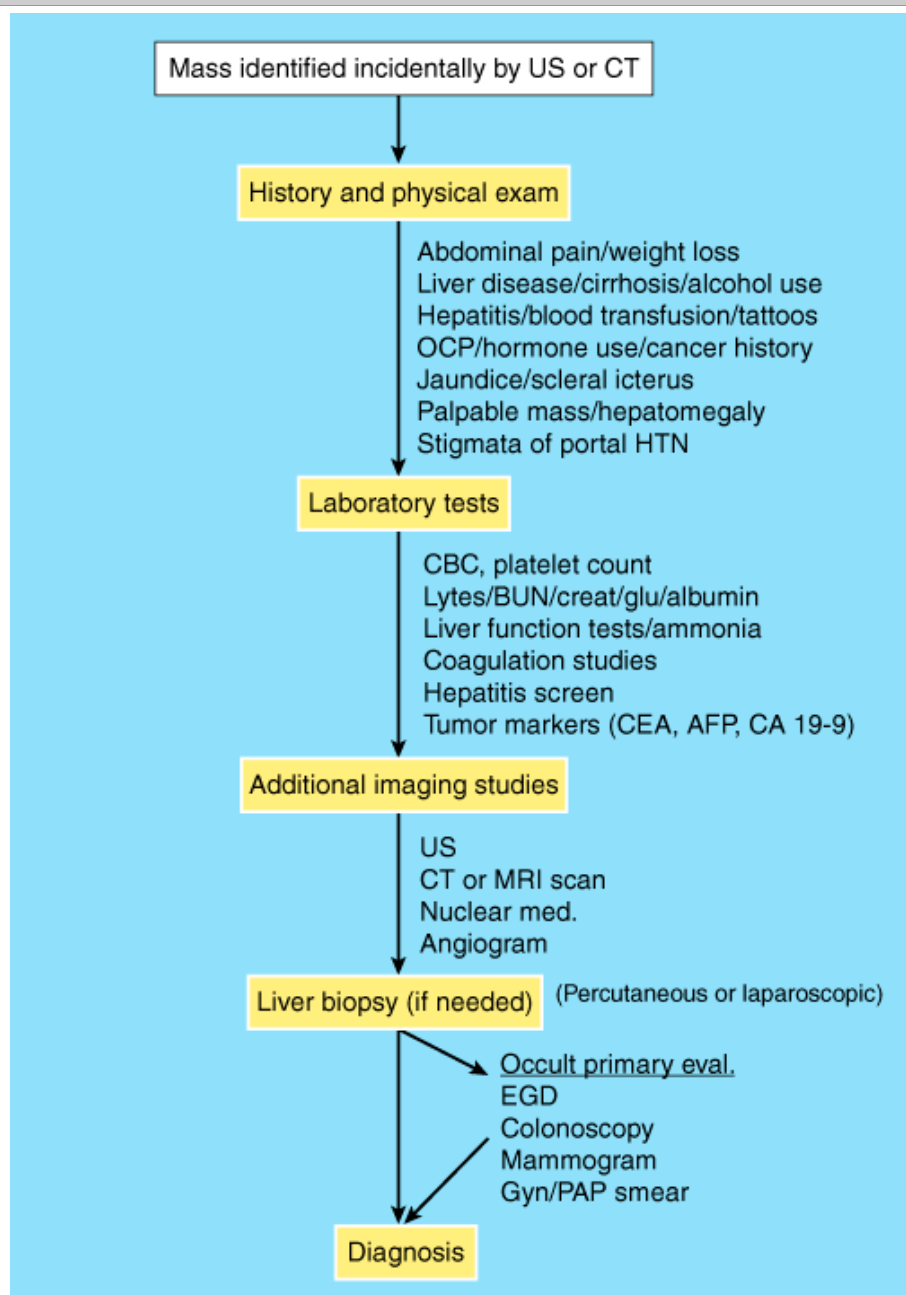

WORK-UP OF AN INCIDENTAL LIVER MASS

A liver mass often is identified incidentally during a radiologic imaging procedure performed for another indication. For example, a liver mass may be discovered during evaluation for gallbladder disease or kidney stones. In addition, with advances in imaging technology,

previously undetected lesions are now identified. Although many of these lesions are benign and will require no further treatment, the concern for malignancy requires a thorough evaluation. Thus, an orderly approach should be taken to the work-up of an incidental liver lesion to minimize unnecessary testing.⁴⁴

The evaluation of an incidental liver mass begins with a history and physical examination (Fig. 31-20). The patient should be asked about abdominal pain, weight loss, previous liver disease, cirrhosis, alcohol use, viral hepatitis, blood transfusions, tattoos, oral contraceptive use (in women), and personal or family history of cancer. On physical examination, jaundice, scleral icterus, hepatomegaly, splenomegaly, palpable mass, or stigmata of portal hypertension should be noted. After completion of the history and physical examination, blood work should be performed, including complete blood count; platelet count; measurement of levels of electrolytes, blood urea nitrogen, creatinine, glucose, and albumin; liver function tests; serum ammonia level; coagulation studies; hepatitis screen; and measurement of levels of the tumor markers carcinoembryonic antigen, alpha-fetoprotein, and cancer antigen 19-9.

Fig. 31-20.

Algorithm for diagnostic work-up of an incidental liver lesion. The evaluation includes history and physical examination, blood work, imaging studies, and liver biopsy (if needed). AFP = alpha-fetoprotein; BUN = blood urea nitrogen; CA 19-9 = cancer antigen 19-9; CEA = carcinoembryonic antigen; creat = creatinine; CBC = complete blood count; CT = computed tomography; EGD = esophagogastroduodenoscopy; glu = glucose; Gyn = gynecologic; HTN = hypertension; MRI = magnetic resonance imaging; OCP = oral contraceptive pill; PAP = Papanicolaou; US = ultrasound.

The differential diagnosis for an incidental liver mass includes cysts, benign solid lesions, and primary or metastatic cancers (Table 31-7). Ultrasound or CT is commonly performed to evaluate respiratory or abdominal symptoms, and these scans are usually what leads to the discovery of an incidental liver lesion. Although hepatic ultrasound is inexpensive, technical limitations are often encountered due to interference by bowel gas, obesity, or overlying ribs; a mass seen on liver ultrasound should be further evaluated with a dedicated contrast helical CT or MRI scan.^{21,22} Additional imaging studies should be performed as indicated. For example, if the working diagnosis is a liver hemangioma and the CT scan findings are not classical for this diagnosis, then a contrast liver MRI should be performed. If the MRI is inconclusive, then an old-fashioned nuclear medicine tagged red blood cell scan can be helpful. If the radiologic imaging results are classic for a benign hemangioma or focal nodular hyperplasia (FNH), then a liver biopsy is not indicated (and actually risks hemorrhage, because both lesions are hypervascular) and observation is warranted as long as the patient is asymptomatic.

Table 31-7 Classification of Liver Lesions
Benign
Cyst
Hemangioma
Focal nodular hyperplasia
Adenoma
Biliary hamartoma
Abscess
Malignant
Hepatocellular carcinoma
Cholangiocarcinoma (bile duct cancer)
Gallbladder cancer
Metastatic colorectal cancer
Metastatic neuroendocrine cancer (carcinoid)
Other metastatic cancers

If all imaging studies are inconclusive, then an image-guided percutaneous liver biopsy should be considered. If the lesion is too small to biopsy or cannot be well visualized or targeted for percutaneous biopsy, then options are either close follow-up imaging (e.g., 3 to 6 months) to document stability or laparoscopic liver biopsy. Laparoscopic liver biopsy also is indicated in cases of cirrhosis with ascites and coagulopathy, in which the bleeding risk is excessive by percutaneous route. If liver biopsy findings demonstrate adenocarcinoma, then the differential diagnosis narrows to metastatic adenocarcinoma from an unknown or occult primary; a primary liver adenocarcinoma, which also is known as *cholangiocarcinoma*; or bile duct cancer (see "Malignant Liver Tumors"). Although pathologic staining can provide clues to the origin, a primary liver cholangiocarcinoma is usually a diagnosis of exclusion after an occult extrahepatic primary malignancy is ruled out. In these cases the work-up for an occult primary carcinoma should include colonoscopy; EGD (upper endoscopy); mammogram, gynecologic examination, and Papanicolaou smear (in women); and prostate-specific antigen testing and prostate evaluation (in men).

HEPATIC CYSTS

Congenital Cysts

The majority of hepatic cysts are asymptomatic. Hepatic cysts are usually identified incidentally and can occur at any time throughout life. The most common benign lesion found in the liver is the congenital or simple cyst. The exact prevalence of simple hepatic cysts in the U.S. population is not known, but the female:male ratio is approximately 4:1, and the prevalence is approximately 2.8 to 3.6%.⁴⁵ Simple cysts

are the result of excluded hyperplastic bile duct rests. Simple cysts usually are identified in hepatic imaging studies as thin-walled, homogeneous, fluid-filled structures with few to no septations. The cyst epithelium is cuboidal and secretes a clear nonbilious serous fluid. With the exception of large cysts, simple cysts are usually asymptomatic. Large simple cysts may cause abdominal pain, epigastric fullness, and early satiety. Occasionally the affected patient presents with an abdominal mass. Asymptomatic simple cysts are best managed conservatively. The preferred treatment for symptomatic cysts is ultrasound- or CT-guided percutaneous cyst aspiration followed by sclerotherapy. This approach is approximately 90% effective in controlling symptoms and ablating the cyst cavity. If percutaneous treatment is unavailable or ineffective, treatment may include either laparoscopic or open surgical cyst fenestration. The laparoscopic approach is being used more frequently and is 90% effective. The excised cyst wall is sent for pathologic analysis to rule out carcinoma, and the remaining cyst wall must be carefully inspected for evidence of neoplastic change. If such change is present, complete resection is required, either by enucleation or formal hepatic resection.

Biliary Cystadenoma

Biliary cystadenomas are slow-growing, unusual, benign lesions that most commonly present as large lesions in the right lobe of the liver. Although these lesions are usually benign, they can undergo malignant transformation. Biliary cystadenomas usually present with abdominal pain. An abdominal mass occasionally can be identified on physical examination. In contrast to simple cysts, biliary cystadenomas have walls that appear thicker with soft tissue nodules and the cyst's septations usually enhance. The protein content of the fluid can be variable and can affect the radiographic images on CT and MRI. Surgical resection is the preferred mode of treatment.

Polycystic Liver Disease

Adult polycystic liver disease (ADPCLD) occurs as an autosomal dominant disease and usually presents in the third decade of life. Some 44 to 76% of affected families are found to have mutations of PKD1 and approximately 75% have mutations of PKD2.⁴⁶ The prevalence and number of hepatic cysts are higher in females and increase with advancing age and with increasing severity of renal cystic disease and renal dysfunction. At age 60 years, approximately 80% of ADPCLD patients will have hepatic cysts, with women having more and larger cysts. This gender difference may be due to the effects of estrogen. Patients with a small number of cysts or with small cysts (<2 cm) usually remain asymptomatic. In contrast, patients who develop many or large cysts, with a cyst:parenchymal volume ratio of >1, usually develop clinical symptoms, including abdominal pain, shortness of breath, and early satiety. Progressive ADPCLD will result in renal failure and the need for hemodialysis. In most patients, the liver parenchymal volume is preserved despite extensive cystic disease. Hepatic decompensation, variceal hemorrhage, ascites, and encephalopathy develop rarely in patients with ADPCLD and only in patients with massive cystic disease. The most common hepatologic complications associated with ADPCLD are intracystic hemorrhage, infection, and posttraumatic rupture. The most common abnormal biochemical test finding is a modestly elevated γ -glutamyltransferase level and the most useful imaging test is CT scanning of the abdomen, which will demonstrate the characteristic polycystic appearance. Other conditions that may be associated with ADPCLD include cerebral aneurysm, diverticulosis, mitral valve prolapse, and inguinal hernia. There is no effective medical therapy for ADPCLD. Cyst aspiration and sclerosis may be considered if the patient has one or a few dominant cysts; however, most patients have multiple cysts and do not improve when this technique is used. Cyst fenestration via an open or laparoscopic approach can be attempted in symptomatic patients; however, approximately 50% of treated patients will have recurrence of their symptoms.⁴⁷ The only definitive therapy for patients with symptomatic ADPCLD is orthotopic liver transplantation. If the patient has renal involvement (polycystic kidney disease) with renal failure, consideration should be given to combined liver-kidney transplantation. Because of the genetic basis of ADPCLD, living-donor transplantation should be considered only if the presence of ADPCLD in the donor can be ruled out.

Caroli's Disease

Caroli's disease is a syndrome of congenital ductal plate malformations of the intrahepatic bile ducts and is characterized by segmental cystic dilatation of the intrahepatic biliary radicals.⁴⁸ Caroli's disease also is associated with an increased incidence of biliary lithiasis, cholangitis, and biliary abscess formation. Caroli's disease usually occurs in the absence of cirrhosis and is associated with cystic renal disease.⁴⁸ The most common presenting symptoms include fever, chills, and abdominal pain. Most patients present by the age of 30 years, and males and females are affected equally. Rarely, patients can present later in life with complications secondary to portal hypertension.

Approximately 33% of affected patients develop biliary lithiasis and 7% develop cholangiocarcinoma. The diagnosis of Caroli's disease is made based on imaging studies. Magnetic resonance cholangiopancreatography, ERCP, and percutaneous transhepatic cholangiography provide more detailed imaging of the biliary tree and confirm communication of the intrahepatic cysts with the biliary tree, which is necessary to solidify the diagnosis. Treatment consists of biliary drainage, with ERCP and percutaneous transhepatic cholangiography serving as first-line therapeutic modalities. If the disease is limited to a single lobe of the liver, hepatic resection can be beneficial. Liver resection can be considered in the patient with hepatic decompensation or unresponsive recurrent cholangitis and possibly in the patient with a small T1 or T2 cholangiocarcinoma.

BENIGN LIVER LESIONS

The liver is an organ that is commonly involved either primarily or secondarily with vascular, metabolic, infectious, and malignant processes. Many classification schemes are used to help narrow the differential diagnosis of liver lesions: solid or cystic, single or multiple, cell of origin (hepatocellular, cholangiocellular, or mesenchymal), and benign or malignant. The most common benign lesions are cysts, hemangiomas, FNH, and hepatocellular adenomas. Many of these lesions have typical features in imaging studies that help confirm the diagnosis.

Cyst

Hepatic cysts are the most frequently encountered liver lesion overall and are described in detail in the section "Hepatic Cysts." Cystic lesions of the liver can arise primarily (congenital) or secondarily from trauma (seroma or biloma), infection (pyogenic or parasitic), or neoplastic disease. Congenital cysts are usually simple cysts containing thin serous fluid and are reported to occur in 5 to 14% of the population, with higher prevalence in women. In most cases, congenital cysts are differentiated from secondary cysts (infectious or neoplastic origin) in that they have no visible wall or solid component and are filled with homogeneous, clear fluid. For benign solid liver lesions, the differential diagnosis includes hemangioma, adenoma, FNH, and bile duct hamartoma (see Table 31-7).

Hemangioma

Hemangiomas (also referred to as *hemangiomata*) are the most common solid benign masses that occur in the liver. They consist of large endothelial-lined vascular spaces and represent congenital vascular lesions that contain fibrous tissue and small blood vessels which eventually grow. They are more common in women and occur in 2 to 20% of the population. They can range from small (≤ 1 cm) to giant cavernous hemangiomas (10 to 25 cm). The most common symptom is pain, which often occurs with lesions larger than 5 to 6 cm. Spontaneous rupture (bleeding) is rare, and the main indication for resection is pain. Surgical resection can be accomplished by enucleation or formal hepatic resection, depending on the location and involvement of intrahepatic vascular structures and hepatic ducts.

The majority of hemangiomas can be diagnosed by liver imaging studies. On biphasic contrast CT scan, large hemangiomas show asymmetrical nodular peripheral enhancement that is isodense with large vessels and exhibit progressive centripetal enhancement fill-in over time (Fig. 31-21).²¹ On MRI, hemangiomas are hypointense on T1-weighted images and hyperintense on T2-weighted images.⁴⁹ With gadolinium enhancement, hemangiomas show a pattern of peripheral nodular enhancement similar to that seen on contrast CT scans. Caution should be exercised in ordering a liver biopsy if the suspected diagnosis is hemangioma because of the risk of bleeding from the biopsy site, especially if the lesion is at the edge of the liver.

Computed tomographic scans showing classic appearance of benign liver lesions. Focal nodular hyperplasia (FNH) is hypervascular on arterial phase, isodense to liver on venous phase, and has a central scar (*upper panels*). Adenoma is hypovascular (*lower left panel*). Hemangioma shows asymmetrical peripheral enhancement (*lower right panel*).

Adenoma

Hepatic adenomas are benign solid neoplasms of the liver. They are most commonly seen in young women (aged 20 years to the forties) and are typically solitary, although multiple adenomas also can occur. Prior or current use of estrogens (oral contraceptives) is a clear risk factor for development of liver adenomas, although they can occur even in the absence of oral contraceptive use. On gross examination, they appear soft and encapsulated and are tan to light brown. Histologically, adenomas lack bile duct glands and Kupffer cells, have no true lobules, and contain hepatocytes that appear congested or vacuolated due to glycogen deposition. On CT scan, adenomas usually have sharply defined borders and can be confused with metastatic tumors. With venous phase contrast, they can look hypodense or isodense in comparison with background liver, whereas on arterial phase contrast subtle hypervascular enhancement often is seen (see Fig. 31-21). On MRI scans, adenomas are hyperintense on T1-weighted images and enhance early after gadolinium injection. On nuclear medicine imaging, they typically appear as "cold," in contrast with FNH.

Hepatic adenomas carry a significant risk of spontaneous rupture with intraperitoneal bleeding. The clinical presentation may be abdominal pain, and in 10 to 25% of cases hepatic adenomas present with spontaneous intraperitoneal hemorrhage. Hepatic adenomas also have a risk of malignant transformation to a well-differentiated HCC. Therefore, it usually is recommended that a hepatic adenoma (once diagnosed) be surgically resected.⁴⁴

Focal Nodular Hyperplasia

FNH is another solid, benign lesion of the liver. Similar to adenomas, they are more common in women of childbearing age, although the link to oral contraceptive use is not as clear as with adenomas. A good-quality biphasic CT scan usually is diagnostic of FNH, on which such lesions appear well circumscribed with a typical central scar (see Fig. 31-21). They show intense homogeneous enhancement on arterial phase contrast images and are often isodense or invisible compared with background liver on the venous phase. On MRI scans, FNH lesions are hypointense on T1-weighted images and isointense to hyperintense on T2-weighted images. After gadolinium administration, lesions are hyperintense but become isointense on delayed images. The fibrous septa extending from the central scar are also more readily seen with MRI. If CT or MRI scans do not show the classic appearance, radionuclide sulfur colloid imaging may be used to diagnose FNH based on select uptake by Kupffer cells. Unlike adenomas, FNH lesions usually do not rupture spontaneously and have no significant risk of malignant

transformation. The main indication for surgical resection is abdominal pain. Oral contraceptive or estrogen use should be stopped when either FNH or adenoma is diagnosed.

Bile Duct Hamartoma

Bile duct hamartomas are typically small liver lesions, 2 to 4 mm in size, visualized on the surface of the liver at laparotomy. They are firm, smooth, and whitish yellow in appearance. They can be difficult to differentiate from small metastatic lesions, and excisional biopsy often is required to establish the diagnosis.

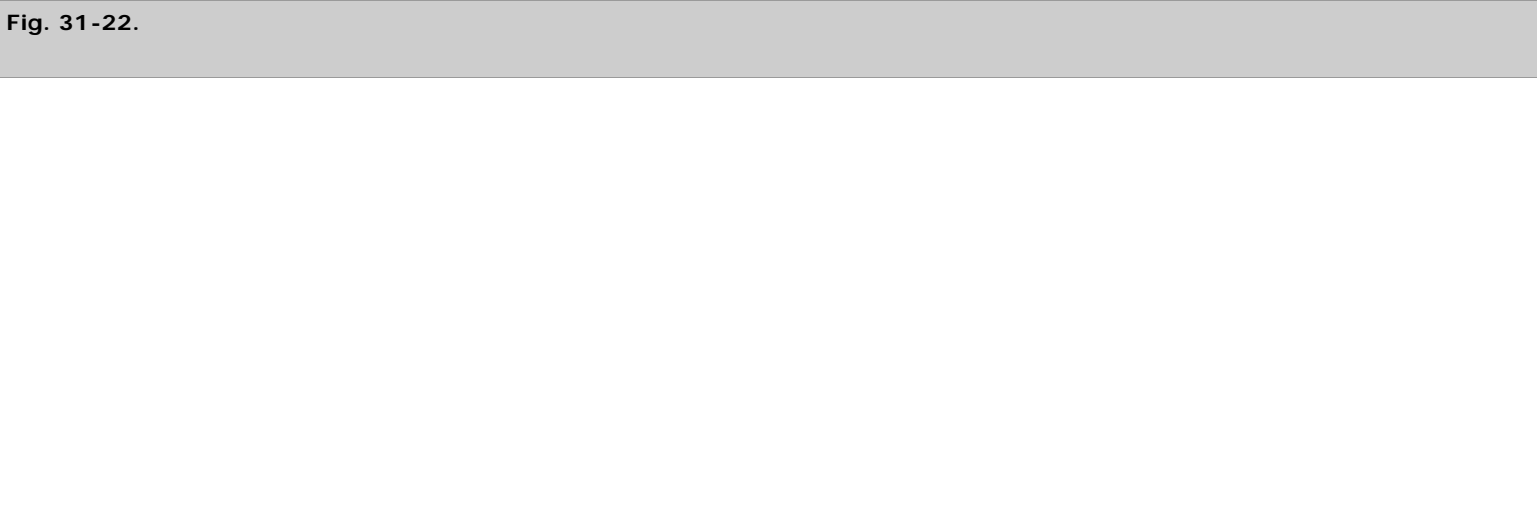

MALIGNANT LIVER TUMORS

Malignant tumors in the liver can be classified as primary (cancers that originate in the liver) or metastatic (cancers that spread to the liver from an extrahepatic primary site) (see Table 31-7). Primary cancers in the liver that originate from hepatocytes are known as *hepatocellular carcinomas* (HCCs or hepatomas), whereas cancers arising in the bile ducts are known as *cholangiocarcinomas*.

In the United States, approximately 150,000 new cases of colorectal cancer are diagnosed each year, and the majority of patients (approximately 60%) will develop hepatic metastases over their lifetime. Hence, the most common tumor seen in the liver is metastatic colorectal cancer. This compares with approximately 18,000 new cases of HCC diagnosed annually in the United States. Interestingly, in a Western series of 1000 consecutive new liver cancer patients seen at a university medical center, 47% were HCC, 17% were colorectal cancer metastases, 11% were cholangiocarcinomas, 7% were neuroendocrine metastases, and 18% were other tumors.⁵⁰ Although these figures do not reflect the incidence or prevalence of these liver cancers, they are indicative of referral patterns in a tertiary academic medical center with a large liver transplantation team and active hepatology clinic.

Hepatocellular Carcinoma

HCC is the fifth most common malignancy worldwide, with an estimated 1,000,000 new cases diagnosed annually. Major risk factors are viral hepatitis (B or C), alcoholic cirrhosis, hemochromatosis, and nonalcoholic steatohepatitis. In Asia, the risk is as high as 30 to 65 per 100,000 persons per year, whereas in the United States the risk is only 2 per 100,000 persons per year.⁵¹ Although cirrhosis is not present in all cases, it has been estimated to be present 70 to 90% of the time. In a person with cirrhosis, the annual conversion rate to HCC is 3 to 6%. In patients with chronic hepatitis C virus infection, cirrhosis usually is present before the HCC develops; however, in cases of hepatitis C virus infection, HCC tumors can occur before the onset of cirrhosis. HCCs are typically hypervascular with blood supplied predominantly from the hepatic artery. Thus, the lesion often appears hypervascular during the arterial phase of CT studies (Fig. 31-22) and relatively hypodense during the delayed phases due to early washout of the contrast medium by the arterial blood. MRI imaging also is effective in characterizing HCC. HCC is variable on T1-weighted images and usually hyperintense on T2-weighted images. As with contrast CT, HCC enhances in the arterial phase after gadolinium injection because of its hypervascularity and becomes hypointense in the delayed phases due to contrast washout. HCC has a tendency to invade the portal vein, and the presence of an enhancing portal vein thrombus is highly suggestive of HCC.

Computed tomographic (CT) images of hepatocellular carcinoma (HCC) and peripheral cholangiocarcinoma. CT scans reveal a large (*upper panel*) and small (*middle panel*) hypervascular HCC. A hypovascular left lobe peripheral cholangiocarcinoma (Cholangio CA) is also shown (*lower panel*).

The treatment of HCC is complex and is best managed by a multidisciplinary liver transplant team. A complete algorithm for the evaluation and management of HCC is shown (Fig. 31-23).

Fig. 31-23.

Algorithm for the management of hepatocellular carcinoma (HCC). The treatment algorithm for HCC begins with determining whether the patient is a resection candidate or liver transplant candidate. Bili = bilirubin level (in milligrams per deciliter); Child's = Child-Turcotte-Pugh class; lap = laparoscopic; LDLT = living-donor liver transplantation; LN = lymph node; MELD = Model for End-Stage Liver Disease; OLTx = orthotopic liver transplantation; Perc = percutaneous; RFA = radiofrequency ablation; TACE = transarterial chemoembolization; Tx = transplantation; UNOS = United Network for Organ Sharing; vasc. = vascular.

For patients without cirrhosis who develop HCC, resection is the treatment of choice. For those patients with Child's class A cirrhosis with preserved liver function and no portal hypertension, resection also is considered. If resection is not possible because of poor liver function and the HCC meets the Milan criteria (one nodule <5 cm, or two or three nodules all <3 cm, no gross vascular invasion or extrahepatic spread), liver transplantation is the treatment of choice.⁵²

The Barcelona-Clinic Liver Cancer Group has refined its HCC management strategy and has developed the American Association for the Study of Liver Diseases Practice Guidelines.^{53,54} Management guidelines vary slightly in Asia, Europe, the United States, and other countries based in part on availability of organ donors for liver transplantation. Living-donor liver transplantation is also an alternative for patients with HCC awaiting transplantation to avoid dropout due to tumor progression.⁵² Specific treatment options are described in the next section.

Cholangiocarcinoma (Bile Duct Cancer) (see also Chap. 32)

Cholangiocarcinoma, or bile duct cancer, is the second most common primary malignancy within the liver. Cholangiocarcinoma is an adenocarcinoma of the bile ducts that forms in the biliary epithelial cells and can be subclassified into peripheral (intrahepatic) bile duct cancer and central (extrahepatic) bile duct cancer. Extrahepatic bile duct cancer can be distally or proximally located. When proximal, it is referred to as a *hilar cholangiocarcinoma* (Klatskin's tumor). Hilar cholangiocarcinoma originates in the wall of the bile duct at the hepatic duct confluence and usually presents with obstructive jaundice rather than an actual liver mass. In contrast, a peripheral (or intrahepatic) cholangiocarcinoma represents a tumor mass within a hepatic lobe or at the periphery of the liver. A biopsy specimen from the cholangiocarcinoma will show adenocarcinoma, but the pathologist is often unable to differentiate metastatic adenocarcinoma to the liver

from true primary bile duct adenocarcinoma. Therefore, a search for a primary site should be undertaken in cases in which an incidentally discovered liver lesion is proven to be an adenocarcinoma on biopsy.

Hilar cholangiocarcinoma is difficult to diagnose and typically presents as a stricture of the proximal hepatic duct causing painless jaundice. It preferentially grows along the length of the common bile duct, often involving the periductal lymphatics with frequent lymph node metastases. Surgical resection offers the only chance for cure of cholangiocarcinoma.^{55,56} The location and extent of tumor dictates the operative approach. In one series of 225 patients with hilar cholangiocarcinoma, 29% were deemed to have unresectable tumors by initial imaging.⁵⁷ Of the remaining 160 patients who underwent exploratory surgery with curative intent, 50% were found to have inoperable tumors. Histologically negative margins, concomitant hepatic resection, and well-differentiated tumor histology were associated with improved outcome after resection. In another series of 61 patients undergoing surgical exploration for hilar cholangiocarcinoma, the 5-year actuarial survival rates for an R0 or R1 resection were 45% and 26%, respectively.⁵⁸ In a large series reported by Nagino and colleagues, 132 patients with hilar cholangiocarcinoma underwent extended hepatectomy with resection of the caudate lobe and extrahepatic bile duct, and/or portal vein resection ($n = 63$) after portal vein embolization.⁵⁹ The 3- and 5-year survival rates were 41.7% and 26.8%, respectively.

In the absence of associated primary sclerosing cholangitis (PSC), surgical resection is the treatment of choice for hilar cholangiocarcinoma. However, approximately 10% of patients with cholangiocarcinoma have PSC.⁶⁰ Furthermore, cholangiocarcinoma in the setting of PSC is frequently multicentric and often is associated with underlying liver disease, with eventual cirrhosis and portal hypertension. As a result, experience has shown that resection of cholangiocarcinoma in patients with PSC yields dismal results. This led transplant centers to consider OLT for patients with hilar cholangiocarcinoma. The results of transplantation were disappointing, however, with high recurrence and overall 3-year survival rates of <30%.⁶¹

Because the growth of hilar cholangiocarcinoma indicates that this disease spreads in a locoregional manner, a rationale for the use of neoadjuvant chemoradiation was developed by the transplant team at the University of Nebraska in the late 1980s. This was adapted in 1993 by the transplant team at the Mayo Clinic, which led to the current Mayo Clinic protocol. The pretransplant Mayo protocol consists of external beam radiation therapy plus a protracted course of IV 5-fluorouracil followed by iridium 192 brachytherapy.⁶² Patients then undergo an abdominal exploration with staging. If findings are negative, patients are given capecitabine for 2 of every 3 weeks until OLT. Even after restaging with CT/MRI and endoscopic ultrasonography, approximately 15 to 20% of patients will have positive findings on abdominal exploration for tumor.^{60,62} The 5-year survival rate for those undergoing transplantation for cholangiocarcinoma at the Mayo Clinic is approximately 70% and compares favorably with the rate for resection.^{60,62} Current eligibility criteria for this Mayo Clinic protocol include unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma with PSC. The tumor must have a radial dimension of ≤ 3 cm with no intrahepatic or extrahepatic metastases, and the patient must not have undergone prior radiation therapy or transperitoneal biopsy.⁶² Whether these same outstanding results can be reproduced at other transplant centers remains unknown.

Peripheral, or intrahepatic, cholangiocarcinoma is less common than hilar cholangiocarcinoma. In a series of 53 patients at Memorial Sloan-Kettering Cancer Center who underwent surgical exploration for a diagnosis of intrahepatic cholangiocarcinoma, 33 (62%) were found to have resectable tumors.⁶³ Actuarial 3-year survival for patients undergoing resection was 55%. Factors predictive of poor survival included vascular invasion, histologically positive margins, and multiple tumors. In a large series in Taiwan, 373 patients with peripheral cholangiocarcinoma underwent surgical treatment from 1977 to 2001. Absence of mucobilia, nonpapillary tumor type, tumor of advanced stage, nonhepatectomy, and lack of postoperative chemotherapy were five independent prognostic factors that adversely affected overall survival.⁶⁴ Liver transplantation has been performed for peripheral cholangiocarcinoma⁶⁵; however, most centers have abandoned this approach because of organ shortages and relatively high recurrence rates.

Gallbladder Cancer (see also Chap. 32)

Gallbladder cancer is a rare aggressive tumor with a very poor prognosis. Over 90% of patients have associated cholelithiasis. In one study examining the mode of presentation over a 10-year period from 1990 to 2000 in 44 patients diagnosed with gallbladder cancer, the diagnosis was found to be made preoperatively in 57%, intraoperatively in 11%, and incidentally after cholecystectomy in 32%.⁶⁶ Surgical approaches can be classified into (a) reoperation for an incidental finding of gallbladder cancer after cholecystectomy, and (b) radical

resection in patients with advanced disease. The results are dismal for radical resection in patients with advanced disease and positive hilar lymph nodes.^{67,68} For incidental gallbladder cancer beyond stage T1, reoperation with central liver resection, hilar lymphadenectomy, and evaluation of cystic duct stump is most commonly performed.^{69,70} The role of formal lobectomy or extended lobectomy as well as common bile duct resection is more controversial. In a single-center study of 23 patients undergoing attempted curative treatment by surgical resection, survival was 85% at 1 year, 63% at 2 years, and 55% at 3 years.⁷⁰ In a multicenter study encompassing 115 patients with incidentally discovered gallbladder cancer who underwent resection,⁶⁹ residual disease in the liver was identified in 46% of patients (0% of those with stage T1 disease, 10% of those with T2 tumors, and 36% of those with T3 disease). T stage also was associated with the risk of metastasis to locoregional lymph nodes (lymph node metastasis for T1 of 13%; for T2, 31%; and for T3, 46%). In another study, a German registry of incidental gallbladder cancer identified 439 patients. Patients with tumors staged as T2 or T3 after cholecystectomy had better survival if they underwent reoperation than if they were managed with observation.⁷¹ Hence, reoperation should be considered for all patients who have T2 or T3 tumors or for whom the accuracy of staging is in question.

Metastatic Colorectal Cancer

Over 50% of patients diagnosed with colorectal cancer will develop hepatic metastases during their lifetime. Traditional teaching suggested that hepatic resection for metastatic colorectal cancer to the liver, if technically feasible, should be performed only for fewer than four metastases.⁷² However, recent studies have challenged this paradigm. In a series of 235 patients who underwent hepatic resection for metastatic colorectal cancer, the 10-year survival rate of patients with four or more nodules was 29%, nearly comparable to the 32% survival rate of patients with only a solitary tumor metastasis.⁷³ In the Memorial Sloan-Kettering Cancer Center series of 98 patients with four or more colorectal hepatic metastases who underwent resection between 1998 and 2002, the 5-year actuarial survival was 33%.⁷⁴ Furthermore, improved chemotherapeutic regimens and surgical techniques have produced aggressive strategies for the management of this disease. Many groups now consider volume of future liver remnant and the health of the background liver, and not actual tumor number, as the primary determinants in selection for an operative approach.^{75,76} Hence, resectability is no longer defined by what is actually removed, but indications for hepatic resection now center on what will remain after resection.⁷⁷ Use of neoadjuvant chemotherapy, portal vein embolization, two-stage hepatectomy, simultaneous ablation, and resection of extrahepatic tumor in select patients have increased the number of patients eligible for a surgical approach.⁷⁸

Neuroendocrine Cancer (Carcinoid Tumor)

Hepatic metastases from neuroendocrine tumors have a protracted natural history and commonly are associated with debilitating endocrinopathies. Several groups have advocated an aggressive surgical approach of cytoreductive surgery, both to control symptoms and to extend survival.^{79,80} In a series of 170 patients undergoing resection of hepatic metastases from neuroendocrine tumors between 1977 and 1998 at the Mayo Clinic, overall survival was 61% and 35% at 5 and 10 years, respectively.⁸¹ There was no difference in survival between patients with carcinoid tumors and those with islet cell tumors. Major hepatectomy was performed in 91 patients (54%), and recurrence rate was 84% at 5 years. Belghiti's group has described a two-stage strategy used in 41 patients with a primary neuroendocrine tumor and synchronous bilobar liver metastases.⁸² In the first stage, the primary tumor is resected and limited resection of metastases in the left hemiliver, combined with right portal vein ligation, is performed. After 8 weeks of hypertrophy, a right or extended right hepatectomy is performed.⁸² In patients treated using this strategy, the 2-, 5-, and 8-year Kaplan-Meier overall survival rates were 94%, 94%, and 79%, respectively, and disease-free survival rates were 85%, 50%, and 26%, respectively.

Other Metastatic Tumors

Nearly every cancer has the propensity to metastasize to the liver. Historically, enthusiasm was low for resecting metastases other than those from a colorectal cancer primary. This was due in part to the recognition that many other primary cancers (such as breast cancer) represent a systemic disease when liver metastases are present. However, more recent studies have shown acceptable 5-year survival rates in the 20 to 40% range for resection of hepatic metastases from breast, renal, and other GI tumors.^{83–85} In a large study of hepatic resection for noncolorectal, nonendocrine liver metastases in 1452 patients, negative prognostic factors were nonbreast origin, age >60 years, disease-free interval of <12 months, need for major hepatectomy, performance of R2 resection, and presence of extrahepatic metastases.⁸⁶

TREATMENT OPTIONS FOR LIVER CANCER

In general, the major treatment options for liver cancer can be categorized as shown in Table 31-8. The decision making for any given patient is complex and is best managed by a multidisciplinary liver and GI tumor board. The treatments listed in Table 31-8 are not mutually exclusive, and the important point is to select the most appropriate initial treatment after a complete evaluation. In general, surveillance imaging (CT or MRI) is performed every 3 to 4 months during the first year after diagnosis to observe for response, progression, or recurrence. The treatment plan is individualized and modified according to the response of the patient.

Table 31-8 Treatment Options for Liver Cancer
Hepatic resection
Liver transplantation
Ablation techniques
• Radiofrequency ablation
• Ethanol ablation
• Cryoablation
• Microwave ablation
Regional liver therapies
• Chemoembolization/embolization
• Hepatic artery pump chemoperfusion
• Internal radiation therapy (yttrium 90 internal radiation)
External beam radiation therapy
• Stereotactic radiosurgery (CyberKnife, Trilogy, Synergy)
• Intensity-modulated radiation therapy
Systemic chemotherapy
Multimodality approach

Hepatic Resection

For primary liver cancers or hepatic metastases, hepatic resection is the gold standard and treatment of choice. Although there are anecdotal reports of long-term survival after ablation and other regional liver therapies, liver resection remains the only real option for cure. For HCC in the setting of cirrhosis, liver transplantation also offers the potential for long-term survival, albeit with the consequences of immunosuppression. Hepatic resection also has been advocated for HCC in select patients with cirrhosis before secondary liver transplantation,⁸⁷ although this approach remains controversial.⁸⁸ Many large series of patients undergoing major hepatectomy now report mortality rates of <5%.^{89–92} Previously, a 1-cm tumor margin was considered desirable; however, recent studies have reported comparable survival rates with smaller margins.^{93,94} The technical aspects of anatomic hepatic lobectomies are described later.

Liver Transplantation

The rationale supporting liver transplantation (OLT) for HCC includes the fact that most HCCs (>80%) arises in the setting of cirrhosis.^{52,61} The cirrhotic liver often does not have enough reserve to tolerate a formal resection. Also, HCC tumors are commonly multifocal and are underestimated by current CT or MRI imaging. Further, recurrence rates are high at 5 years after resection (>50%). Hence, OLT is an appealing treatment, because it removes the cancer and the cirrhotic liver that leads to HCC. Approximately 6000 liver transplantations are performed each year in the United States, with 1-year survival rates approaching 90%. In April 2008, approximately 16,400 patients were on the waiting list for liver transplantation.⁹⁵

Initial series of OLT for HCC reported in the 1990s included advanced cases of HCC, and the 5-year survival rates were only 20 to 50%.⁶¹ This compared poorly with overall 5-year survival rates of 70 to 75% for OLT in the Organ Procurement and Transplantation Network/United

Network for Organ Sharing (OPTN/UNOS) database. Mazzaferro and colleagues at Milan subsequently showed that survival rates were markedly improved when OLT was limited to patients with early-stage HCC (stage I or stage II) with one tumor \leq 5 cm, or three tumors with the largest being \leq 3 cm, along with an absence of gross vascular invasion or extrahepatic spread.^{96,97} Multiple studies have validated these findings, although some groups have proposed an expansion of the Milan criteria.^{52,61,98}

In 2002, OPTN/UNOS adopted the Model for End-Stage Liver Disease (MELD) score [a 6- to 40-point scale based on serum total bilirubin level, creatinine level, and international normalized ratio (INR)] for allocation of deceased donor liver organs in the United States. In an attempt to decrease the high mortality rate for patients with preserved liver function and progressive HCC, patients with stage II HCC were given priority points (currently 22 MELD points). This had a positive effect for HCC liver transplant candidates, leading to decreased waiting list dropout and increased transplant rates with excellent long-term outcomes.⁹⁹ The goal is to better equate death rates on the liver transplant waiting list for patients with stage II HCC with rates for patients with chronic liver disease without HCC.

Radiofrequency Ablation

In 1891, d'Arsonval discovered that radiofrequency (RF) waves delivered as an alternating electric current (>10 kHz) could pass through living tissue without causing pain or neuromuscular excitation. The resistance of the tissue to the rapidly alternating current produced heat. This discovery contributed to the development of the surgical application of electrocautery. In 1908, Beer used RF coagulation to destroy urinary bladder tumors. Cushing and Bovie later applied RF ablation to intracranial tumors. In 1961, Lounsberry studied the histologic changes of the liver after RFA in animal models. He found that RF caused local tissue destruction with uniform necrosis. In the early 1990s, two groups proposed that RFA can be an effective method for destroying unresectable malignant liver tumors.^{100,101} Both groups found that RFA produced lesions with well-demarcated areas of necrosis without viable tumor cells present. Clinical reports after short-term follow-up suggested that RFA was safe and effective in the treatment of liver tumors.^{102–104} However, Abdalla and colleagues examined data for 358 consecutive patients with colorectal liver metastases treated with curative intent over a 10-year period (1992 to 2002).¹⁰⁵ Liver-only recurrence after RFA was four times the rate after resection (44% vs. 11% of patients), and RFA alone or in combination with resection did not provide survival rates comparable to those with resection alone. Nonetheless, RFA remains a common procedure that can be performed by a percutaneous, minimally invasive laparoscopic, or open approach.^{106,107} It also has been used successfully to ablate small HCCs as a bridge to liver transplantation.¹⁰⁸ Recently, results were reported for the first randomized clinical trial involving RFA treatment for HCC in 291 Chinese patients with three or fewer HCC tumors ranging in size from 3 to 7.5 cm.¹⁰⁹ Patients were randomly assigned to treatment arms of RFA alone ($n = 100$), transarterial chemoembolization (TACE) alone ($n = 95$), or combined TACE plus RFA ($n = 96$). At a median follow-up of 28.5 months, median survival was 22 months in the RFA group, 24 months in the TACE group, and 37 months in the TACE plus RFA group. Patients treated with TACE plus RFA had significantly better overall survival than those treated with TACE alone ($P < .001$) or RFA alone ($P < .001$).

Ethanol Ablation, Cryosurgery, and Microwave Ablation

Percutaneous ethanol injection has been shown to be a safe and effective treatment for small HCCs.⁵² The ethanol usually is delivered by percutaneous injection under ultrasound or CT guidance. Percutaneous ethanol injection also is used to treat small HCC tumors as a bridge to liver transplantation in some centers to avoid patient dropout.¹¹⁰ Although cryosurgery was used in the late 1980s and 1990s for ablation of liver tumors, many have abandoned this approach in favor of RFA because of the latter's fewer side effects and ease of use. Microwave ablation is the newest thermal ablative technique and is used in the management of unresectable liver tumors to produce a coagulation necrosis. A multicenter phase II U.S. trial was recently reported using a 915-MHz microwave generator.¹¹¹ Eighty-seven patients underwent 94 ablation procedures for 224 hepatic tumors. Forty-five percent of the procedures were performed using an open approach, 7% laparoscopically, and 48% percutaneously. The average tumor size was 3.6 cm (range, 0.5 to 9.0 cm). At a mean follow-up of 19 months, 47% of the patients were alive with no evidence of disease. Local recurrence at the ablation site occurred in 2.7% of tumors, and regional recurrence occurred in 43% of patients. There were no procedure-related deaths. Further studies are required to define the role of this technology in relation to the other ablation options available.

Chemoembolization and Hepatic Artery Pump Chemoperfusion

Chemoembolization is the process of injecting chemotherapeutic drugs combined with embolization particles into the hepatic artery that supplies the liver tumor using a percutaneous, transfemoral approach. It is most commonly used for treatment of unresectable HCC. Two randomized trials as well as a meta-analysis have shown a survival benefit with chemoembolization.^{112–114} In a study by Lo and colleagues, 80 Asian patients were randomly assigned to receive either chemoembolization with cisplatin in lipiodol or symptomatic treatment only.¹¹² Chemoembolization resulted in a marked tumor response, and the actuarial survival was significantly better in the chemoembolization group (1- and 3-year survival of 57% and 26%, respectively) than in the control group (1- and 3-year survival of 32% and 3%, respectively). In another randomized trial, a Barcelona group compared chemoembolization with doxorubicin vs. supportive care and showed that chemoembolization significantly improved survival.¹¹³ Finally, in a large prospective cohort study of 8510 patients with unresectable HCC in Japan who received transcatheter arterial lipiodol chemoembolization, the 5-year survival rate was 26% and median survival time was 34 months.¹¹⁵ The TACE-related mortality rate after the initial therapy was 0.5%. Complications of TACE include liver dysfunction or liver failure, hepatic abscess, and hepatic artery thrombosis. Recent studies also have shown promising results for chemoembolization with drug-eluting beads (doxorubicin) in treatment of HCC.¹¹⁶

In the 1990s hepatic artery pump chemoperfusion with floxuridine for colorectal cancer metastases to the liver was used both for treatment of inoperable disease and in the adjuvant setting.¹¹⁷ However, in the modern era of improved chemotherapeutic options, this treatment modality is seldom used outside of a clinical trial.

Yttrium 90 Microspheres

Selective internal radioembolization is a promising new treatment modality for patients with inoperable primary or metastatic liver tumors. The treatment is a minimally invasive transcatheter therapy in which radioactive microspheres are infused into the hepatic arteries via a transfemoral percutaneous approach. The yttrium 90 microspheres are directly injected into the hepatic artery branches that supply the tumor. Once infused, the microspheres deliver doses of high-energy, low-penetration radiation selectively to the tumor. The main indications are inoperable HCC¹¹⁸ and colorectal cancer hepatic metastases for which systemic chemotherapy has failed.^{119,120} In a recent study involving 137 patients with unresectable chemorefractory liver metastases treated with radioembolization, there was a response rate of 42.8% (2.1% complete response, 40.7% partial response) according to World Health Organization criteria.¹²⁰ One-year survival rate was 47.8% and 2-year survival rate was 30.9%. Median survival was 457 days for patients with colorectal tumor metastases, 776 days for those with neuroendocrine tumor metastases, and 207 days for those with noncolorectal, nonneuroendocrine tumor metastases. The two products available in the United States are SIR-Spheres and TheraSphere.

Stereotactic Radiosurgery

Although stereotactic radiosurgery (with CyberKnife and other systems) is in widespread use for brain and spinal tumors, body application to HCC or metastatic liver tumors has only recently occurred. In a phase I study, 31 patients with unresectable HCCs and 10 with unresectable cholangiocarcinomas completed a six-fraction course of stereotactic body radiotherapy.¹²¹ The treatment was well tolerated, and median survival was 11.7 and 15.0 months for the two groups, respectively. A similar safety profile was observed in a study in the Netherlands.¹²² Further clinical trials are required to define the future role of stereotactic radiosurgery in treatment of HCC and metastatic tumors.

Systemic Chemotherapy

A complete review of chemotherapy options for primary and metastatic liver cancers is beyond the scope of this chapter. For treatment of HCC, a phase II trial of the multikinase inhibitor sorafenib showed some efficacy,¹²³ and therefore a phase III randomized international multicenter trial (Sorafenib HCC Assessment Randomized Protocol, or SHARP) was initiated enrolling 602 patients with Child's class A cirrhosis and inoperable HCC. At interim analysis, the trial was discontinued because a survival benefit was found in the treatment group. Llovet and associates presented the findings at the 2007 American Society of Clinical Oncology annual meeting, which showed that sorafenib leads to a 44% improvement in overall survival compared with placebo.¹²⁴ The median overall survival for patients receiving sorafenib was 10.7 months vs. 7.9 months for patients in the control arm. Based on these findings, sorafenib received accelerated Food and Drug Administration approval for the treatment of advanced unresectable HCC. Future studies will likely examine the role of sorafenib in

combination with other treatment modalities.

HEPATIC RESECTION SURGICAL TECHNIQUES

Nomenclature

Due to the confusion in language with regard to anatomic descriptions of hepatic resections, a common nomenclature was introduced at the International Hepato-Pancreato-Biliary Association meeting in Brisbane, Australia, in 2000 (Table 31-9).^{125,126} The goal was to provide universal terminology for liver anatomy and hepatic resections, because there was much overlap among the designations for hepatic lobes, sections, sectors, and segments used by surgeons worldwide (Fig. 31-24). The most common or prevailing anatomic pattern was used as the basis for naming liver anatomy, and the surgical procedure nomenclature adopted for hepatic resections was based on the assigned anatomic terminology.¹²⁷ Adoption of a common language should enable hepatic surgeons to better understand and interpret liver surgery publications from different continents and disseminate their knowledge to the next generation of hepatobiliary surgeons. Nonetheless, even today the literature is full of both old and new liver resection terminology, so the surgeon in training must be familiar with all the various classifications.

Table 31-9 Brisbane 2000 Liver Terminology	
Older hepatic resection terminology	Brisbane 2000 hepatic resection terminology
Right hepatic lobectomy	Right hepatectomy or right hemihepatectomy
Left hepatic lobectomy	Left hepatectomy or left hemihepatectomy
Right hepatic trisegmentectomy	Right trisectionectomy or extended right hepatectomy (or hemihepatectomy)
Left hepatic trisegmentectomy	
Left lateral segmentectomy	Left trisectionectomy or extended left hepatectomy (or hemihepatectomy)
Right posterior lobectomy	
Caudate lobectomy	Left lateral sectionectomy or bisegmentectomy 2, 3
	Right posterior sectionectomy
	Caudate lobectomy or segmentectomy 1
	Alternative "sector" terminology
	Right anterior sectorectomy
	Right posterior sectorectomy or right lateral sectorectomy
	Left medial sectorectomy or left paramedian sectorectomy (bisegmentectomy 3, 4)
	Left lateral sectorectomy (segmentectomy 2)

Fig. 31-24.

Hepatic resection nomenclature and anatomy. Hepatic segments removed in the formal major hepatic resections are indicated. The International Hepato-Pancreato-Biliary Association (IHPBA) Brisbane 2000 terminology also is presented. IVC = inferior vena cava; LHV = left hepatic vein; MHV = middle hepatic vein; RHV = right hepatic vein.

Techniques and Devices for Dividing the Hepatic Parenchyma

Hepatic resection surgery has evolved over the past 50 years. A better understanding of liver anatomy and physiology, coupled with improved anesthesia techniques and widespread use of intraoperative ultrasound, has led to virtually "bloodless" liver surgery in the modern era (the year 2000 to the present). Innovations in technology have expanded the list of liver parenchymal transection devices^{128–130} and hemostatic agents (Table 31-10). Suffice it to say that each device or agent has a learning curve and that undoubtedly every experienced hepatic surgeon has his or her personal preferences.

Table 31-10 Techniques and Devices for Dividing Liver Parenchyma and Achieving Hemostasis
Blunt fracture and clips
Monopolar cautery (Bovie)
Bipolar cautery
Argon beam coagulator
CUSA ultrasonic dissector
Hydro-Jet water-jet dissector
Harmonic Scalpel, AutoSonix ultrasonic transector-coagulator
LigaSure tissue fusion system
SurgRx EnSeal tissue sealing and transection system
Gyrus PK cutting forceps
Endovascular staplers
TissueLink sealing devices
Habib 4X Laparoscopic sealer
InLine bipolar linear coagulator
Topical agents (fibrin glues, Surgicel, Gelfoam, Avitene, Tisseel, Floseal, Crosseal)

One major advance was the application of vascular stapling devices for division of the hepatic and portal veins.^{131–133} Based on early reports of successful stapling of extrahepatic vessels, stapling devices have now been used in the parenchymal transection phase, which remains a source of potential blood loss due to back bleeding from the middle hepatic vein.^{134,135} One advantage of the stapling technique

is the speed with which the transection can be performed, which minimizes surface bleeding and period of ischemia for the remnant liver. However, a major disadvantage of the stapling technique is the cost of multiple stapler cartridges. This is balanced by the decreased expenses reported with avoidance of ICU admission and blood transfusion, as well as shortened operating room time. Another consideration in the use of staplers for parenchymal transection is the potential for bile leaks. However, in a large series of 101 consecutive right hemihepatectomies performed using the stapling technique, there was only one reported bile leak (1%), which sealed after ERCP.¹³⁵

Steps in Commonly Performed Hepatic Resections

A fundamental understanding of hepatic anatomy is vital for any surgeon with the desire to perform hepatobiliary surgery. Each hepatic resection surgery can be broken down into a series of orderly steps. The key to being a proficient hepatic surgeon is not to move one's hands swiftly but rather to accomplish the operation by completing the steps in an orchestrated fashion. The surgeon should not move to step 5 until steps 1 through 4 are complete. Mastery of the operative steps coupled with knowledge of liver anatomy and the common anatomic variants provides the foundation for safe hepatic surgery. (The same basic principle can be applied to any complex surgical procedure.) There are many different techniques and sequences for accomplishing each of the anatomic (and nonanatomic) hepatic operations. The authors present their preferred approach in a stepwise fashion for right hepatic lobectomy (right hemihepatectomy), left hepatic lobectomy (left hemihepatectomy), and left lateral segmentectomy (left lateral sectionectomy). Provision of a detailed approach for every type of liver resection is beyond the scope of this chapter, and readers are referred to several excellent descriptions.¹³⁶

STEPS COMMON TO ALL OPEN MAJOR HEPATIC RESECTIONS

1. Make the skin incision—right subcostal with midline extension.
2. Open the abdomen and place a fixed table retractor (Thompson).
3. Take down the round and falciform ligaments, and expose the anterior surface of the hepatic veins.
4. For a left hepatectomy, divide the left triangular ligament; for a right hepatectomy, mobilize the right lobe from the right coronary and triangular ligaments.
5. Open the gastrohepatic ligament and assess for replaced hepatic arteries.
6. Perform an open cholecystectomy; leave the gallbladder with the cystic duct intact (until end of case).
7. Perform liver ultrasound and confirm the operation to be performed.

RIGHT HEPATIC LOBECTOMY (RIGHT HEPATECTOMY OR HEMIHEPATECTOMY)

8. Mobilize the liver from the inferior vena cava (IVC) in "piggyback" fashion; ligate the short hepatic veins up to the right hepatic vein (RHV).
9. Perform a right hilar dissection—gently lower the hilar plate, then doubly ligate and divide the right hepatic artery (RHA), staying high on the right side of the common bile duct.
10. Divide the inflow (right portal vein, or RPV) with a vascular stapler (white 2.5-mm cartridge), after taking the small lateral portal vein branch off the RPV to the caudate/right lobe.
11. Divide the outflow (right hepatic vein, or RHV) with the vascular stapler (white cartridge).
12. Notch or divide the caudate process crossing to the right hepatic lobe.
13. Make a counterincision at the right base of the gallbladder fossa; pass a large Kelly clamp deep to the hilar plate and emerge anterior to the IVC; place an umbilical tape in the tunnel behind the hilar plate.
14. Divide the right hilar plate with right hepatic ducts using the vascular stapler (white cartridge).
15. Repeat ultrasound and confirm the transection plane, staying just to the right of the middle hepatic vein (MHV).
16. Bovie down approximately 1 cm in the liver parenchyma, then switch to a LigaSure device.
17. Continue parenchymal division with a LigaSure device until segment V/VIII MHV branches are encountered.
18. Initiate the Pringle maneuver around the porta hepatis (Potts loop cinched up with right angle clamp).
19. Complete the parenchymal slice with sequential crushing vascular stapling (pretunnel with a large Kelly clamp), usually 4 to 6 minutes for the entire slice.
20. Check the cut edge for surgical bleeding; place a figure-of-eight suture if bleeding is encountered.

21. Release the Pringle maneuver and dry up the cut edge with a saline-cooled radiofrequency sealant device.
22. Inspect the IVC and right retroperitoneal space for hemostasis.
23. Perform completion ultrasound to confirm left portal vein (LPV) inflow and hepatic vein outflow.
24. Shoot a saline cholangiogram via the cystic duct stump to confirm that the cut edge is watertight.
25. Shoot a contrast fluoroscopic cholangiogram (optional) to confirm the patency of the proximal left hepatic duct and distal common bile duct; secure the cystic duct stump in the usual manner.
26. Tack the proximal falciform ligament back to the diaphragm side with a single figure-of-eight suture.
27. Place a Jackson-Pratt drain in the right subphrenic space and close the abdomen (Fig. 31-25).

Fig. 31-25.

Completed right hepatic lobectomy (right hepatectomy) with the right portal vein, right hepatic artery, and right bile duct ligated and divided. The right hepatic vein is ligated and divided with a vascular stapler. Middle hepatic vein branches inside the liver are divided with the vascular stapler.

Comments

Although some liver surgeons advocate a one-step division of the entire intrahepatic Glissonian pedicle as described by Launois and Jamieson,¹³⁷ it is the authors' preference to divide the RHA and RPV in an extrahepatic fashion and restrict the intrahepatic maneuver for division of the right hilar plate with the right hepatic ducts. As for the transection plane, the key is to perform accurate ultrasound visualization and mapping of the MHV and to stay just to the right of it. Weaving in and out or bisecting the MHV can lead to torrential back bleeding. Also, for bulky right lobe tumors adherent to the diaphragm or retroperitoneum, an anterior approach with division of the parenchyma can be performed before right lobe mobilization.^{138,139} The anterior approach also can be facilitated by use of the "hanging maneuver."¹⁴⁰

LEFT HEPATIC LOBECTOMY (LEFT HEPATECTOMY OR HEMI HEPATECTOMY)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory left hepatic artery (LHA) if present.
10. Clamp the round ligament (ligament teres) and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Dissect the left hilum at the base of the umbilical fissure and lower the hilar plate anterior to the left portal pedicle.
13. Incise the peritoneum overlying the hilum from the left side and doubly ligate the LHA (after test clamping and confirming a palpable pulse in the RHA).
14. Dissect the portal vein at the base of the umbilical fissure (it will take a nearly 90-degree bend from the transverse to the umbilical portion).
15. Divide the LPV with a vascular stapler (white cartridge), staying just distal to (beyond) the take-off of the caudate inflow branch (if the caudate lobe is being preserved).
16. Divide the ligamentum venosum (Arantius' ligament) caudally.
17. Make a counterincision in segment IVB 1 cm above the base of the umbilical fissure and pass a blunt Kelly clamp behind the left hilar plate, aiming for the left lower quadrant and exiting just anterior (and superficial) to the caudate lobe.
18. Place an umbilical tape in the tunnel behind the left hilar plate.
19. Divide the left hilar plate and left hepatic duct with a vascular stapler (white cartridge).
20. Fold the left lateral segment up and back to the right, exposing the window at the base of the left hepatic vein (LHV) as it enters the IVC. This is facilitated by dividing any loose areolar tissue overlying the ligamentum venosum (Arantius' ligament), which is divided proximally.
21. Pass a large, blunt right-angle clamp in the window between the RHV and the MHV, and hug the back of the MHV, aiming for the deep edge of the LHV. *Do not force it or make a hole in the IVC or MHV.*
22. Pass an umbilical tape through this window and divide the LHV and MHV common trunk with a vascular stapler.
23. Repeat ultrasound and confirm the transection plane on the anterior surface, staying close to the demarcated line. Do not bisect the MHV as it passes tangentially from the left to the right lobe.
24. Bovie down approximately 1 cm in the liver parenchyma, then switch to a LigaSure device.
25. Continue parenchymal division with the LigaSure device until segment V/VIII MHV branches are encountered.
26. Initiate a Pringle maneuver around the porta hepatis (Potts loop cinched up with right angle clamp).
27. Complete the parenchymal slice with sequential crushing vascular stapling (pretunnel with a large Kelly clamp). As the slice is deepened, gradually carry the transection down to exit just anterior to the caudate at the level of Arantius' ligament.
28. Check the cut edge for surgical bleeding; place a figure-of-eight suture if bleeding is encountered.
29. Release the Pringle maneuver and dry up the cut edge with a saline-cooled radiofrequency sealant device.
30. Perform completion ultrasound to confirm RPV inflow and RHV outflow.
31. Shoot a saline cholangiogram via the cystic duct stump to confirm that the cut edge is watertight.
32. Shoot a contrast fluoroscopic cholangiogram (optional) to confirm the patency of the proximal right hepatic duct and the distal common bile duct; secure the cystic duct stump in the usual manner.
33. Place a Jackson-Pratt drain in the left subphrenic space and close the abdomen (Fig. 31-26).

Fig. 31-26.

Completed left hepatic lobectomy (left hepatectomy) resecting segments II, III, and IV.

Comments

Because the right posterior duct comes off the left hepatic duct in approximately 20% of cases (see Fig. 31-9) and the right anterior duct comes off the left hepatic duct in approximately 5% of cases,⁶ it is vital to divide the left hepatic duct at the base of the umbilical fissure and not more centrally in the hilum as it bifurcates. If the left hepatic duct were divided as it appears to bifurcate from the right hepatic duct, then approximately 20 to 25% of the time either the right posterior or right anterior duct would be transected. After the left hepatic duct is divided as described earlier (steps 17 through 19), the liver parenchyma is scored and divided horizontally approximately 1 cm above the left hilum; the surgeon thus assumes that an aberrant right anterior or posterior duct is coming off the left hepatic duct in the hilum and preserves it. Then as the parenchymal transection reaches the left side of the gallbladder fossa, the transection plane turns vertical to run parallel to Cantlie's line (or the left edge of the gallbladder bed). The left lobe of the liver will be well demarcated at this point (after the vascular inflow has been divided), which guides the transection plane on the anterior surface. In general, the transection plane should be close to the demarcation line to minimize the amount of devascularized liver remaining. When dividing the LHV and MHV, the surgeon should keep in mind that they have a common trunk approximately 90% of the time. If it is not easy to open the window deep to the MHV and LHV, then division of the MHV and LHV can be accomplished after the parenchymal transection.

LEFT LATERAL SEGMENTECTOMY (LEFT LATERAL SECTIONECTOMY)

8. Widely open the gastrohepatic ligament flush with the undersurface of the left lateral section and the caudate lobe.
9. Doubly ligate and divide a replaced or accessory LHA if present.
10. Clamp the round ligament and pull it anteriorly as a handle to expose the left hilum.
11. Divide any existing parenchymal bridge between segments III and IVB.
12. Carry the dissection down from the end of the round ligament, and the segment III pedicle will be encountered.
13. Incise the peritoneal reflection on the left side of the round ligament as it inserts into the umbilical fissure. This will facilitate encircling the segment III and II pedicles, which can be divided separately with a vascular stapler. When encircling the segment II

pedicle, take care to avoid injury to the caudate inflow vessels coming off the LPV.

14. Divide the liver parenchyma, staying flush on the left side of the falciform ligament using a Bovie cautery and/or LigaSure device.

15. Divide the LHV inside the liver parenchyma with a vascular stapler (white cartridge) as the parenchymal transection is complete.

16. A Pringle maneuver usually is not required for a left lateral sectionectomy because complete devascularization occurs before transection and little back bleeding is encountered.

Comments

If the segment III and II LHA branches are large, they can be individually ligated in the left hilum before the pedicles (with portal vein and hepatic duct branches) are taken. If the tumor is more peripheral in the left lateral segment, then the segment III and II pedicles can be divided with a vascular stapler inside the liver during the parenchymal transection.

Pringle and Ischemic Preconditioning

Pringle described clamping of the portal triad a century ago in the landmark paper "Notes on the Arrest of Hepatic Hemorrhage Due to Trauma."⁴ Although the Pringle maneuver was initially described for controlling bleeding due to traumatic liver injury, it is commonly used during elective hepatic resections.^{141,142} The goal is to minimize blood loss and hypotension, which add significant morbidity to the operation. Further, intraoperative blood transfusion has been shown to be an independent risk factor for increased postoperative infection as well as worse patient survival in some studies. Therefore, all efforts should be made to minimize blood loss during hepatic resection.

Although the liver has been shown to tolerate up to 1 hour of warm ischemia, some technical variations of the Pringle maneuver include intermittent vascular occlusion with cycles of approximately 15 minutes on and 5 minutes off. Experimental and clinical studies have demonstrated the efficacy of intermittent vascular occlusion in decreasing ischemia/reperfusion injury compared with continuous vascular occlusion, with less elevation of postoperative liver enzyme levels.¹⁴³ Another variation is selective hemihepatic vascular occlusion, which can reduce the severity of visceral congestion and total liver ischemia. In one prospective trial of total vs. selective portal triad clamping, both techniques of inflow clamping were found to be equally effective for patients with normal livers, but greater liver damage was observed with total inflow occlusion in patients with cirrhotic livers.¹⁴⁴

In an attempt to decrease the ischemic damage associated with inflow occlusion, some hepatic surgeons have advocated the use of ischemic preconditioning.¹⁴⁵ *Ischemic preconditioning* refers to the brief interruption of blood flow to an organ, followed by a short reperfusion period, and then a more prolonged period of ischemia. In a randomized clinical trial involving 100 patients undergoing major hepatic resection, Clavien and colleagues reported significantly less liver injury in the group who received ischemic preconditioning with a 10-minute clamp, a 10-minute reperfusion, and then a 30-minute clamp than in those who received a 30-minute clamp alone.¹⁴⁶ Patients with steatosis also were especially protected by ischemic preconditioning, and the mechanism was shown to be related in part to preservation of the adenosine triphosphate content of liver tissue.

Preoperative Portal Vein Embolization

The observation that tumor thrombosis of a major portal vein branch induced ipsilateral lobar atrophy and contralateral lobe hypertrophy led to the concept of intentional preoperative portal vein embolization (PVE) to induce compensatory hypertrophy of the remnant liver. This procedure was first described in the 1980s and is accomplished via a percutaneous, transhepatic route.^{147,148} Numerous studies have subsequently confirmed that PVE is effective in inducing hypertrophy of nonembolized hepatic segments.^{59,149} PVE usually is performed in the setting of a planned right or left trisectionectomy or extended hepatic lobectomy when it is thought that the patient's remnant liver will be too small to support liver function. The future liver remnant volume (e.g., the volume of segments II, III, and I) in a patient undergoing a planned right trisectionectomy can be directly measured by helical CT and then divided by the total estimated liver volume to calculate the percentage of the future liver remnant. If the future liver remnant is thought to be too small, then PVE should be considered to increase the size of the future liver remnant.¹⁵⁰ In general, surgery is planned approximately 4 weeks after PVE to allow adequate time for hypertrophy.

There is no universal agreement on what constitutes a future liver remnant adequate to avoid postoperative liver failure. It is thought that 25 to 30% of the total liver volume is adequate in patients with normal background liver.¹⁵¹ Vauthey and associates reported that major postoperative complications were increased when the estimated future liver remnant was <25%.¹⁵² Farges and colleagues conducted a prospective study to assess the benefits of PVE before right hepatectomy. They demonstrated that PVE had no beneficial effect on the postoperative course in patients with normal livers but significantly reduced postoperative complications in patients with chronic liver diseases.¹⁵³ A larger remnant may be necessary even in patients with normal livers when a complex hepatectomy is planned or when the background liver is steatotic.¹⁵⁴ This is especially relevant with the rise in fatty liver disease. A larger remnant may also be needed when patients have received preoperative chemotherapy. Some have suggested that 40% of the total hepatic volume should remain to minimize postoperative complications in patients who have underlying liver disease or who have received preoperative chemotherapy for colorectal cancer metastases.^{155,156} In a recent study encompassing 112 patients who underwent PVE, major complications, hepatic insufficiency, length of hospital stay, and 90-day mortality rate were significantly greater in patients with a standardized future liver remnant of $\leq 20\%$ or a degree of hypertrophy of <5% than in patients with higher values.¹⁵⁷ In another study, the authors performed PVE during neoadjuvant chemotherapy for colorectal cancer metastases. After a median wait of 30 days after PVE, patients receiving neoadjuvant chemotherapy showed median liver growth of 22% in the contralateral (nonembolized) lobe compared with 26% for those not receiving chemotherapy (not a statistically significant difference), which indicated that liver growth occurs after PVE even when cytotoxic chemotherapy is administered.¹⁵⁸ PVE-related complications occur at a relatively low rate and include bleeding, hemobilia, liver abscess, incomplete embolization, and small bowel obstruction.

Staged Hepatectomy and Repeat Hepatic Resection for Recurrent Liver Cancer

A two-stage hepatectomy is a sequential resection strategy to remove all metastatic liver tumors when it is impossible to resect all disease in a single operative procedure. The first-stage hepatectomy usually consists of clearance of the left hemiliver by nonanatomic resection, followed by right portal vein ligation or embolization to induce left lobe hypertrophy.^{159,160} This is followed by a second-stage major right hepatectomy or extended right hepatectomy to resect the right liver metastases. This approach is most commonly used in cases of initially unresectable colorectal hepatic metastases and has yielded very good results.¹⁶⁰

The majority of patients undergoing hepatic resection for colorectal cancer metastases experience a recurrence. For those with limited disease recurrence confined to the liver, repeat hepatectomy is a reasonable option and can be performed with low morbidity and mortality in experienced hands.¹⁶¹ In one study, 126 patients who underwent a second liver resection for colorectal cancer metastases had 1-, 3-, and 5-year survival rates of 86%, 51%, and 34%, respectively. By multivariate analysis, the presence of more than one lesion and a tumor size of >5 cm were independent prognostic indicators of reduced survival.¹⁶² In another study, 40 patients underwent a second hepatectomy for liver metastases from colorectal cancer and experienced a survival benefit similar to that from the first hepatectomy; however, the results suggested that this approach should be limited to those patients who do not have extrahepatic disease and for whom >1 year has elapsed since the first operation.¹⁶³ A meta-analysis of 21 studies examining clinical outcomes after first and second liver resections for colorectal cancer metastases showed that repeat hepatectomy was safe and provided a survival benefit equal to that from the first liver resection.¹⁶⁴

Repeat hepatectomy also has been performed in patients with HCC. Nakajima and colleagues reported on follow-up of 94 patients who underwent curative liver resection for HCC from 1991 to 1996.¹⁶⁵ Of these, 57 patients had isolated recurrent disease in the liver. Twelve of these 57 patients underwent repeat hepatic resection, whereas the other 45 patients received ablation therapy. The overall survival rate in those undergoing a second hepatectomy was 90% at 2 years; however, the disease-free survival rate was only 31% at 2 years, significantly lower than the 62% rate after initial hepatectomy. Likewise, in another group of 84 patients who underwent second hepatectomy for recurrent HCC, the overall 5-year survival rate was 50%, but the recurrence-free survival rate was only 10%.¹⁶⁶ In a report of 67 patients undergoing a second resection for HCC, overall 1-, 3-, and 5-year survival rates were 93%, 70%, and 56%, respectively.¹⁶⁷ Multivariate analysis showed that absence of portal invasion at the second resection, single HCC at primary hepatectomy, and disease-free interval of ≥ 1 year after primary hepatectomy were independent prognostic factors after the second resection.

LAPAROSCOPIC LIVER RESECTION

Laparoscopic liver surgery has expanded from simple unroofing of hepatic cysts to resection of peripheral benign lesions to formal anatomic lobectomies for malignancy and more recently to laparoscopic hepatectomy for live donor liver transplantation. This evolution can be attributed largely to advances in technology as well as to a better understanding of hepatic anatomy and physiology. The result is a growing spectrum of hepatic lesions that can potentially be treated with a minimally invasive surgical approach. There is general agreement that surgeons getting started with the techniques should begin with cases involving giant hepatic cysts and peripheral (segment II and III or segment V and VI) benign lesions (Fig. 31-27).^{168–171} Then, with experience, more difficult cases can be taken on, including cirrhotic livers, malignancies, and anatomic resections.^{171–174} Large central lesions and bulky right lobe lesions with hepatic vein, IVC, or proximal hilar involvement are best addressed through an open approach. Also, there is consensus that laparoscopic liver resection should be performed by surgeons who are experienced in both open hepatic resection surgery and minimally invasive surgery.¹⁷¹ Intraoperative laparoscopic liver ultrasonography is imperative to identify lesions and major vasculature to guide the operation. Technologies used to facilitate the parenchymal transection include the bipolar cautery, CUSA ultrasonic dissector, Harmonic Scalpel, LigaSure tissue fusion system, TissueLink wound-sealing devices, Habib 4X Laparoscopic sealer, SurgRx EnSeal sealer, and vascular stapling devices. These devices can be used for precoagulation, transection, and hemostasis, with each device having its strengths and weaknesses.

Laparoscopic resection of a giant right lobe hepatic cyst. Preoperative and 1-year postoperative computed tomographic (CT) images show the liver before and after laparoscopic removal of the cyst.

Results with laparoscopic liver resections have been excellent. Advantages of laparoscopic liver resection include decreased postoperative pain, faster return of GI function, shorter length of hospital stay, and quicker recovery time.¹⁷⁵ Although no randomized trials of laparoscopic liver resection for cancer have been performed, studies of laparoscopic surgery for HCC and colorectal cancer metastases yield overall and disease-free survival rates after short- and medium-term follow-up that are comparable to those for open surgical series.^{176–178} A meta-analysis of eight nonrandomized studies (409 resections) compared laparoscopic hepatic resection (165 cases) with open resection (244 cases).¹⁷⁹ When matched for the presence of cancer and extent of resection, the laparoscopic cases showed no difference in oncologic clearance (margins), overall 5-year survival (61% for laparoscopic vs. 62% for open), or 5-year disease-free survival (31% for laparoscopic vs. 29% for open). The largest series reported to date consists of 335 hepatic resections, of which 105 were for malignancy.¹⁷¹ Importantly, there was no perioperative mortality and no episodes of tumor seeding. In addition to the laparoscopic hepatic surgery for certain benign lesions and malignant tumors, Cherqui and colleagues described laparoscopic living-donor hepatectomy for liver transplantation in children,¹⁸⁰ and Koffron and colleagues recently reported laparoscopically assisted right lobe donor hepatectomy.¹⁸¹

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 32. Gallbladder and the Extrahepatic Biliary System >

KEY POINTS

1. The physiology of the gallbladder and sphincter of Oddi are regulated by a complex interplay of hormones and neuronal inputs designed to coordinate bile release with food consumption. Dysfunctions related to this activity are linked to the development of gallbladder pathologies described in this chapter.
2. In Western countries, the most common type of gallstones are cholesterol stones. The pathogenesis of these stones relates to supersaturation of bile with cholesterol and subsequent precipitation.
3. The main risk factor for gallbladder disease in Western countries is cholelithiasis. The main complications include cholecystitis, choledocholithiasis, cholangitis, and biliary pancreatitis. In addition, cholelithiasis plays the role as the major risk factor for the development of gallbladder cancer.
4. Laparoscopic cholecystectomy has been demonstrated to be a safe and effective alternative to open cholecystectomy and has become the treatment of choice for symptomatic gallstones. Knowledge of the various anatomic anomalies of the cystic duct and artery is helpful in guiding the dissection of these structures as well as avoiding injury to the common bile duct during cholecystectomy.
5. Common bile duct injuries, although uncommon, can be devastating to patients. Proper exposure of Calot's triangle and careful identification of the anatomic structures are keys to avoiding these injuries. Once a bile duct injury is diagnosed, the best outcomes are seen at large referral centers with experienced biliary surgeons.
6. Carcinoma of the gallbladder and bile duct generally have a poor prognosis because patients usually present late in the disease process and have poor response to chemo and radiation therapies. Surgery offers the best chance for survival and has good long-term survival in patients with early-stage disease.

ANATOMY

Gallbladder

The gallbladder is a pear-shaped sac, about 7 to 10 cm long, with an average capacity of 30 to 50 mL. When obstructed, the gallbladder can distend markedly and contain up to 300 mL.¹ The gallbladder is located in a fossa on the inferior surface of the liver. A line from this fossa to the inferior vena cava divides the liver into right and left liver lobes. The gallbladder is divided into four anatomic areas: the fundus, the corpus (body), the infundibulum, and the neck. The fundus is the rounded, blind end that normally extends 1 to 2 cm beyond the liver's margin. It contains most of the smooth muscles of the organ, in contrast to the body, which is the main storage area and contains most of the elastic tissue. The body extends from the fundus and tapers into the neck, a funnel-shaped area that connects with the cystic duct. The neck usually follows a gentle curve, the convexity of which may be enlarged to form the infundibulum or Hartmann's pouch. The neck lies in the deepest

part of the gallbladder fossa and extends into the free portion of the hepatoduodenal ligament (Fig. 32-1).

Fig. 32-1.

Anterior aspect of the biliary anatomy. a = right hepatic duct; b = left hepatic duct; c = common hepatic duct; d = portal vein; e = hepatic artery; f = gastroduodenal artery; g = left gastric artery; h = common bile duct; i = fundus of the gallbladder; j = body of gallbladder; k = infundibulum; l = cystic duct; m = cystic artery; n = superior pancreaticoduodenal artery. Note: the situation of the hepatic bile duct confluence anterior to the right branch of the portal vein, the posterior course of the right hepatic artery behind the common hepatic duct.

The same peritoneal lining that covers the liver covers the fundus and the inferior surface of the gallbladder. Occasionally, the gallbladder has a complete peritoneal covering, and is suspended in a mesentery off the inferior surface of the liver and, rarely, it is embedded deep inside the liver parenchyma (an intrahepatic gallbladder).

The gallbladder is lined by a single, highly folded, tall columnar epithelium that contains cholesterol and fat globules. The mucus secreted into the gallbladder originates in the tubuloalveolar glands found in the mucosa lining the infundibulum and neck of the gallbladder, but are absent from the body and fundus. The epithelial lining of the gallbladder is supported by a

lamina propria. The muscle layer has circular longitudinal and oblique fibers, but without well-developed layers. The perimuscular subserosa contains connective tissue, nerves, vessels, lymphatics, and adipocytes. It is covered by the serosa except where the gallbladder is embedded in the liver. The gallbladder differs histologically from the rest of the GI tract in that it lacks a muscularis mucosa and submucosa.

The cystic artery that supplies the gallbladder is usually a branch of the right hepatic artery (>90% of the time). The course of the cystic artery may vary, but it nearly always is found within the hepatocystic triangle, the area bound by the cystic duct, common hepatic duct, and the liver margin (triangle of Calot). When the cystic artery reaches the neck of the gallbladder, it divides into anterior and posterior divisions. Venous return is carried either through small veins that enter directly into the liver or, rarely, to a large cystic vein that carries blood back to the portal vein. Gallbladder lymphatics drain into nodes at the neck of the gallbladder. Frequently, a visible lymph node overlies the insertion of the cystic artery into the gallbladder wall. The nerves of the gallbladder arise from the vagus and from sympathetic branches that pass through the celiac plexus. The preganglionic sympathetic level is T8 and T9. Impulses from the liver, gallbladder, and the bile ducts pass by means of sympathetic afferent fibers through the splanchnic nerves and mediate the pain of biliary colic. The hepatic branch of the vagus nerve supplies cholinergic fibers to the gallbladder, bile ducts, and the liver. The vagal branches also have peptide-containing nerves containing agents such as substance P, somatostatin, enkephalins, and vasoactive intestinal polypeptide.²

Bile Ducts

The extrahepatic bile ducts consist of the right and left hepatic ducts, the common hepatic duct, the cystic duct, and the common bile duct or choledochus. The common bile duct enters the second portion of the duodenum through a muscular structure, the sphincter of Oddi.³

The left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join to form a common hepatic duct, close to their emergence from the liver. The common hepatic duct is 1 to 4 cm in length and has a diameter of approximately 4 mm. It lies in front of the portal vein and to the right of the hepatic artery. The common hepatic duct is joined at an acute angle by the cystic duct to form the common bile duct.

The length of the cystic duct is quite variable. It may be short or absent and have a high union with the hepatic duct, or long and run parallel, behind, or spiral to the main hepatic duct before joining it, sometimes as far as at the duodenum. Variations of the cystic duct and its point of union with the common hepatic duct are surgically important (Fig. 32-2). The segment of the cystic duct adjacent to the gallbladder neck bears a variable number of mucosal folds called the *spiral valves of Heister*. They do not have any valvular function but may make cannulation of the cystic duct difficult.

Fig. 32-2.

Variations of the cystic duct anatomy. **A.** Low junction between the cystic duct and common hepatic duct. **B.** Cystic duct adherent to the common hepatic duct. **C.** High junction between the cystic and the common hepatic duct. **D.** Cystic duct drains into right hepatic duct. **E.** Long cystic duct that joins common hepatic duct behind the duodenum. **F.** Absence of cystic duct. **G.** Cystic duct crosses posterior to common hepatic duct and joins it anteriorly. **H.** Cystic duct courses anterior to common hepatic duct and joins it posteriorly.

The common bile duct is about 7 to 11 cm in length and 5 to 10 mm in diameter. The upper third (supraduodenal portion) passes downward in the free edge of the hepatoduodenal ligament, to the right of the hepatic artery and anterior to the portal vein. The middle third (retroduodenal portion) of the common bile duct curves behind the first portion of the duodenum and diverges laterally from the portal vein and the hepatic arteries. The lower third (pancreatic portion) curves behind the head of the pancreas in a groove, or traverses through it and enters the second part of the duodenum. There, the pancreatic duct frequently joins it. The common bile duct runs obliquely downward within the wall of the duodenum for 1 to 2 cm before opening on a papilla of mucous membrane (ampulla of Vater), about 10 cm distal to the pylorus. The union of the common bile duct and the main pancreatic duct follows one of three configurations. In about 70% of people, these ducts unite outside the duodenal wall and traverse the duodenal wall as a single duct. In about 20%, they join within the duodenal wall and have a short or no common duct, but open through the same opening into the duodenum. In about 10%, they exit via separate openings into the duodenum. The sphincter of Oddi, a thick coat of circular smooth muscle, surrounds the common bile duct at the ampulla of Vater (Fig. 32-3). It controls the flow of bile, and in some cases pancreatic juice, into the duodenum.

Fig. 32-3.

The sphincter of Oddi.

The extrahepatic bile ducts are lined by a columnar mucosa with numerous mucous glands in the common bile duct. A fibroareolar tissue containing scant smooth muscle cells surrounds the mucosa. A distinct muscle layer is not present in the human common bile duct. The arterial supply to the bile ducts is derived from the gastroduodenal and the right hepatic arteries, with major trunks running along the medial and lateral walls of the common duct (sometimes referred to as 3 o'clock and 9 o'clock). These arteries anastomose freely within the duct walls. The density of nerve fibers and ganglia increase near the sphincter of Oddi, but the nerve supply to the common bile duct and the sphincter of Oddi is the same as for the gallbladder.^{1,2}

Anomalies

The classic description of the extrahepatic biliary tree and its arteries applies only in about one third of patients.⁴ The gallbladder may have abnormal positions, be intrahepatic, be rudimentary, have anomalous forms, or be duplicated. Isolated congenital absence of the gallbladder is very rare, with a reported incidence of 0.03%. Before the diagnosis is made, the presence of an intrahepatic bladder or anomalous position must be ruled out. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of about one in every 4000 persons. This occurs in two major varieties: the more common form in which each gallbladder has its own cystic duct that empties independently into the same or different parts of the extrahepatic biliary tree, and as two cystic ducts that merge before they enter the common bile duct. Duplication is only clinically important when some pathologic processes affect one or both organs. A left-sided gallbladder

with a cystic duct emptying into the left hepatic duct or the common bile duct and a retrodisplacement of the gallbladder are both extremely rare. A partial or totally intrahepatic gallbladder is associated with an increased incidence of cholelithiasis.

Small ducts (of Luschka) may drain directly from the liver into the body of the gallbladder. If present, but not recognized at the time of a cholecystectomy, a bile leak with the accumulation of bile (biloma) may occur in the abdomen. An accessory right hepatic duct occurs in about 5% of cases. Variations of how the common bile duct enters the duodenum are described in Bile Ducts above.

Anomalies of the hepatic artery and the cystic artery are quite common, occurring in as many as 50% of cases.⁵ In about 5% of cases, there are two right hepatic arteries, one from the common hepatic artery and the other from the superior mesenteric artery. In about 20% of patients, the right hepatic artery comes off the superior mesenteric artery. The right hepatic artery may course anterior to the common duct. The right hepatic artery may be vulnerable during surgical procedures, in particular when it runs parallel to the cystic duct or in the mesentery of the gallbladder. The cystic artery arises from the right hepatic artery in about 90% of cases, but may arise from the left hepatic, common hepatic, gastroduodenal, or superior mesenteric arteries (Fig. 32-4).

Fig. 32-4.

Variations in the arterial supply to the gallbladder. **A.** Cystic artery from right hepatic artery, about 80–90%. **B.** Cystic artery from right hepatic artery (accessory or replaced) from superior mesenteric artery, about 10%. **C.** Two cystic arteries, one from the right hepatic, the other from the common hepatic artery, rare. **D.** Two cystic arteries, one from the right hepatic, the other from the left hepatic artery, rare. **E.** The cystic artery branching from the right hepatic artery and running anterior to the common hepatic duct, rare. **F.** Two cystic arteries arising from the right hepatic artery, rare.

PHYSIOLOGY

Bile Formation and Composition

The liver produces bile continuously and excretes it into the bile canaliculi. The normal adult consuming an average diet produces within the liver 500 to 1000 mL of bile a day. The secretion of bile is responsive to neurogenic, humoral, and chemical stimuli. Vagal stimulation increases secretion of bile, whereas splanchnic nerve stimulation results in decreased bile flow. Hydrochloric acid, partly digested proteins, and fatty acids in the duodenum stimulate the release of secretin from the duodenum that, in turn, increases bile production and bile flow. Bile flows from the liver through to the hepatic ducts, into the common hepatic duct, through the common bile duct, and finally into the duodenum. With an intact sphincter of Oddi, bile flow is directed into the gallbladder.

Bile is mainly composed of water, electrolytes, bile salts, proteins, lipids, and bile pigments. Sodium, potassium, calcium, and chlorine have the same concentration in bile as in plasma or extracellular fluid. The pH of hepatic bile is usually neutral or slightly alkaline, but varies with diet; an increase in protein shifts the bile to a more acidic pH. The primary bile salts, cholate and chenodeoxycholate, are synthesized in the liver from cholesterol. They are conjugated there with taurine and glycine, and act within the bile as anions (bile acids) that are balanced by sodium. Bile salts are excreted into the bile by the hepatocyte and aid in the digestion and absorption of fats in the intestines.⁶ In the intestines, about 80% of the conjugated bile acids are absorbed in the terminal ileum. The remainder is dehydroxylated (deconjugated) by gut bacteria, forming secondary bile acids deoxycholate and lithocholate. These are absorbed in the colon, transported to the liver, conjugated, and secreted into the bile. Eventually, about 95% of the bile acid pool is reabsorbed and returned via the portal venous system to the liver, the so-called *enterohepatic circulation*. Five percent is excreted in the stool, leaving the relatively small amount of bile acids to have maximum effect.

Cholesterol and phospholipids synthesized in the liver are the principal lipids found in bile. The synthesis of phospholipids and cholesterol by the liver is, in part, regulated by bile acids. The color of the bile is due to the presence of the pigment bilirubin diglucuronide, which is the metabolic product from the breakdown of hemoglobin, and is present in bile in concentrations 100 times greater than in plasma. Once in the intestine, bacteria convert it into urobilinogen, a small fraction of which is absorbed and secreted into the bile.

Gallbladder Function

The gallbladder, the bile ducts, and the sphincter of Oddi act together to store and regulate the flow of bile. The main function of the gallbladder is to concentrate and store hepatic bile and to deliver bile into the duodenum in response to a meal.

ABSORPTION AND SECRETION

In the fasting state, approximately 80% of the bile secreted by the liver is stored in the gallbladder. This storage is made possible because of the remarkable absorptive capacity of the gallbladder, as the gallbladder mucosa has the greatest absorptive power per unit area of any structure in the body. It rapidly absorbs sodium, chloride, and water against significant concentration gradients, concentrating the bile as much as 10-fold and leading to a marked change in bile composition. This rapid absorption is one of the mechanisms that prevent a rise in pressure within the biliary system under normal circumstances. Gradual relaxation as well as emptying of the gallbladder during the fasting period also plays a role in maintaining a relatively low intraluminal pressure in the biliary tree.

The epithelial cells of the gallbladder secrete at least two important products into the gallbladder lumen: glycoproteins and

hydrogen ions. The mucosal glands in the infundibulum and the neck of the gallbladder secrete mucus glycoproteins that are believed to protect the mucosa from the lytic action of bile and to facilitate the passage of bile through the cystic duct. This mucus makes up the colorless "white bile" seen in hydrops of the gallbladder resulting from cystic duct obstruction. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in the gallbladder bile pH. The acidification promotes calcium solubility, thereby preventing its precipitation as calcium salts.⁶

MOTOR ACTIVITY

Gallbladder filling is facilitated by tonic contraction of the sphincter of Oddi, which creates a pressure gradient between the bile ducts and the gallbladder. During fasting, the gallbladder does not simply fill passively. In association with phase II of the interdigestive migrating myenteric motor complex in the gut, the gallbladder repeatedly empties small volumes of bile into the duodenum. This process is mediated at least in part by the hormone motilin. In response to a meal, the gallbladder empties by a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone cholecystokinin (CCK). CCK is released endogenously from the duodenal mucosa in response to a meal.⁷ When stimulated by eating, the gallbladder empties 50 to 70% of its contents within 30 to 40 minutes. Over the following 60 to 90 minutes, the gallbladder gradually refills. This is correlated with a reduced CCK level. Other hormonal and neural pathways also are involved in the coordinated action of the gallbladder and the sphincter of Oddi. Defects in the motor activity of the gallbladder are thought to play a role in cholesterol nucleation and gallstone formation.⁸

NEUROHORMONAL REGULATION

The vagus nerve stimulates contraction of the gallbladder, and splanchnic sympathetic stimulation is inhibitory to its motor activity. Parasympathomimetic drugs contract the gallbladder, whereas atropine leads to relaxation. Neurally mediated reflexes link the sphincter of Oddi with the gallbladder, stomach, and duodenum to coordinate the flow of bile into the duodenum. Antral distention of the stomach causes both gallbladder contraction and relaxation of the sphincter of Oddi.

Hormonal receptors are located on the smooth muscles, vessels, nerves, and epithelium of the gallbladder. CCK is a peptide that comes from epithelial cells of the upper GI tract and is found in the highest concentrations in the duodenum. CCK is released into the bloodstream by acid, fat, and amino acids in the duodenum.⁹ CCK has a plasma half-life of 2 to 3 minutes and is metabolized by both the liver and the kidneys. CCK acts directly on smooth muscle receptors of the gallbladder and stimulates gallbladder contraction. It also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum. CCK stimulation of the gallbladder and the biliary tree also is mediated by cholinergic vagal neurons. In patients who have had a vagotomy, the response to CCK stimulation is diminished and the size and the volume of the gallbladder are increased.

Vasoactive intestinal polypeptide inhibits contraction and causes gallbladder relaxation. Somatostatin and its analogues are potent inhibitors of gallbladder contraction. Patients treated with somatostatin analogues and those with somatostatinoma have a high incidence of gallstones, presumably due to the inhibition of gallbladder contraction and emptying. Other hormones such as substance P and enkephalin affect gallbladder motility, but the physiologic role is unclear.⁷

Sphincter of Oddi

The sphincter of Oddi regulates flow of bile (and pancreatic juice) into the duodenum, prevents the regurgitation of duodenal contents into the biliary tree, and diverts bile into the gallbladder. It is a complex structure that is functionally independent from the duodenal musculature and creates a high-pressure zone between the bile duct and the duodenum. The sphincter of Oddi is about 4 to 6 mm in length and has a basal resting pressure of about 13 mmHg above the duodenal pressure. On

manometry, the sphincter shows phasic contractions with a frequency of about four per minute and an amplitude of 12 to 140 mmHg.⁸ The spontaneous motility of the sphincter of Oddi is regulated by the interstitial cells of Cajal through intrinsic and extrinsic inputs from hormones and neurons acting on the smooth muscle cells.¹⁰ Relaxation occurs with a rise in CCK, leading to diminished amplitude of phasic contractions and reduced basal pressure, allowing increased flow of bile into the duodenum (Fig. 32-5). During fasting, the sphincter of Oddi activity is coordinated with the periodic partial gallbladder emptying and an increase in bile flow that occurs during phase II of the migrating myoelectric motor complexes.¹¹

The effect of cholecystokinin on the gallbladder and the sphincter of Oddi. **A.** During fasting, with the sphincter of Oddi

contracted and the gallbladder filling. **B.** In response to a meal, the sphincter of Oddi relaxed and the gallbladder emptying.

DIAGNOSTIC STUDIES

A variety of diagnostic modalities are available for the patient with suspected disease of the gallbladder and the bile ducts. In 1924 the diagnosis of gallstones was improved significantly by the introduction of oral cholecystography by Graham and Cole. For decades it was the mainstay of investigation for gallstones. In the 1950s biliary scintigraphy was developed, as well as intrahepatic and endoscopic retrograde cholangiography (ERC), allowing imaging of the biliary tract. Later ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) vastly improved the ability to image the biliary tract.¹²

Blood Tests

When patients with suspected diseases of the gallbladder or the extrahepatic biliary tree are evaluated, a complete blood count and liver function tests are routinely requested. An elevated white blood cell (WBC) count may indicate or raise suspicion of cholecystitis. If associated with an elevation of bilirubin, alkaline phosphatase, and aminotransferase, cholangitis should be suspected. Cholestasis, an obstruction to bile flow, is characterized by an elevation of bilirubin (i.e., the conjugated form), and a rise in alkaline phosphatase. Serum aminotransferases may be normal or mildly elevated. In patients with biliary colic or chronic cholecystitis, blood tests will typically be normal.

Ultrasonography

An ultrasound is the initial investigation of any patient suspected of disease of the biliary tree.¹³ It is noninvasive, painless, does not submit the patient to radiation, and can be performed on critically ill patients. It is dependent upon the skills and the experience of the operator, and it is dynamic (i.e., static images do not give the same information as those obtained during the ultrasound investigation itself). Adjacent organs can frequently be examined at the same time. Obese patients, patients with ascites, and patients with distended bowel may be difficult to examine satisfactorily with an ultrasound.

Ultrasound will show stones in the gallbladder with sensitivity and specificity of >90%. Stones are acoustically dense and reflect the ultrasound waves back to the ultrasonic transducer. Because stones block the passage of sound waves to the region behind them, they also produce an acoustic shadow (Fig. 32-6). Stones move with changes in position. Polyps may be calcified and reflect shadows, but do not move with change in posture. Some stones form a layer in the gallbladder; others a sediment or sludge. A thickened gallbladder wall and local tenderness indicate cholecystitis. The patient has acute cholecystitis if a layer of edema is seen within the wall of the gallbladder or between the gallbladder and the liver in association with localized tenderness. When a stone obstructs the neck of the gallbladder, the gallbladder may become very large, but thin walled. A contracted, thick-walled gallbladder is indicative of chronic cholecystitis.

Fig. 32-6.

An ultrasonography of the gallbladder. Arrows indicate the acoustic shadows from stones in the gallbladder.

The extrahepatic bile ducts are also well visualized by ultrasound, except for the retroduodenal portion. Dilation of the ducts in a patient with jaundice establishes an extrahepatic obstruction as a cause for the jaundice. Frequently, the site and, sometimes, the cause of obstruction can be determined by ultrasound. Small stones in the common bile duct frequently get lodged at the distal end of it, behind the duodenum, and are, therefore, difficult to detect. A dilated common bile duct on ultrasound, small stones in the gallbladder, and the clinical presentation allow one to assume that a stone or stones are causing the obstruction. Periapillary tumors can be difficult to diagnose on ultrasound, but beyond the retroduodenal portion, the level of obstruction and the cause may be visualized quite well. Ultrasound can be helpful in evaluating tumor invasion and flow in the portal vein, an important guideline for resectability of periampullary and pancreatic head tumors.¹⁴

Oral Cholecystography

Once considered the diagnostic procedure of choice for gallstones, oral cholecystography has largely been replaced by ultrasonography. It involves oral administration of a radiopaque compound that is absorbed, excreted by the liver, and passed into the gallbladder. Stones are noted on a film as filling defects in a visualized, opacified gallbladder. Oral cholecystography is of no value in patients with intestinal malabsorption, vomiting, obstructive jaundice, and hepatic failure.

Biliary Radionuclide Scanning (Hida Scan)

Biliary scintigraphy provides a noninvasive evaluation of the liver, gallbladder, bile ducts, and duodenum with both anatomic and functional information. ^{99m}Techetium-labeled derivatives of dimethyl iminodiacetic acid (HIDA) are injected intravenously, cleared by the Kupffer cells in the liver, and excreted in the bile. Uptake by the liver is detected within 10 minutes, and the gallbladder, the bile ducts, and the duodenum are visualized within 60 minutes in fasting subjects. The primary use of biliary scintigraphy is in the diagnosis of acute cholecystitis, which appears as a nonvisualized gallbladder, with prompt filling of the common bile duct and duodenum. Evidence of cystic duct obstruction on biliary scintigraphy is highly diagnostic for acute cholecystitis. The sensitivity and specificity for the diagnosis are about 95% each. False-positive results are increased in patients with gallbladder stasis, as in critically ill patients and in patients receiving parenteral nutrition. Filling of the gallbladder and common bile duct with delayed or absent filling of the duodenum indicates an obstruction at the

ampulla. Biliary leaks as a complication of surgery of the gallbladder or the biliary tree can be confirmed and frequently localized by biliary scintigraphy.¹⁵

Computed Tomography

Abdominal CT scans are inferior to ultrasonography in diagnosing gallstones. The major application of CT scans is to define the course and status of the extrahepatic biliary tree and adjacent structures. It is the test of choice in evaluating the patient with suspected malignancy of the gallbladder, the extrahepatic biliary system, or nearby organs, in particular, the head of the pancreas. Use of CT scan is an integral part of the differential diagnosis of obstructive jaundice (Fig. 32-7). Spiral CT scanning provides additional staging information, including vascular involvement in patients with periampullary tumors.¹⁶

Fig. 32-7.

Computed tomography scan of the upper abdomen from a patient with cancer of the distal common bile duct. The cancer obstructs the common bile duct as well as the pancreatic duct. 1 = the portal vein; 2 = a dilated intrahepatic bile duct; 3 = dilated cystic duct and the neck of the gallbladder; 4 = dilated common hepatic duct; 5 = the bifurcation of the common hepatic artery into the gastroduodenal artery and the proper hepatic artery; 6 = dilated pancreatic duct; 7 = the splenic vein.

Percutaneous Transhepatic Cholangiography

Intrahepatic bile ducts are accessed percutaneously with a small needle under fluoroscopic guidance. Once the position in a bile duct has been confirmed, a guidewire is passed and, subsequently, a catheter is passed over the wire (Fig. 32-8).

Through the catheter, a cholangiogram can be performed and therapeutic interventions done, such as biliary drain insertions and stent placements. Percutaneous transhepatic cholangiography (PTC) has little role in the management of patients with uncomplicated gallstone disease, but is particularly useful in patients with bile duct strictures and tumors, as it defines the anatomy of the biliary tree proximal to the affected segment. As with any invasive procedure, there are potential risks. For PTC, these are mainly bleeding, cholangitis, bile leak, and other catheter-related problems.¹⁵

Schematic diagram of percutaneous transhepatic cholangiogram and drainage for obstructing proximal cholangiocarcinoma. **A.** Dilated intrahepatic bile duct is entered percutaneously with a fine needle. **B.** Small guidewire is passed through the needle into the duct. **C.** A plastic catheter has been passed over the wire, and the wire is subsequently removed. A cholangiogram is performed through the catheter. **D.** An external drainage catheter in place. **E.** Long wire placed via the catheter and advanced past the tumor and into the duodenum. **F.** Internal stent has been placed through the tumor.

Magnetic Resonance Imaging

Available since the mid-1990s, MRI provides anatomic details of the liver, gallbladder, and pancreas similar to those obtained from CT. Many MRI techniques (i.e., heavily T2-weighted sequences, pulse sequences with or without contrast

materials) can generate high resolution anatomic images of the biliary tree and the pancreatic duct. It has a sensitivity and specificity of 95 and 89%, respectively, at detecting choledocholithiasis.¹⁷ MRI with magnetic resonance cholangiopancreatography (MRCP) offers a single noninvasive test for the diagnosis of biliary tract and pancreatic disease¹⁸ (Fig. 32-9).

Magnetic resonance cholangiopancreatography. This view shows the course of the extrahepatic bile ducts (*arrow*) and the pancreatic duct (*arrowheads*).

Endoscopic Retrograde Cholangiography and Endoscopic Ultrasound

Using a side-viewing endoscope, the common bile duct can be cannulated and a cholangiogram performed using fluoroscopy (Fig. 32-10). The procedure requires IV sedation for the patient. The advantages of ERC include direct visualization of the ampullary region and direct access to the distal common bile duct, with the possibility of therapeutic intervention. The test is rarely needed for uncomplicated gallstone disease, but for stones in the common bile duct, in particular, when associated with obstructive jaundice, cholangitis, or gallstone pancreatitis, ERC is the diagnostic and often therapeutic procedure of choice. Once the endoscopic cholangiogram has shown ductal stones, sphincterotomy and stone extraction can be performed, and the common bile duct cleared of stones. In the hands of experts, the success rate of common bile duct cannulation and cholangiography is >90%. Complications of diagnostic ERC include pancreatitis and cholangitis, and occur in up to 5% of patients.¹⁹ The development of small fiber-optic cameras that can be threaded through endoscopes used for

endoscopic retrograde cholangiopancreatography (ERCP) has facilitated the development of intraductal endoscopy. By providing direct visualization of the biliary and pancreatic ducts, this technology has been shown to increase the effectiveness of ERCP in the diagnosis of certain biliary and pancreatic diseases.^{20,21} Intraductal endoscopy has been shown to have therapeutic applications that include biliary stone lithotripsy and extraction in high-risk surgical patients.²² As with most endoscopic procedures, intraductal endoscopy generally is considered safe, but there are no large trials that specifically address this issue. Typical complications such as bile duct perforation, minor bleeding from sphincterotomy or lithotripsy, and cholangitis have been described.²³ Further refinement of this technology will enhance ERCP as a diagnostic and therapeutic tool.

Endoscopic retrograde cholangiography. **A.** A schematic picture showing the side-viewing endoscope in the duodenum and a catheter in the common bile duct. **B.** An endoscopic cholangiography showing stones in the common bile duct. The catheter has been placed in the ampulla of Vater (*arrow*). Note the duodenal shadow indicated with *arrowheads*.

Endoscopic Ultrasound

An endoscopic ultrasound requires a special endoscope with an ultrasound transducer at its tip. The results are operator dependent, but offer noninvasive imaging of the bile ducts and adjacent structures. It is of particular value in the evaluation of tumors and their resectability. The ultrasound endoscope has a biopsy channel, allowing needle biopsies of a tumor under ultrasonic guidance. Endoscopic ultrasound also has been used to identify bile duct stones, and although it is less sensitive than ERC, the technique is less invasive.

GALLSTONE DISEASE

Prevalence and Incidence

Gallstone disease is one of the most common problems affecting the digestive tract. Autopsy reports have shown a prevalence of gallstones from 11 to 36%.²⁴ The prevalence of gallstones is related to many factors, including age, gender, and ethnic background. Certain conditions predispose to the development of gallstones. Obesity, pregnancy, dietary factors, Crohn's disease, terminal ileal resection, gastric surgery, hereditary spherocytosis, sickle cell disease, and thalassemia are all associated with an increased risk of developing gallstones.⁸ Women are three times more likely to develop gallstones than men, and first-degree relatives of patients with gallstones have a twofold greater prevalence.²⁵

Natural History

Most patients will remain asymptomatic from their gallstones throughout life. For unknown reasons, some patients progress to a symptomatic stage, with biliary colic caused by a stone obstructing the cystic duct. Symptomatic gallstone disease may progress to complications related to the gallstones.²⁶ These include acute cholecystitis, choledocholithiasis with or without cholangitis, gallstone pancreatitis, cholecystocholedochal fistula, cholecystoduodenal or cholecystoenteric fistula leading to gallstone ileus, and gallbladder carcinoma. Rarely, complication of gallstones is the presenting picture.

Gallstones in patients without biliary symptoms are commonly diagnosed incidentally on ultrasonography, CT scans, abdominal radiography, or at laparotomy. Several studies have examined the likelihood of developing biliary colic or developing significant complications of gallstone disease. Approximately 3% of asymptomatic individuals become symptomatic per year (i.e., develop biliary colic). Once symptomatic, patients tend to have recurring bouts of biliary colic. Complicated gallstone disease develops in 3 to 5% of symptomatic patients per year. Over a 20-year period, about two thirds of asymptomatic patients with gallstones remain symptom free.²⁷

Because few patients develop complications without previous biliary symptoms, prophylactic cholecystectomy in asymptomatic persons with gallstones is rarely indicated. For elderly patients with diabetes, for individuals who will be isolated from medical care for extended periods of time, and in populations with increased risk of gallbladder cancer, a prophylactic cholecystectomy may be advisable. Porcelain gallbladder, a rare premalignant condition in which the wall of the gallbladder becomes calcified, is an absolute indication for cholecystectomy.

Gallstone Formation

Gallstones form as a result of solids settling out of solution. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Gallstones are classified by their cholesterol content as either cholesterol stones or pigment stones. Pigment stones can be further classified as either black or brown. In Western countries, about 80% of gallstones are cholesterol stones and about 15 to 20% are black pigment stones.²⁸ Brown pigment stones account for only a small percentage. Both types of pigment stones are more common in Asia.

CHOLESTEROL STONES

Pure cholesterol stones are uncommon and account for <10% of all stones. They usually occur as single large stones with smooth surfaces. Most other cholesterol stones contain variable amounts of bile pigments and calcium, but are always >70% cholesterol by weight. These stones are usually multiple, of variable size, and may be hard and faceted or irregular, mulberry-shaped, and soft (Fig. 32-11). Colors range from whitish yellow and green to black. Most cholesterol stones are radiolucent; <10% are radiopaque. Whether pure or of mixed nature, the common primary event in the formation of cholesterol stones is supersaturation of bile with cholesterol. Therefore, high bile cholesterol levels and cholesterol gallstones are considered as one disease. Cholesterol is highly nonpolar and insoluble in water and bile. Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and lecithin (the main phospholipid in bile). Supersaturation almost always is caused by cholesterol hypersecretion rather than by a reduced secretion of phospholipid or bile salts.²

Gallbladder with cholesterol stones. Note the different shapes and sizes.

Cholesterol is secreted into bile as cholesterol-phospholipid vesicles. Cholesterol is held in solution by micelles, a conjugated bile salt-phospholipid-cholesterol complex, as well as by the cholesterol-phospholipid vesicles. The presence of vesicles and micelles in the same aqueous compartment allows the movement of lipids between the two. Vesicular maturation occurs when vesicular lipids are incorporated into micelles. Vesicular phospholipids are incorporated into micelles more readily than vesicular cholesterol. Therefore, vesicles may become enriched in cholesterol, become unstable, and then nucleate cholesterol crystals. In unsaturated bile, cholesterol enrichment of vesicles is inconsequential. In the supersaturated bile, cholesterol-dense zones develop on the surface of the cholesterol-enriched vesicles, leading to the appearance of cholesterol crystals. About one third of biliary cholesterol is transported in micelles, but the cholesterol-phospholipid vesicles carry the majority of biliary cholesterol²⁹ (Fig. 32-12).

Fig. 32-12.

The three major components of bile plotted on triangular coordinates. A given point represents the relative molar ratios of bile salts, lecithin, and cholesterol. The area labeled "micellar liquid" shows the range of concentrations found consistent with a clear micellar solution (single phase), where cholesterol is fully solubilized. The shaded area directly above this region corresponds to a metastable zone, supersaturated with cholesterol. Bile with a composition that falls above the shaded area has exceeded the solubilization capacity of cholesterol and precipitation of cholesterol crystals occurs.

(Reproduced with permission from Holzbach RT: Pathogenesis and medical treatment of gallstones, in Slesinger MH, Fordtran JS, eds: *Gastrointestinal Diseases*. Philadelphia: WB Saunders, 1989, p 1672.)

PIGMENT STONES

Pigment stones contain <20% cholesterol and are dark because of the presence of calcium bilirubinate. Otherwise, black and brown pigment stones have little in common and should be considered as separate entities.

Black pigment stones are usually small, brittle, black, and sometimes spiculated. They are formed by supersaturation of calcium bilirubinate, carbonate, and phosphate, most often secondary to hemolytic disorders such as hereditary spherocytosis and sickle cell disease, and in those with cirrhosis. Like cholesterol stones, they almost always form in the gallbladder.

Unconjugated bilirubin is much less soluble than conjugated bilirubin in bile. Deconjugation of bilirubin occurs normally in bile at a slow rate. Excessive levels of conjugated bilirubin, as in hemolytic states, lead to an increased rate of production of unconjugated bilirubin. Cirrhosis may lead to increased secretion of unconjugated bilirubin. When altered conditions lead to increased levels of deconjugated bilirubin in bile, precipitation with calcium occurs. In Asian countries such as Japan, black stones account for a much higher percentage of gallstones than in the Western hemisphere.

Brown stones are usually <1 cm in diameter, brownish-yellow, soft, and often mushy. They may form either in the gallbladder or in the bile ducts, usually secondary to bacterial infection caused by bile stasis. Precipitated calcium bilirubinate and bacterial cell bodies compose the major part of the stone. Bacteria such as *Escherichia coli* secrete β -glucuronidase that enzymatically cleaves bilirubin glucuronide to produce the insoluble unconjugated bilirubin. It precipitates with calcium, and along with dead bacterial cell bodies, forms soft brown stones in the biliary tree.

Brown stones are typically found in the biliary tree of Asian populations and are associated with stasis secondary to parasite infection. In Western populations, brown stones occur as primary bile duct stones in patients with biliary strictures or other

common bile duct stones that cause stasis and bacterial contamination.^{2,30}

Symptomatic Gallstones

CHRONIC CHOLECYSTITIS (BILIARY COLIC)

About two thirds of patients with gallstone disease present with chronic cholecystitis characterized by recurrent attacks of pain, often inaccurately labeled *biliary colic*. The pain develops when a stone obstructs the cystic duct, resulting in a progressive increase of tension in the gallbladder wall. The pathologic changes, which often do not correlate well with symptoms, vary from an apparently normal gallbladder with minor chronic inflammation in the mucosa, to a shrunken, nonfunctioning gallbladder with gross transmural fibrosis and adhesions to nearby structures. The mucosa is initially normal or hypertrophied, but later becomes atrophied, with the epithelium protruding into the muscle coat, leading to the formation of the so-called *Aschoff-Rokitansky sinuses*.

Clinical Presentation

The chief symptom associated with symptomatic gallstones is pain. The pain is constant and increases in severity over the first half hour or so and typically lasts 1 to 5 hours. It is located in the epigastrium or right upper quadrant and frequently radiates to the right upper back or between the scapulae (Fig. 32-13). The pain is severe and comes on abruptly, typically during the night or after a fatty meal. It often is associated with nausea and sometimes vomiting. The pain is episodic. The patient suffers discrete attacks of pain, between which they feel well. Physical examination may reveal mild right upper quadrant tenderness during an episode of pain. If the patient is pain free, the physical examination is usually unremarkable. Laboratory values, such as WBC count and liver function tests, are usually normal in patients with uncomplicated gallstones.

A. Sites of the most severe pain during an episode of biliary pain in 107 patients with gallstones (% values add up to >100% because of multiple responses). The subxiphoid and right subcostal areas were the most common sites; note that the left subcostal area was not an unusual site of pain. **B.** Sites of pain radiation (%) during an episode of biliary pain in the same group of patients.

(Reprinted from Gunn A, Keddie N: Some clinical observations on patients with gallstones. *The Lancet* 300(7771):239–241, Copyright 1972, with permission from Elsevier.)

Atypical presentation of gallstone disease is common. Association with meals is present in only about 50% of patients. Some patients report milder attacks of pain, but relate it to meals. The pain may be located primarily in the back or the left upper or lower right quadrant. Bloating and belching may be present and associated with the attacks of pain. In patients with atypical presentation, other conditions with upper abdominal pain should be sought out, even in the presence of gallstones. These include peptic ulcer disease, gastroesophageal reflux disease, abdominal wall hernias, irritable bowel disease, diverticular disease, liver diseases, renal calculi, pleuritic pain, and myocardial pain. Many patients with other conditions have gallstones.

When the pain lasts >24 hours, an impacted stone in the cystic duct or acute cholecystitis (see Acute Cholecystitis below) should be suspected. An impacted stone without cholecystitis will result in what is called *hydrops of the gallbladder*. The bile gets absorbed, but the gallbladder epithelium continues to secrete mucus, and the gallbladder becomes distended with mucinous material. The gallbladder may be palpable but usually is not tender. Hydrops of the gallbladder may result in edema of the gallbladder wall, inflammation, infection, and perforation. Although hydrops may persist with few consequences, early cholecystectomy is generally indicated to avoid complications.

Diagnosis

The diagnosis of symptomatic gallstones or chronic calculous cholecystitis depends on the presence of typical symptoms and the demonstration of stones on diagnostic imaging. An abdominal ultrasound is the standard diagnostic test for gallstones (see Ultrasonography above).³¹ Gallstones are occasionally identified on abdominal radiographs or CT scans. In these cases, if the patient has typical symptoms, an ultrasound of the gallbladder and the biliary tree should be added before surgical

intervention. Stones diagnosed incidentally in patients without symptoms should be left in place as discussed previously in Natural History. Occasionally, patients with typical attacks of biliary pain have no evidence of stones on ultrasonography. Sometimes only sludge in the gallbladder is demonstrated on ultrasonography. If the patient has recurrent attacks of typical biliary pain and sludge is detected on two or more occasions, cholecystectomy is warranted. In addition to sludge and stones, cholesterosis and adenomyomatosis of the gallbladder may cause typical biliary symptoms and may be detected on ultrasonography. Cholesterosis is caused by the accumulation of cholesterol in macrophages in the gallbladder mucosa, either locally or as polyps. It produces the classic macroscopic appearance of a "strawberry gallbladder." Adenomyomatosis or cholecystitis glandularis proliferans is characterized on microscopy by hypertrophic smooth muscle bundles and by the ingrowths of mucosal glands into the muscle layer (epithelial sinus formation). Granulomatous polyps develop in the lumen at the fundus, and the gallbladder wall is thickened and septae or strictures may be seen in the gallbladder. In symptomatic patients, cholecystectomy is the treatment of choice for patients with these conditions.³²

Management

Patients with symptomatic gallstones should be advised to have elective laparoscopic cholecystectomy. While waiting for surgery, or if surgery has to be postponed, the patient should be advised to avoid dietary fats and large meals. Diabetic patients with symptomatic gallstones should have a cholecystectomy promptly, as they are more prone to develop acute cholecystitis that is often severe. Pregnant women with symptomatic gallstones who cannot be managed expectantly with diet modifications can safely undergo laparoscopic cholecystectomy during the second trimester. Laparoscopic cholecystectomy is safe and effective in children as well as in the elderly.^{33,34} Cholecystectomy, open or laparoscopic, for patients with symptomatic gallstones offers excellent long-term results. About 90% of patients with typical biliary symptoms and stones are rendered symptom free after cholecystectomy. For patients with atypical symptoms or dyspepsia (flatulence, belching, bloating, and dietary fat intolerance) the results are not as favorable.

ACUTE CHOLECYSTITIS

Pathogenesis

Acute cholecystitis is secondary to gallstones in 90 to 95% of cases. Acute acalculous cholecystitis is a condition that typically occurs in patients with other acute systemic diseases (see Acalculous Cholecystitis section below). In <1% of acute cholecystitis, the cause is a tumor obstructing the cystic duct. Obstruction of the cystic duct by a gallstone is the initiating event that leads to gallbladder distention, inflammation, and edema of the gallbladder wall. Why inflammation develops only occasionally with cystic duct obstruction is unknown. It is probably related to the duration of obstruction of the cystic duct. Initially, acute cholecystitis is an inflammatory process, probably mediated by the mucosal toxin lysolecithin, a product of lecithin, as well as bile salts and platelet-activating factor. Increase in prostaglandin synthesis amplifies the inflammatory response. Secondary bacterial contamination is documented in 15 to 30% of patients undergoing cholecystectomy for acute uncomplicated cholecystitis. In acute cholecystitis, the gallbladder wall becomes grossly thickened and reddish with subserosal hemorrhages. Pericholecystic fluid often is present. The mucosa may show hyperemia and patchy necrosis. In severe cases, about 5 to 10%, the inflammatory process progresses and leads to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged and the inflammation resolves.³⁵

When the gallbladder remains obstructed and secondary bacterial infection supervenes, an acute gangrenous cholecystitis develops, and an abscess or empyema forms within the gallbladder. Rarely, perforation of ischemic areas occurs. The perforation is usually contained in the subhepatic space by the omentum and adjacent organs. However, free perforation with

peritonitis, intrahepatic perforation with intrahepatic abscesses, and perforation into adjacent organs (duodenum or colon) with cholecystoenteric fistula occur. When gas-forming organisms are part of the secondary bacterial infection, gas may be seen in the gallbladder lumen and in the wall of the gallbladder on abdominal radiographs and CT scans, an entity called an *emphysematous gallbladder*.

Clinical Manifestations

About 80% of patients with acute cholecystitis give a history compatible with chronic cholecystitis. Acute cholecystitis begins as an attack of biliary colic, but in contrast to biliary colic, the pain does not subside; it is unremitting and may persist for several days. The pain is typically in the right upper quadrant or epigastrium, and may radiate to the right upper part of the back or the interscapular area. It is usually more severe than the pain associated with uncomplicated biliary colic. The patient is often febrile, complains of anorexia, nausea, and vomiting, and is reluctant to move, as the inflammatory process affects the parietal peritoneum. On physical examination, focal tenderness and guarding are usually present in the right upper quadrant. A mass, the gallbladder and adherent omentum, is occasionally palpable; however, guarding may prevent this. A Murphy's sign, an inspiratory arrest with deep palpation in the right subcostal area, is characteristic of acute cholecystitis.

A mild to moderate leukocytosis ($12,000$ to $15,000$ cells/mm³) is usually present. However, some patients may have a normal WBC. A high WBC (above $20,000$) is suggestive of a complicated form of cholecystitis such as gangrenous cholecystitis, perforation, or associated cholangitis. Serum liver chemistries are usually normal, but a mild elevation of serum bilirubin, <4 mg/mL, may be present along with mild elevation of alkaline phosphatase, transaminases, and amylase.³¹ Severe jaundice is suggestive of common bile duct stones or obstruction of the bile ducts by severe pericholecystic inflammation secondary to impaction of a stone in the infundibulum of the gallbladder that mechanically obstructs the bile duct (Mirizzi's syndrome). In elderly patients and in those with diabetes mellitus, acute cholecystitis may have a subtle presentation resulting in a delay in diagnosis. The incidence of complications is higher in these patients, who also have approximately 10-fold the mortality rate compared to that of younger and healthier patients.

The differential diagnosis for acute cholecystitis includes a peptic ulcer with or without perforation, pancreatitis, appendicitis, hepatitis, perihepatitis (Fitz-Hugh–Curtis syndrome), myocardial ischemia, pneumonia, pleuritis, and herpes zoster involving the intercostal nerve.

Diagnosis

Ultrasonography is the most useful radiologic test for diagnosing acute cholecystitis. It has a sensitivity and specificity of 95%. In addition to being a sensitive test for documenting the presence or absence of stones, it will show the thickening of the gallbladder wall and the pericholecystic fluid (Fig. 32-14). Focal tenderness over the gallbladder when compressed by the sonographic probe (sonographic Murphy's sign) also is suggestive of acute cholecystitis. Biliary radionuclide scanning (HIDA scan) may be of help in the atypical case. Lack of filling of the gallbladder after 4 hours indicates an obstructed cystic duct and, in the clinical setting of acute cholecystitis, is highly sensitive and specific for acute cholecystitis. A normal HIDA scan excludes acute cholecystitis. CT scan is frequently performed on patients with acute abdominal pain. It demonstrates thickening of the gallbladder wall, pericholecystic fluid, and the presence of gallstones as well as air in the gallbladder wall, but is less sensitive than ultrasonography.

Ultrasonography from a patient with acute cholecystitis. The *arrowheads* indicate the thickened gallbladder wall. There are several stones in the gallbladder (*arrows*) throwing acoustic shadows.

Treatment

Patients who present with acute cholecystitis will need IV fluids, antibiotics, and analgesia. The antibiotics should cover gram-negative aerobes as well as anaerobes. A third-generation cephalosporin with good anaerobic coverage or a second-generation cephalosporin combined with metronidazole is a typical regimen. For patients with allergies to cephalosporins, an aminoglycoside with metronidazole is appropriate. Although the inflammation in acute cholecystitis may be sterile in some patients, more than one half will have positive cultures from the gallbladder bile. It is difficult to know who is secondarily infected; therefore, antibiotics have become a part of the management in most medical centers.

Cholecystectomy is the definitive treatment for acute cholecystitis.³⁶ In the past, the timing of cholecystectomy has been a matter of debate. Early cholecystectomy performed within 2 to 3 days of the illness is preferred over interval or delayed cholecystectomy that is performed 6 to 10 weeks after initial medical treatment and recuperation. Several studies have shown that unless the patient is unfit for surgery, early cholecystectomy should be recommended, as it offers the patient a definitive solution in one hospital admission, quicker recovery times, and an earlier return to work.³⁷

Laparoscopic cholecystectomy is the procedure of choice for acute cholecystitis. The conversion rate to an open cholecystectomy is higher (10 to 15%) in the setting of acute cholecystitis than with chronic cholecystitis. The procedure is more tedious and takes longer than in the elective setting. However, when compared to the delayed operation, early operation carries a similar complication rate.

When patients present late, after 3 to 4 days of illness, or if they are unfit for surgery, they can be treated with antibiotics with laparoscopic cholecystectomy scheduled for approximately 2 months later. Approximately 20% of patients will fail to respond to initial medical therapy and require an intervention. Laparoscopic cholecystectomy could be attempted, but the conversion rate is high and some prefer to go directly for an open cholecystectomy. For those unfit for surgery, a percutaneous cholecystostomy or an open cholecystostomy under local analgesia can be performed. Failure to improve after cholecystostomy usually is due to gangrene of the gallbladder or perforation. For these patients, surgery is unavoidable. For those who respond after cholecystostomy, the tube can be removed once cholangiography through it shows a patent ductus

cysticus. Laparoscopic cholecystectomy may then be scheduled in the near future.³⁸ For the rare patients who can't tolerate surgery, the stones can be extracted via the cholecystostomy tube before its removal.³⁹

CHOLEDOCHOLITHIASIS

Common bile duct stones may be small or large, single or multiple, and are found in 6 to 12% of patients with stones in the gallbladder. The incidence increases with age. About 20 to 25% of patients above the age of 60 with symptomatic gallstones have stones in the common bile duct as well as in the gallbladder.⁴⁰ The vast majority of ductal stones in Western countries are formed within the gallbladder and migrate down the cystic duct to the common bile duct. These are classified as secondary common bile duct stones, in contrast to the primary stones that form in the bile ducts. The secondary stones are usually cholesterol stones, whereas the primary stones are usually of the brown pigment type. The primary stones are associated with biliary stasis and infection and are more commonly seen in Asian populations. The causes of biliary stasis that lead to the development of primary stones include biliary stricture, papillary stenosis, tumors, or other (secondary) stones.

Clinical Manifestations

Choledochal stones may be silent and often are discovered incidentally. They may cause obstruction, complete or incomplete, or they may manifest with cholangitis or gallstone pancreatitis. The pain caused by a stone in the bile duct is very similar to that of biliary colic caused by impaction of a stone in the cystic duct. Nausea and vomiting are common. Physical examination may be normal, but mild epigastric or right upper quadrant tenderness as well as mild icterus are common. The symptoms may also be intermittent, such as pain and transient jaundice caused by a stone that temporarily impacts the ampulla but subsequently moves away, acting as a ball valve. A small stone may pass through the ampulla spontaneously with resolution of symptoms. Finally, the stones may become completely impacted, causing severe progressive jaundice. Elevation of serum bilirubin, alkaline phosphatase, and transaminases are commonly seen in patients with bile duct stones. However, in about one third of patients with common bile duct stones, the liver chemistries are normal.

Commonly, the first test, ultrasonography, is useful for documenting stones in the gallbladder (if still present), as well as determining the size of the common bile duct. As stones in the bile ducts tend to move down to the distal part of the common duct, bowel gas can preclude their demonstration on ultrasonography. A dilated common bile duct (>8 mm in diameter) on ultrasonography in a patient with gallstones, jaundice, and biliary pain is highly suggestive of common bile duct stones. Magnetic resonance cholangiography (MRC) provides excellent anatomic detail and has a sensitivity and specificity of 95 and 89%, respectively, at detecting choledocholithiasis >5 mm in diameter.¹⁸ Endoscopic cholangiography is the gold standard for diagnosing common bile duct stones. It has the distinct advantage of providing a therapeutic option at the time of diagnosis. In experienced hands, cannulation of the ampulla of Vater and diagnostic cholangiography are achieved in >90% of cases, with associated morbidity of <5% (mainly cholangitis and pancreatitis). Endoscopic ultrasound has been demonstrated to be as good as ERCP for detecting common bile duct stones (sensitivity of 91% and specificity of 100%), but it lacks therapeutic intervention and requires expertise, making it less available.⁴¹ PTC is rarely needed in patients with secondary common bile duct stones but is frequently performed for both diagnostic and therapeutic reasons in patients with primary bile duct stones.

Treatment

For patients with symptomatic gallstones and suspected common bile duct stones, either preoperative endoscopic cholangiography or an intraoperative cholangiogram will document the bile duct stones.⁴² If an endoscopic cholangiogram

reveals stones, sphincterotomy and ductal clearance of the stones is appropriate, followed by a laparoscopic cholecystectomy. An intraoperative cholangiogram at the time of cholecystectomy will also document the presence or absence of bile duct stones⁴³ (Fig. 32-15). Laparoscopic common bile duct exploration via the cystic duct or with formal choledochotomy allows the stones to be retrieved in the same setting (see Choledochal Exploration). If the expertise and/or the instrumentation for laparoscopic common bile duct exploration are not available, a drain should be left adjacent to the cystic duct and the patient scheduled for endoscopic sphincterotomy the following day. An open common bile duct exploration is an option if the endoscopic method has already been tried or is, for some reason, not feasible. If a choledochotomy is performed, a T tube is left in place. Stones impacted in the ampulla may be difficult for both endoscopic ductal clearance as well as common bile duct exploration (open or laparoscopic). In these cases the common bile duct is usually quite dilated (about 2 cm in diameter). A choledochoduodenostomy or a Roux-en-Y choledochojejunostomy may be the best option under this circumstance.⁴⁴

An endoscopic sphincterotomy. **A.** The sphincterotome in place. **B.** Completed sphincterotomy. **C.** Endoscopic picture of completed sphincterotomy.

Retained or recurrent stones following cholecystectomy are best treated endoscopically (Fig. 32-16). If the stones were deliberately left in place at the time of surgery or diagnosed shortly after the cholecystectomy, they are classified as *retained*; those diagnosed months or years later are termed *recurrent*. If a common bile duct exploration was performed and a T tube left in place, a T-tube cholangiogram is obtained before its removal. Retained stones can be retrieved either endoscopically or via the T-tube tract once it has matured (2 to 4 weeks). The T tube is then removed and a catheter passed through the tract into the common bile duct. Under fluoroscopic guidance, the stones are retrieved with baskets or balloons. Recurrent stones may be multiple and large. A generous endoscopic sphincterotomy will allow stone retrieval as well as spontaneous passage of retained and recurrent stones. Patients >70 years old presenting with bile duct stones should have their ductal stones cleared endoscopically. Studies comparing surgery to endoscopic treatment have documented less morbidity and mortality for endoscopic treatment in this group of patients.⁴⁵ They do not need to be submitted for a cholecystectomy, as only about 15% will become symptomatic from their gallbladder stones, and such patients can be treated as the need arises by a cholecystectomy.⁴⁶

Retained common bile duct stones. The patient presented 3 weeks after laparoscopic cholecystectomy. **A.** An ultrasound shows a normal or mildly dilated common bile duct with a stone. Note the location of the right hepatic artery anterior to the common hepatic duct (an anatomic variation). **B.** An endoscopic retrograde cholangiography from the same patient shows multiple stones in the common bile duct. Only the top one showed on ultrasound as the other stones lie in the distal common bile duct behind the duodenum.

CHOLANGITIS

Cholangitis is one of the two main complications of choledochal stones, the other being gallstone pancreatitis. Acute cholangitis is an ascending bacterial infection in association with partial or complete obstruction of the bile ducts. Hepatic bile is sterile, and bile in the bile ducts is kept sterile by continuous bile flow and by the presence of antibacterial substances in bile, such as immunoglobulin. Mechanical hindrance to bile flow facilitates bacterial contamination. Positive bile cultures are common in the presence of bile duct stones as well as with other causes of obstruction. Biliary bacterial contamination alone does not lead to clinical cholangitis; the combination of both significant bacterial contamination and biliary obstruction is required for its development. Gallstones are the most common cause of obstruction in cholangitis; other causes are benign and malignant strictures, parasites, instrumentation of the ducts and indwelling stents, and partially obstructed biliary-enteric anastomosis. The most common organisms cultured from bile in patients with cholangitis include *E. coli*, *Klebsiella pneumoniae*, *Streptococcus faecalis*, *Enterobacter*, and *Bacteroides fragilis*.⁴⁷

Clinical Presentation

Cholangitis may present as anything from a mild, intermittent, and self-limited disease to a fulminant, potentially life-threatening septicemia. The patient with gallstone-induced cholangitis is typically older and female. The most common presentation is fever, epigastric or right upper quadrant pain, and jaundice. These classic symptoms, well known as *Charcot's triad*, are present in about two thirds of patients. The illness may progress rapidly with septicemia and disorientation, known as *Reynolds pentad* (e.g., fever, jaundice, right upper quadrant pain, septic shock, and mental status changes). However, the presentation may be atypical, with little if any fever, jaundice, or pain. This occurs most commonly in the elderly, who may have unremarkable symptoms until they collapse with septicemia. Patients with indwelling stents rarely become jaundiced. On abdominal examination, the findings are indistinguishable from those of acute cholecystitis.⁴⁸

Diagnosis and Management

Leukocytosis, hyperbilirubinemia, and elevation of alkaline phosphatase and transaminases are common and, when present, support the clinical diagnosis of cholangitis. Ultrasonography is helpful, as it will document the presence of gallbladder stones, demonstrate dilated ducts, and possibly pinpoint the site of obstruction; however, rarely will it elucidate the exact cause. The definitive diagnostic test is ERC. In cases in which ERC is not available, PTC is indicated. Both ERC and PTC will show the level and the reason for the obstruction, allow culture of the bile, possibly allow the removal of stones if present, and drainage of the bile ducts with drainage catheters or stents. CT scanning and MRI will show pancreatic and periampullary masses, if present, in addition to the ductal dilatation.

The initial treatment of patients with cholangitis includes IV antibiotics and fluid resuscitation. These patients may require intensive care unit monitoring and vasopressor support. Most patients will respond to these measures. However, the obstructed bile duct must be drained as soon as the patient has been stabilized. About 15% of patients will not respond to antibiotics and fluid resuscitation, and an emergency biliary decompression may be required. Biliary decompression may be accomplished endoscopically, via the percutaneous transhepatic route, or surgically. The selection of procedure should be based on the level and the nature of the biliary obstruction. Patients with choledocholithiasis or periampullary malignancies are best approached endoscopically, with sphincterotomy and stone removal, or by placement of an endoscopic biliary stent.⁴⁹ In patients in whom the obstruction is more proximal or perihilar, or when a stricture in a biliary-enteric anastomosis is the cause or the endoscopic route has failed, percutaneous transhepatic drainage is used. When neither ERC nor PTC is available, an emergent operation for decompression of the common bile duct with a T tube may be necessary and lifesaving. Definitive operative therapy should be deferred until the cholangitis has been treated and the proper diagnosis established. Patients with indwelling stents and cholangitis usually require repeated imaging and exchange of the stent over

a guidewire.

Acute cholangitis is associated with an overall mortality rate of approximately 5%. When associated with renal failure, cardiac impairment, hepatic abscesses, and malignancies, the morbidity and mortality rates are much higher.

BILIARY PANCREATITIS

Gallstones in the common bile duct are associated with acute pancreatitis. Obstruction of the pancreatic duct by an impacted stone or temporary obstruction by a stone passing through the ampulla may lead to pancreatitis. The exact mechanism by which the obstruction of the pancreatic duct leads to pancreatitis is still not clear. An ultrasonogram of the biliary tree in patients with pancreatitis is essential. If gallstones are present and the pancreatitis is severe, an ERC with sphincterotomy and stone extraction may abort the episode of pancreatitis. Once the pancreatitis has subsided, the gallbladder should be removed during the same admission. When gallstones are present and the pancreatitis is mild and self-limited, the stone has probably passed. For these patients, a cholecystectomy and an intraoperative cholangiogram or a preoperative ERC is indicated.

Cholangiohepatitis

Cholangiohepatitis, also known as *recurrent pyogenic cholangitis*, is endemic to the Orient. It also has been encountered in the Chinese population in the United States, as well as in Europe and Australia. It affects both sexes equally and occurs most frequently in the third and fourth decades of life. Cholangiohepatitis is caused by bacterial contamination (commonly *E. coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*) of the biliary tree, and often is associated with biliary parasites such as *Clonorchis sinensis*, *Opisthorchis viverrini*, and *Ascaris lumbricoides*. Bacterial enzymes cause deconjugation of bilirubin, which precipitates as bile sludge. The sludge and dead bacterial cell bodies form brown pigment stones. The nucleus of the stone may contain an adult *Clonorchis* worm, an ovum, or an ascarid. These stones are formed throughout the biliary tree and cause partial obstruction that contributes to the repeated bouts of cholangitis. Biliary strictures form as a result of recurrent cholangitis and lead to further stone formation, infection, hepatic abscesses, and liver failure (secondary biliary cirrhosis).⁵⁰

The patient usually presents with pain in the right upper quadrant and epigastrium, fever, and jaundice. Recurrence of symptoms is one of the most characteristic features of the disease. The episodes may vary in severity but, without intervention, will gradually lead to malnutrition and hepatic insufficiency. An ultrasound will detect stones in the biliary tree, pneumobilia from infection due to gas-forming organisms, liver abscesses, and, occasionally, strictures. The gallbladder may be thickened, but is inflamed in about 20% of patients, and rarely contains stones. MRCP and PTC are the mainstays of biliary imaging for cholangiohepatitis. They can detect obstructions, define strictures and stones, and allow emergent decompression of the biliary tree in the septic patient. Hepatic abscesses may be drained percutaneously. The long-term goal of therapy is to extract stones and debris and relieve strictures. It may take several procedures and require a Roux-en-Y hepaticojejunostomy to establish biliary-enteric continuity. Occasionally, resection of involved areas of the liver may offer the best form of treatment. Recurrences are common and the prognosis is poor once hepatic insufficiency has developed.⁵¹

OPERATIVE INTERVENTIONS FOR GALLSTONE DISEASE

Cholecystostomy

A cholecystostomy decompresses and drains the distended, inflamed, hydropic, or purulent gallbladder. It is applicable if the

patient is not fit to tolerate an abdominal operation. Ultrasound-guided percutaneous drainage with a pigtail catheter is the procedure of choice. The catheter is inserted over a guidewire that has been passed through the abdominal wall, the liver, and into the gallbladder (Fig. 32-17). By passing the catheter through the liver, the risk of bile leak around the catheter is minimized.⁵³ The catheter can be removed when the inflammation has resolved and the patient's condition improved. The gallbladder can be removed later, if indicated, usually by laparoscopy. Surgical cholecystostomy with a large catheter placed under local anesthesia is rarely required today.

Fig. 32-17.

Percutaneous cholecystostomy. A pigtail catheter has been placed through the abdominal wall, the right lobe of the liver, and into the gallbladder.

Cholecystectomy

Cholecystectomy is the most common major abdominal procedure performed in Western countries. Carl Langenbuch performed the first successful cholecystectomy in 1882, and for >100 years, it was the standard treatment for symptomatic gallbladder stones. Open cholecystectomy was a safe and effective treatment for both acute and chronic cholecystitis. In 1987, laparoscopic cholecystectomy was introduced by Philippe Mouret in France and quickly revolutionized the treatment of gallstones. It not only supplanted open cholecystectomy, but also more or less ended attempts for noninvasive management of gallstones, such as extracorporeal shock wave and bile salt therapy. Laparoscopic cholecystectomy offers a cure for gallstones with a minimally invasive procedure, minor pain and scarring, and early return to full activity. Today, laparoscopic cholecystectomy is the treatment of choice for symptomatic gallstones.

Absolute contraindications for the procedure are uncontrolled coagulopathy and end-stage liver disease. Rarely, patients with severe obstructive pulmonary disease or congestive heart failure (e.g., cardiac ejection fraction <20%) may not tolerate pneumoperitoneum with carbon dioxide and require open cholecystectomy. Conditions formerly believed to be relative contraindications such as acute cholecystitis, gangrene and empyema of the gallbladder, biliary-enteric fistulae, obesity, pregnancy, ventriculoperitoneal shunt, cirrhosis, and previous upper abdominal procedures are now considered risk factors

for a potentially difficult laparoscopic cholecystectomy. When important anatomic structures cannot be clearly identified or when no progress is made over a set period of time, a conversion to an open procedure is usually indicated. In the elective setting, conversion to an open procedure is needed in about 5% of patients.⁵⁴ Emergent procedures may require more skill on the part of the surgeon and be needed in patients with complicated gallstone disease; the incidence of conversion is 10 to 30%. Conversion to an open procedure is not a failure, and the possibility should be discussed with the patient preoperatively.

Serious complications are rare. The mortality rate for laparoscopic cholecystectomy is about 0.1%. Wound infection and cardiopulmonary complication rates are considerably lower following laparoscopic cholecystectomy than are those for an open procedure. However, laparoscopic cholecystectomy is associated with a higher injury rate to the bile ducts (see section on Injury to the Biliary Tract below).⁵⁵

Patients undergoing cholecystectomy should have a complete blood count and liver function tests preoperatively. Prophylaxis against deep venous thrombosis with either low molecular weight heparin or compression stockings is indicated. The patient should be instructed to empty their bladder before coming to the operating room. Urinary catheters are rarely needed. An orogastric tube is placed if the stomach is distended with gas and is removed at the end of the operation.

LAPAROSCOPIC CHOLECYSTECTOMY

The patient is placed supine on the operating table with the surgeon standing at the patient's left side. Some surgeons prefer to stand between the patient's legs while doing laparoscopic procedures in the upper abdomen. The pneumoperitoneum is created with carbon dioxide gas, either with an open technique or by closed needle technique. Initially, a small incision is made in the upper edge of the umbilicus. With the closed technique, a special hollow insufflation needle (Veress needle) that is spring-loaded with a retractable cutting outer sheath is inserted into the peritoneal cavity and used for insufflation. Once an adequate pneumoperitoneum is established, a 10-mm trocar is inserted through the supraumbilical incision. With the open technique, the supraumbilical incision is carried through the fascia and into the peritoneal cavity. A special blunt cannula (Hasson cannula) is inserted into the peritoneal cavity and anchored to the fascia. The laparoscope with the attached video camera is passed through the umbilical port and the abdomen inspected. Three additional ports are placed under direct vision (Fig. 32-18). A 10-mm port is placed in the epigastrium, a 5-mm port in the middle of the clavicular line, and a 5-mm port in the right flank, in line with the gallbladder fundus. Occasionally, a fifth port is required for better visualization in patients recovering from pancreatitis or those with semi-acute cholecystitis, as well as in very obese patients.

Laparoscopic cholecystectomy. **A.** The trocar placement. **B.** The fundus has been grasped and retracted cephalad to expose the proximal gallbladder and the hepatoduodenal ligament. Another grasper retracts the gallbladder infundibulum posterolaterally to better expose the triangle of Calot (hepatocystic triangle bound by the common hepatic duct, cystic duct, and the liver margin). **C.** The triangle of Calot has been opened and the neck of the gallbladder and part of the cystic duct dissected free. A clip is being placed on the cystic duct–gallbladder junction. **D.** A small opening has been made into the cystic duct, and a cholangiogram catheter is to be inserted. **E.** The cystic duct has been divided, and the cystic artery is being divided. **F.** An intraoperative picture showing a grasper pulling the infundibulum of the gallbladder laterally, exposing the triangle of Calot that has been dissected. The cystic artery can be seen crossing the dissected area upward and to the left.

Through the lateralmost port, a grasper is used to grasp the gallbladder fundus. It is retracted over the liver edge upward and toward the patient's right shoulder to expose the proximal gallbladder and the hilar area. Exposure of the hilar area may be facilitated by placing the patient in reverse Trendelenburg position with slight tilting of the table to bring the right side up. Through the midclavicular port a second grasper is used to grasp the gallbladder infundibulum and retract it laterally to expose the triangle of Calot. Before this, it may be necessary to take down any adhesions between the omentum, duodenum, or colon, and the gallbladder. Most of the dissection is carried out through the epigastric port using a dissector, hook cautery, or scissors.

The dissection starts at the junction of the gallbladder and the cystic duct. A helpful anatomic landmark is the cystic artery lymph node. The peritoneum, fat, and loose areolar tissue around the gallbladder and the cystic duct–gallbladder junction is dissected off toward the bile duct. This is continued until the gallbladder neck and the proximal cystic duct are clearly identified. The next step is the identification of the cystic artery, which usually runs parallel to and somewhat behind the cystic duct. A hemoclip is placed on the proximal cystic duct. If an intraoperative cholangiogram is to be performed, a small incision is made on the anterior surface of the cystic duct, just proximal to the clip, and a cholangiogram catheter is passed into the cystic duct. Once the cholangiogram is completed, the catheter is removed and two clips are placed proximal to the incision, and the cystic duct is divided. A wide cystic duct may be too big for clips, requiring the placement of a pre-tied loop

ligature to close. The cystic artery is then clipped and divided.

Finally, the gallbladder is dissected out of the gallbladder fossa, using either a hook or scissors with electrocautery. Before the gallbladder is removed from the liver edge, the operative field is carefully searched for bleeding points and the placement of the clips on the cystic duct and cystic artery is inspected. The gallbladder is removed through the umbilical incision. The fascial defect and skin incision may need to be enlarged if the stones are large. If the gallbladder is acutely inflamed or gangrenous, or if the gallbladder is perforated, it is placed in a retrieval bag before it is removed from the abdomen. Any bile or blood that has accumulated during the procedure is sucked away, and if stones were spilled, they are retrieved, placed inside a retrieval bag, and removed. If the gallbladder was severely inflamed, gangrenous, or if any bile or blood is expected to accumulate, a closed suction drain can be placed through one of the 5-mm ports and left underneath the right liver lobe close to the gallbladder fossa.

OPEN CHOLECYSTECTOMY

The same surgical principles apply for laparoscopic and open cholecystectomies. Open cholecystectomy has become an uncommon procedure, usually performed either as a conversion from laparoscopic cholecystectomy or as a second procedure in patients who require laparotomy for another reason. After the cystic artery and cystic duct have been identified, the gallbladder is dissected free from the liver bed, starting at the fundus. The dissection is carried proximally toward the cystic artery and the cystic duct, which are then ligated and divided.

INTRAOPERATIVE CHOLANGIOGRAM OR ULTRASOUND

The bile ducts are visualized under fluoroscopy by injecting contrast through a catheter placed in the cystic duct (Fig. 32-19A). Their size can then be evaluated, the presence or absence of common bile duct stones assessed, and filling defects confirmed, as the dye passes into the duodenum. Routine intraoperative cholangiography will detect stones in approximately 7% of patients, as well as outlining the anatomy and detecting injury^{56,57} (Fig. 32-19B). A selective intraoperative cholangiogram can be performed when the patient has a history of abnormal liver function tests, pancreatitis, jaundice, a large duct and small stones, a dilated duct on preoperative ultrasonography, and if preoperative endoscopic cholangiography for the above reasons was unsuccessful. Laparoscopic ultrasonography is as accurate as intraoperative cholangiography in detecting common bile duct stones and it is less invasive; however, it requires more skill to perform and interpret.^{58,59}

- A.** An intraoperative cholangiogram. The bile ducts are of normal size, with no intraluminal filling defects. The left and the right hepatic ducts are visualized, the distal common bile duct tapers down, and the contrast empties into the duodenum. Cholangiography grasper that holds the catheter and the cystic duct stump partly projects over the common hepatic duct.
- B.** An intraoperative cholangiogram showing common bile duct stone (*arrow*). A small amount of contrast has passed into the duodenum.

Choledochal Exploration

Common bile duct stones that are detected intraoperatively on intraoperative cholangiography or ultrasonography may be managed with laparoscopic choledochal exploration as a part of the laparoscopic cholecystectomy procedure. Patients with common bile duct stones detected preoperatively, but endoscopic clearance was either not available or unsuccessful, should also have their ductal stones managed during the cholecystectomy.

If the stones in the duct are small, they may sometimes be flushed into the duodenum with saline irrigation via the cholangiography catheter after the sphincter of Oddi has been relaxed with glucagon. If irrigation is unsuccessful, a balloon catheter may be passed via the cystic duct and down the common bile duct, where it is inflated and withdrawn to retrieve the stones. The next attempt is usually made with a wire basket passed under fluoroscopic guidance to catch the stones (Fig. 32-20). If needed, a flexible choledochoscope is the next step. The cystic duct may have to be dilated to allow its passage. Once in the common bile duct, the stones may be caught into a wire basket under direct vision or pushed into the duodenum. When the duct has been cleared, the cystic duct is ligated and cut and the cholecystectomy completed. Occasionally, a choledochotomy, an incision into the common bile duct itself, is necessary. The flexible choledochoscope is then passed into the duct for visualization and clearance of stones. The choledochotomy is sutured with a T tube left in the common bile duct

with one end taken out through the abdominal wall for decompression of the bile ducts. By managing common bile duct stones at the time of the cholecystectomy, the patients can have all of their gallstone disease treated with one invasive procedure. It does, however, depend on the available surgical expertise.⁶⁰

Laparoscopic bile duct exploration. I. Transcystic basket retrieval using fluoroscopy. **A.** The basket has been advanced past the stone and opened. **B.** The stone has been entrapped in the basket, and together, they are removed from the cystic duct. II. Transcystic choledochoscopy and stone removal. **C.** The basket has been passed through the working channel of the scope, and the stone is entrapped under direct vision. **D.** Entrapped stone. **E.** A view from the choledochoscope. III. Choledochotomy and stone removal. **F.** A small incision is made in the common bile duct. **G.** The common bile duct is cleared of stones. **H.** A T tube left in the common bile duct with one end taken out through the abdominal wall for decompression of the bile ducts.

Choledochal Drainage Procedures

Rarely, when the stones cannot be cleared and/or when the duct is very dilated (larger than 1.5 cm in diameter), a choledochal drainage procedure is performed (Fig. 32-21). Choledochoduodenostomy is performed by mobilizing the second part of the duodenum (a Kocher maneuver) and anastomosing it side to side with the common bile duct.

Biliary enteric anastomoses. There are three types. I. Choledochoduodenostomy. **A.** The distal common bile duct is opened longitudinally, as is the duodenum. **B.** Interrupted sutures are placed between the common bile duct and the duodenum. **C.** Completed choledochoduodenostomy. II. Choledochojejunostomy. **D.** The common bile duct and small bowel are divided. **E.** A Roux-en-Y limb of jejunum is anastomosed to the choledochus. III. Hepaticojejunostomy. **F.** The entire extrahepatic biliary tree has been resected and the reconstruction done with a Roux-en-Y limb of jejunum. **G.** Percutaneous transhepatic stents are placed across hepaticojejunostomy.

A choledochojejunostomy is done by bringing up a 45-cm Roux-en-Y limb of jejunum and anastomosing it end to side to the choledochus.

Choledochojejunostomy or, more often, a hepaticojejunostomy, also can be used to repair common bile duct strictures or as a palliative procedure for malignant obstruction in the periampullary region. If the common bile duct has been transected or injured, it can be managed by an end-to-end choledochojejunostomy.

Transduodenal Sphincterotomy

In the majority of cases, endoscopic sphincterotomy has replaced open transduodenal sphincterotomy. If an open procedure for common bile duct stones is being done in which the stones are impacted, recurrent, or multiple, the transduodenal approach may be feasible. The duodenum is incised transversely. The sphincter then is incised at the 11 o'clock position to avoid injury to the pancreatic duct. The impacted stones are removed as are large stones from the duct. There is no need to fully clear the duct of stones, as they can pass spontaneously through the cut sphincter.

OTHER BENIGN DISEASES AND LESIONS

Acalculous Cholecystitis

Acute inflammation of the gallbladder can occur without gallstones. Acalculous cholecystitis typically develops in critically ill patients in the intensive care unit. Patients on parenteral nutrition with extensive burns, sepsis, major operations, multiple trauma, or prolonged illness with multiple organ system failure are at risk for developing acalculous cholecystitis. The cause is unknown, but gallbladder distention with bile stasis and ischemia has been implicated as causative factors. Pathologic

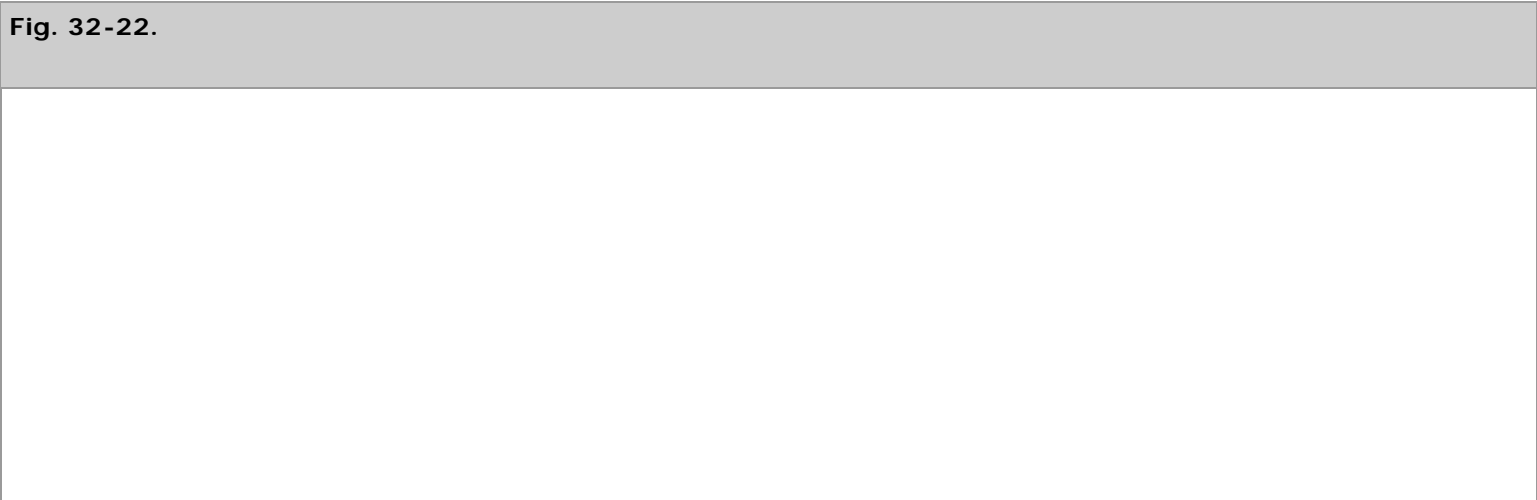

examination of the gallbladder wall reveals edema of the serosa and muscular layers, with patchy thrombosis of arterioles and venules.^{61,62}

The symptoms and signs depend on the condition of the patient, but in the alert patient, they are similar to acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. In the sedated or unconscious patient, the clinical features are often masked, but fever and elevated WBC count, as well as elevation of alkaline phosphatase and bilirubin are indications for further investigation.

Ultrasonography is usually the diagnostic test of choice, as it can be done bedside in the intensive care unit. It can demonstrate the distended gallbladder with thickened wall, biliary sludge, pericholecystic fluid, and the presence or absence of abscess formation. Abdominal CT scan can aid in the diagnosis of acalculous cholecystitis and additionally allows imaging of the abdominal cavity and chest to rule out other sources of infection. A HIDA scan can be useful and will show nonvisualization of the gallbladder, but it is a less sensitive test with high false-positive rates in patients who are fasting, on total parenteral nutrition, or have liver disease.⁶³ Acalculous cholecystitis requires urgent intervention. Percutaneous ultrasound- or CT-guided cholecystostomy is the treatment of choice for these patients, as they are usually unfit for surgery (see Fig. 32-17). If the diagnosis is uncertain, percutaneous cholecystostomy is both diagnostic and therapeutic. About 90% of patients will improve with the percutaneous cholecystostomy. However, if they do not improve, other steps, such as open cholecystostomy or cholecystectomy, may be required. If needed, cholecystectomy is performed after the patient has recovered from the underlying disease.

Biliary Cysts

Choledochal cysts are congenital cystic dilatations of the extrahepatic and/or intrahepatic biliary tree. They are rare—the incidence is between 1:100,000 and 1:150,000 in populations of Western countries—but are more commonly seen in populations of Eastern countries. Choledochal cysts affect females three to eight times more often than males. Although frequently diagnosed in infancy or childhood, as many as one half of the patients have reached adulthood when diagnosed. The cause is unknown. Weakness of the bile duct wall and increased pressure secondary to partial biliary obstruction are required for biliary cyst formation. More than 90% of patients have an anomalous pancreaticobiliary duct junction, with the pancreatic duct joining the common bile duct >1 cm proximal to the ampulla. This results in a long common channel that may allow free reflux of pancreatic secretions into the biliary tract, leading to inflammatory changes, increased biliary pressure, and cyst formation. Choledochal cysts are classified into five types (Fig. 32-22). The cysts are lined with cuboidal epithelium and can vary in size from 2 cm in diameter to giant cysts.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery*, 9th Edition; <http://www.accessmedicine.com>
 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Classification of choledochal cysts. Type I, fusiform or cystic dilations of the extrahepatic biliary tree, is the most common type, making up >50% of the choledochal cysts. Type II, saccular diverticulum of an extrahepatic bile duct. Rare, <5% of choledochal cysts. Type III, bile duct dilatation within the duodenal wall (choledochoceles), makes up about 5% of choledochal cysts. Type IVa and IVb, multiple cysts, make up 5–10% of choledochal cysts. Type IVa affects both extrahepatic and intrahepatic bile ducts while Type IVb cysts affect the extrahepatic bile ducts only. Type V, intrahepatic biliary cysts, is very rare and makes up 1% of choledochal cysts.

Adults commonly present with jaundice or cholangitis. Less than one half of patients present with the classic clinical triad of abdominal pain, jaundice, and a mass. Ultrasonography or CT scanning will confirm the diagnosis, but endoscopic, transhepatic, or MRC is required to assess the biliary anatomy and to plan the appropriate surgical treatment. For types I, II, and IV, excision of the extrahepatic biliary tree, including cholecystectomy, with a Roux-en-Y hepaticojejunostomy are ideal. In type IV, additional segmental resection of the liver may be appropriate, particularly if intrahepatic stones, strictures, or abscesses are present, or if the dilations are confined to one lobe. The risk of cholangiocarcinoma developing in choledochal cysts is as high as 15% in adults, and supports complete excision when they are diagnosed. For type III, sphincterotomy is recommended.⁶⁴

Sclerosing Cholangitis

Sclerosing cholangitis is an uncommon disease characterized by inflammatory strictures involving the intrahepatic and extrahepatic biliary tree. It is a progressive disease that eventually results in secondary biliary cirrhosis. Sometimes, biliary strictures are clearly secondary to bile duct stones, acute cholangitis, previous biliary surgery, or toxic agents, and are termed *secondary sclerosing cholangitis*. However, primary sclerosing cholangitis is a disease entity of its own, with no known attributing cause. It is associated with ulcerative colitis in about two thirds of patients. Other diseases associated with sclerosing cholangitis include Riedel's thyroiditis and retroperitoneal fibrosis. Autoimmune reaction, chronic low-grade bacterial or viral infection, toxic reaction, and genetic factors have all been suggested to play a role in its pathogenesis. The human leukocyte antigen haplotypes HLA-B8, -DR3, -DQ2, and -DRw52A, commonly found in patients with autoimmune diseases, also are more frequently seen in patients with sclerosing cholangitis than in controls. Patients with sclerosing cholangitis are at risk for developing cholangiocarcinoma. Eventually, 10 to 20% of the patients will develop cancer. Cholangiocarcinoma can present at any time during the disease process and does not correlate with the extent of sclerosing cholangitis or the development of liver failure, but frequently follows an aggressive course.

The mean age of presentation is 30 to 45 years, and men are affected twice as commonly as women. The usual presentation is intermittent jaundice, fatigue, weight loss, pruritus, and abdominal pain. Symptoms of acute cholangitis are rare, without preceding biliary tract intervention or surgery. More than one half of patients are symptomatic when diagnosed. In several patients with ulcerative colitis, abnormal liver function tests found on routine testing lead to the diagnosis. The clinical course in sclerosing cholangitis is highly variable, but cyclic remissions and exacerbations are typical. However, some patients remain asymptomatic for years, while others progress rapidly with the obliterative inflammatory changes leading to secondary biliary cirrhosis and liver failure. In patients with associated ulcerative colitis, the course of each disease seems independent of the other. Colectomy for the colitis makes no difference to the course of primary sclerosing cholangitis. The median survival for patients with primary sclerosing cholangitis from the time of diagnosis ranges from 10 to 12 years, and most die from hepatic failure.⁶⁵

The clinical presentation and elevation of alkaline phosphatase and bilirubin may suggest the diagnosis, but ERC, revealing multiple dilatations and strictures (beading) of both the intra- and extrahepatic biliary tree, confirms it. The hepatic duct bifurcation is often the most severely affected segment. A liver biopsy may not be diagnostic, but is important to determine the degree of hepatic fibrosis and the presence of cirrhosis. Sclerosing cholangitis is followed by ERC and liver biopsies to provide appropriate management.

There is no known effective medical therapy for primary sclerosing cholangitis and no known curative treatment. Corticosteroids, immunosuppressants, ursodeoxycholic acid, and antibiotics have been disappointing. Biliary strictures can be dilated and stented either endoscopically or percutaneously. These measures have given short-term improvements in symptoms and serum bilirubin levels, and long-term improvements in only less than one half of the patients. Surgical management with resection of the extrahepatic biliary tree and hepaticojejunostomy has produced reasonable results in patients with extrahepatic and bifurcation strictures, but without cirrhosis or significant hepatic fibrosis.⁶⁶ In patients with sclerosing cholangitis and advanced liver disease, liver transplantation is the only option. It offers excellent results, with overall 5-year survival as high as 85%. Primary sclerosing cholangitis recurs in 10 to 20% of patients and may require retransplantation.^{67,68}

Stenosis of the Sphincter of Oddi

A benign stenosis of the outlet of the common bile duct is usually associated with inflammation, fibrosis, or muscular hypertrophy. The pathogenesis is unclear, but trauma from the passage of stones, sphincter motility disorders, and congenital anomalies have been suggested. Episodic pain of the biliary type with abnormal liver function tests is a common presentation. However, recurrent jaundice or pancreatitis also may play a role. A dilated common bile duct that is difficult to cannulate with delayed emptying of the contrast are useful diagnostic features. Ampullary manometry and special provocation tests are available in specialized units. If the diagnosis is well established, endoscopic or operative sphincterotomy will yield good results.⁶⁹

Bile Duct Strictures

Benign bile duct strictures can have numerous causes. However, the vast majority were caused by operative injury, most commonly by laparoscopic cholecystectomy (see the section on Injury to the Biliary Tract below). Other causes include fibrosis due to chronic pancreatitis, common bile duct stones, acute cholangitis, biliary obstruction due to cholecystolithiasis (Mirizzi's syndrome), sclerosing cholangitis, cholangiohepatitis, and strictures of a biliary-enteric anastomosis. Bile duct strictures that go unrecognized or are improperly managed may lead to recurrent cholangitis, secondary biliary cirrhosis, and portal hypertension.⁷⁰

Patients with bile duct strictures most commonly present with episodes of cholangitis. Less commonly, they may present with jaundice without evidence of infection. Liver function tests usually show evidence of cholestasis. An ultrasound or a CT scan will show dilated bile ducts proximal to the stricture, as well as provide some information about the level of the stenosis. MRC will also provide good anatomic information about the location and the degree of dilatation. In patients with intrahepatic ductal dilatation, a percutaneous transhepatic cholangiogram will outline the proximal biliary tree, define the stricture and its location, and allow decompression of the biliary tree with transhepatic catheters or stents (Fig. 32-23). An endoscopic cholangiogram will outline the distal bile duct. Treatment depends on the location and the cause of the stricture. Percutaneous or endoscopic dilatation and/or stent placement give good results in more than one half of patients. Surgery with Roux-en-Y choledochojejunostomy or hepaticojejunostomy is the standard of care with good or excellent results in 80 to 90% of patients.⁷¹ Choledochoduodenostomy may be a choice for strictures in the distal-most part of the common bile duct.

INJURY TO THE BILIARY TRACT

Gallbladder

Injuries to the gallbladder are uncommon. Penetrating injuries are usually caused by gunshot wounds or stab wounds, and rarely by a needle biopsy procedure of the liver. Nonpenetrating trauma is extremely rare. These types of injury to the gallbladder include contusion, avulsion, laceration, rupture, and traumatic cholecystitis. The treatment of choice is cholecystectomy and the prognosis is directly related to the type and incidence of associated injury.

Extrahepatic Bile Ducts

Penetrating trauma to the extrahepatic bile ducts is rare and is usually associated with trauma to other viscera. The great majority of injuries of the extrahepatic biliary duct system are iatrogenic, occurring in the course of laparoscopic or open cholecystectomies.⁷² Less commonly, biliary injury is associated with common bile duct exploration, division or mobilization of the duodenum during gastrectomy, and dissection of the hepatic hilum during liver resections. The exact incidence of bile duct injury during cholecystectomy is unknown, but data suggest that during open cholecystectomy the incidence is relatively low (about 0.1 to 0.2%). However, the incidence during laparoscopic cholecystectomy, as derived from state and national databases, estimates the rate of major injury to range between 0.1% to 0.55%, and the incidence of minor injuries and bile leaks to be about 0.3%, a total of 0.85%. Limited view, difficult orientation and assessment of depth on a two-dimensional

image, and the lack of tactile sensation and unusual manual skills that are needed have led to the rise in bile duct injury during laparoscopic cholecystectomy.⁷³

A number of different factors are associated with bile duct injury during laparoscopic cholecystectomy. These include acute or chronic inflammation, obesity, anatomic variations, and bleeding. Surgical technique with inadequate exposure and failure to identify structures before ligating or dividing them are the most common cause of significant biliary injury. The bile ducts may be narrow and can be mistaken for the cystic duct. The cystic duct may run along side the common bile duct before joining it, leading the surgeon to the wrong place. Additionally, the cystic duct may enter the right hepatic duct, and the right hepatic duct may run aberrantly, coursing through the triangle of Calot and entering the common hepatic duct. A number of intraoperative technical factors have been implicated in biliary injuries. Excessive cephalad retraction of the gallbladder may align the cystic duct with the common bile duct, and the latter is then mistaken for the cystic duct and clipped and divided. The use of an angled laparoscope instead of an end-viewing one will help visualize the anatomic structures, in particular those around the triangle of Calot. An angled scope also will aid in the proper placement of clips. Careless use of electrocautery may lead to thermal injury. Dissection deep into the liver parenchyma may cause injury to intrahepatic ducts, and poor clip placement close to the hilar area or to structures not well visualized can result in a clip across a bile duct.^{74,75}

The routine use of intraoperative cholangiography to prevent bile duct injury is controversial.⁷⁶ It may limit the extent of injury but does not seem to prevent it. However, if a bile duct injury is suspected during cholecystectomy, a cholangiogram must be obtained to detect and identify the anatomic features. It is important to check that the whole biliary system fills with contrast and to be sure there are no leaks.

DIAGNOSIS

Only about 25% of major bile duct injuries (common bile duct or hepatic duct) are recognized at the time of operation. Most commonly, intraoperative bile leakage, recognition of the correct anatomy, and an abnormal cholangiogram lead to the diagnosis of a bile duct injury. More than half of patients with biliary injury will present within the first postoperative month. The remainder will present months or years later, with recurrent cholangitis or cirrhosis from a remote bile duct injury. In the early postoperative period, patients present either with progressive elevation of liver function tests due to an occluded or a stenosed bile duct, or with a bile leak from an injured duct. Bile leak, most commonly from the cystic duct stump, a transected aberrant right hepatic duct, or a lateral injury to the main bile duct, usually presents with pain, fever, and a mild elevation of liver function tests. A CT scan or an ultrasound will show either a collection (biloma) in the gallbladder area or free fluid (bile) in the peritoneum (Fig. 32-24). Bilius drainage through operatively placed drains or through the wounds is abnormal. The site of the bile leak can be confirmed noninvasively with a HIDA scan. In patients with a surgical drain or a percutaneously placed catheter, injection of water-soluble contrast media through the drainage tract (sinogram) can often define the site of leakage and the anatomy of the biliary tree.⁷⁷

A. Computed tomographic scan of a patient with bile leak after cholecystectomy. The *short arrows* indicate the intraperitoneal collections. Both air and bile are seen in the gallbladder bed (*long arrow*) as well as a surgical clip. **B.** An endoscopic retrograde cholangiography from the same patient showing a leak from the cystic duct stump (*arrow*). Note the

CT scan and ultrasound also are important in the initial evaluation of the jaundiced patient, as they can demonstrate the dilated part of the biliary tree proximal to the stenosis or obstruction, and may identify the level of the extrahepatic bile duct obstruction. In the jaundiced patient with dilated intrahepatic ducts, a percutaneous cholangiogram will outline the anatomy and the proximal extent of the injury and allow decompression of the biliary tree with catheter or stent placements. An endoscopic cholangiogram demonstrates the anatomy distal to the injury and may allow the placement of stents across a stricture to relieve an obstruction (see Fig. 32-23). MRI cholangiography, if available, provides an excellent, noninvasive delineation of the biliary anatomy both proximal and distal to the injury.

MANAGEMENT

The management of bile duct injuries depends on the type, extent, and level of injury, and the time of its diagnosis. Initial proper treatment of bile duct injury diagnosed during the cholecystectomy can avoid the development of a bile duct stricture. If a major injury is discovered and an experienced biliary surgeon is not available, an external drain and, if necessary, transhepatic biliary catheters are placed, and the patient is transferred to a referral center.⁷³

Transected bile ducts <3 mm or those draining a single hepatic segment can safely be ligated. If the injured duct is ≥ 4 mm, it is likely to drain multiple segments or an entire lobe, and thus needs to be reimplanted. Lateral injury to the common bile duct or the common hepatic duct, recognized at the time of surgery, is best managed with a T-tube placement. If the injury is a small incision in the duct, the T tube may be placed through it as if it were a formal choledochotomy. In more extensive lateral injuries, the T tube should be placed through a separate choledochotomy and the injury closed over the T-tube end to minimize the risk of subsequent stricture formation.

Major bile duct injuries such as transection of the common hepatic or common bile duct are best managed at the time of injury. In many of these major injuries, the bile duct has not only been transected, but a variable length of the duct removed. This injury usually requires a biliary enteric anastomosis with a jejunal loop. Either an end-to-side Roux-en-Y choledochojejunostomy, or more commonly a Roux-en-Y hepaticojejunostomy, should be performed. Transhepatic biliary catheters are placed through the anastomosis to stent it and to provide access to the biliary tract for drainage and imaging. Although rare, when the injury is to the distal common bile duct, a choledochoduodenostomy can be performed. If there is no or minimal loss of ductal length, a duct-to-duct repair may be done over a T tube that is placed through a separate incision. It is critical to perform a tension-free anastomosis to minimize the high risk of postoperative stricture formation.⁶⁶

Cystic duct leaks can usually be managed with percutaneous drainage of intra-abdominal fluid collections followed by an endoscopic biliary stenting (see Fig. 32-24).

Major injuries diagnosed postoperatively require transhepatic biliary catheter placement for biliary decompression as well as percutaneous drainage of intra-abdominal bile collections, if any. When the acute inflammation has resolved 6 to 8 weeks later, operative repair is performed.

Patients with bile duct stricture from an injury or as a sequela of previous repair usually present with either progressive elevation of liver function tests or cholangitis. The initial management usually includes transhepatic biliary drainage catheter placement for decompression as well as for defining the anatomy and the location and the extent of the damage. These catheters will also serve as useful technical aids during subsequent biliary enteric anastomosis. An anastomosis is performed between the duct proximal to the injury and a Roux loop of jejunum. Balloon dilatation of a stricture usually requires multiple attempts and rarely provides adequate long-term relief. Self-expanding metal or plastic stents, placed either

percutaneously or endoscopically across the stricture, can provide temporary drainage and, in the high-risk patient, permanent drainage of the biliary tree.

OUTCOME

Good results can be expected in 70 to 90% of patients with bile duct injuries.⁷⁸ The best results are obtained when the injury is recognized during the cholecystectomy and repaired by an experienced biliary tract surgeon. The operative mortality rate varies from 0 to almost 30% in various series, but commonly is about 5 to 8%. Common complications that are specific for bile duct repairs include cholangitis, external biliary fistula, bile leak, subhepatic and subphrenic abscesses, and hemobilia. Restenosis of a biliary enteric anastomosis occurs in about 10% of patients, and may manifest up to 20 years after the initial procedure. Approximately two thirds of recurrent strictures become symptomatic within 2 years after repair. The more proximal strictures are associated with a lower success rate than are distal ones. The worst results are in patients with many operative revisions and in those who have evidence of liver failure and portal hypertension. However, previous repair does not preclude successful outcome of repeated attempts, particularly in patients with good liver function. Patients with deteriorating liver function are candidates for liver transplants.

TUMORS

Carcinoma of the Gallbladder

Cancer of the gallbladder is a rare malignancy that occurs predominantly in the elderly. It is an aggressive tumor, with poor prognosis except when incidentally diagnosed at an early stage after cholecystectomy for cholelithiasis. The overall reported 5-year survival rate is about 5%.⁷⁹

INCIDENCE

Gallbladder cancer is the fifth most common GI malignancy in Western countries. However, it accounts for only 2 to 4% of all malignant GI tumors, with about 5000 new cases diagnosed annually in the United States. It is two to three times more common in females than males, and the peak incidence is in the seventh decade of life. Its occurrence in random autopsy series is about 0.4%, but approximately 1% of patients undergoing cholecystectomy for gallstone disease are found incidentally to have gallbladder cancer. The incidence of gallbladder cancer is particularly high in native populations of the United States, Mexico, and Chile. The annual incidence in Native American females with gallstones approaches 75 per 100,000, compared with the overall incidence of gallbladder cancer of 2.5 cases per 100,000 residents in the United States.⁸⁰

ETIOLOGY

Cholithiasis is the most important risk factor for gallbladder carcinoma, and up to 95% of patients with carcinoma of the gallbladder have gallstones.⁸¹ However, the 20-year risk of developing cancer for patients with gallstones is <0.5% for the overall population and 1.5% for high-risk groups. The pathogenesis has not been defined but is probably related to chronic inflammation. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.⁸² The risk of developing cancer of the gallbladder is higher in patients with symptomatic than asymptomatic gallstones.

Polypoid lesions of the gallbladder are associated with increased risk of cancer, particularly in polyps >10 mm.⁸³ The calcified "porcelain" gallbladder is associated with >20% incidence of gallbladder carcinoma. These gallbladders should be removed, even if the patients are asymptomatic. Patients with choledochal cysts have an increased risk of developing cancer anywhere

in the biliary tree, but the incidence is highest in the gallbladder. Sclerosing cholangitis, anomalous pancreaticobiliary duct junction, and exposure to carcinogens (azotoluene, nitrosamines) also are associated with cancer of the gallbladder.

PATHOLOGY

Between 80 and 90% of the gallbladder tumors are adenocarcinomas. Squamous cell, adenosquamous, oat cell, and other anaplastic lesions occur rarely. The histologic subtypes of gallbladder adenocarcinomas include papillary, nodular, and tubular. Less than 10% are of the papillary type, but these are associated with an overall better outcome, as they are most commonly diagnosed while localized to the gallbladder. Cancer of the gallbladder spreads through the lymphatics, with venous drainage, and with direct invasion into the liver parenchyma. Lymphatic flow from the gallbladder drains first to the cystic duct node (Calot's), then the pericholedochal and hilar nodes, and finally the peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. The gallbladder veins drain directly into the adjacent liver, usually segments IV and V, where tumor invasion is common (Fig. 32-25). The gallbladder wall differs histologically from the intestines in that it lacks a muscularis mucosa and submucosa. Lymphatics are present in the subserosal layer only. Therefore, cancers invading but not growing through the muscular layer have minimal risk of nodal disease. When diagnosed, about 25% of gallbladder cancers are localized to the gallbladder wall, 35% have regional nodal involvement and/or extension into adjacent liver, and approximately 40% have distant metastasis.⁸⁴

Computed tomography scan of a patient with gallbladder cancer. The image shown is at the level of the liver hilum. The portal vein is bifurcating into the left and right portal branch. The tumor has invaded segment IV of the liver (*arrowheads*) and obstructed the common hepatic duct, resulting in intrahepatic ductal dilatation (*arrows*).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis. These include abdominal discomfort, right upper quadrant pain, nausea, and vomiting. Jaundice, weight loss, anorexia, ascites, and abdominal mass are less common presenting symptoms. More than one half of gallbladder cancers are not diagnosed before surgery. Common misdiagnoses include chronic cholecystitis, acute cholecystitis, choledocholithiasis, hydrops of the gallbladder, and pancreatic cancer. Laboratory findings are not diagnostic but, if abnormal, are most often consistent with biliary obstruction. Ultrasonography often reveals a thickened, irregular gallbladder wall or a mass replacing the gallbladder. Ultrasonography may visualize tumor invasion of the liver, lymphadenopathy, and a dilated biliary tree. The sensitivity of ultrasonography in detecting gallbladder cancer ranges from 70 to 100%. A CT scan is an important tool for staging and may identify a gallbladder mass or local invasion into adjacent organs. In addition, a spiral CT scan can demonstrate vascular invasion; however, CT scan is a poor method for identifying nodal spread. In jaundiced patients, a percutaneous transhepatic or endoscopic cholangiogram may be helpful to delineate the extent of biliary tree involvement, and typically shows a long stricture of the common bile duct. With newer MRI techniques, MRCP has evolved into a single noninvasive imaging method that allows complete assessment of biliary, vascular, nodal, hepatic, and adjacent organ involvement.⁸⁵ If diagnostic studies suggest that the tumor is unresectable, a CT scan or ultrasound-guided biopsy of the tumor can be obtained to provide a pathologic diagnosis.

TREATMENT

Surgery remains the only curative option for gallbladder cancer as well as for cholangiocarcinoma. However, palliative procedures for patients with unresectable cancer and jaundice or duodenal obstruction remain the most frequently performed surgery for gallbladder cancers. Today, patients with obstructive jaundice can frequently be managed with either endoscopic or percutaneously placed biliary stents. There are no proven effective options for adjuvant radiation or chemotherapy for patients with gallbladder cancer.

The pathologic stage of gallbladder cancer determines the operative treatment for patients with localized gallbladder cancer. Patients without evidence of distant metastasis warrant exploration for tissue diagnosis, pathologic staging, and possible curative resection.

Tumors limited to the muscular layer of the gallbladder (T1) are usually identified incidentally, after cholecystectomy for gallstone disease. There is near universal agreement that simple cholecystectomy is an adequate treatment for T1 lesions and results in a near 100% overall 5-year survival rate. When the tumor invades the perimuscular connective tissue without extension beyond the serosa or into the liver (T2 tumors), an extended cholecystectomy should be performed.⁸⁶ That includes resection of liver segments IVB and V, and lymphadenectomy of the cystic duct, and pericholedochal, portal, right celiac, and posterior pancreaticoduodenal lymph nodes. One half of patients with T2 tumors are found to have nodal disease on pathologic examination. Therefore, regional lymphadenectomy is an important part of surgery for T2 cancers.⁸⁷ For tumors that grow beyond the serosa or invade the liver or other organs (T3 and T4 tumors), there is a high likelihood of intraperitoneal and distant spread. If no peritoneal or nodal involvement is found, complete tumor excision with an extended right hepatectomy (segments IV, V, VI, VII, and VIII) must be performed for adequate tumor clearance. An aggressive approach in patients who will tolerate surgery has resulted in an increased survival for T3 and T4 lesions.

PROGNOSIS

Most patients with gallbladder cancer have unresectable disease at the time of diagnosis. The 5-year survival rate of all patients with gallbladder cancer is <5%, with a median survival of 6 months.⁸⁸ Patients with T1 disease treated with cholecystectomy have an excellent prognosis (85 to 100% 5-year survival rate). The 5-year survival rate for T2 lesions treated with an extended cholecystectomy and lymphadenectomy compared with simple cholecystectomy is >70% vs. 25 to 40%, respectively. Patients with advanced but resectable gallbladder cancer are reported to have 5-year survival rates of 20 to 50%. However, the median survival for patients with distant metastasis at the time of presentation is only 1 to 3 months. Recurrence after resection of gallbladder cancer occurs most commonly in the liver or the celiac or retropancreatic nodes. The prognosis for recurrent disease is very poor. Death occurs most commonly secondary to biliary sepsis or liver failure. The main goal of follow-up is to provide palliative care. The most common problems are pruritus and cholangitis associated with obstructive jaundice, bowel obstruction secondary to carcinomatosis, and pain.

Bile Duct Carcinoma

Cholangiocarcinoma is a rare tumor arising from the biliary epithelium and may occur anywhere along the biliary tree. About two thirds are located at the hepatic duct bifurcation. Surgical resection offers the only chance for cure; however, many patients have advanced disease at the time of diagnosis. Therefore, palliative procedures aimed to provide biliary drainage to prevent liver failure and cholangitis are often the only therapeutic possibilities. Most patients with unresectable disease die within 1 year of diagnosis.⁸⁹

INCIDENCE

The autopsy incidence of bile duct carcinoma is about 0.3%. The overall incidence of cholangiocarcinoma in the United States is about 1.0 per 100,000 people per year, with about 3000 new cases diagnosed annually. The male to female ratio is 1.3:1, and the average age of presentation is between 50 and 70 years.

ETIOLOGY

Risk factors associated with cholangiocarcinoma include primary sclerosing cholangitis, choledochal cysts, ulcerative colitis, hepatolithiasis, biliary-enteric anastomosis, and biliary tract infections with *Clonorchis* or in chronic typhoid carriers. Features common to most risk factors include biliary stasis, bile duct stones, and infection. Other risk factors associated with cholangiocarcinoma are liver flukes, dietary nitrosamines, Thorotrast, and exposure to dioxin.^{90,91}

PATHOLOGY

Over 95% of bile duct cancers are adenocarcinomas. Morphologically, they are divided into nodular (the most common type), scirrhous, diffusely infiltrating, or papillary. Anatomically, they are divided into distal, proximal, or perihilar tumors. Intrahepatic cholangiocarcinomas occur, but they are treated like hepatocellular carcinoma, with hepatectomy when possible. About two thirds of cholangiocarcinomas are located in the perihilar location. Perihilar cholangiocarcinomas, also referred to as Klatskin tumors, are further classified based on anatomic location by the Bismuth-Corlette classification (Fig. 32-26). Type I tumors are confined to the common hepatic duct, but type II tumors involve the bifurcation without involvement of the secondary intrahepatic ducts. Type IIIa and IIIb tumors extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors involve both the right and left secondary intrahepatic ducts.

Bismuth-Corlette classification of bile duct tumors.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Painless jaundice is the most common presentation. Pruritus, mild right upper quadrant pain, anorexia, fatigue, and weight loss also may be present. Cholangitis is the presenting symptom in about 10% of patients, but occurs more commonly after biliary manipulation in these patients. Except for jaundice, physical examination is usually normal in patients with cholangiocarcinoma. Occasionally, asymptomatic patients are found to have cholangiocarcinoma while being evaluated for elevated alkaline phosphatase and γ -glutamyltransferase levels. Tumor markers such CA 125 and carcinoembryonic antigen can be elevated in cholangiocarcinoma but tend to be nonspecific because they also increase in other GI and gynecologic malignancies or cholangiopathologies. The tumor marker most commonly used to aid the diagnosis of cholangiocarcinoma is CA 19-9, which has a sensitivity of 79% and specificity of 98% if the serum value is >129 U/mL.⁹² However, mild elevations in CA 19-9 can be seen in cholangitis, other GI and gynecologic neoplasms, and in patients who lack the Lewis blood type antigen.⁹³

The initial tests are usually ultrasound or CT scan. A perihilar tumor causes dilatation of the intrahepatic biliary tree, but normal or collapsed gallbladder and extrahepatic bile ducts distal to the tumor. Distal bile duct cancer leads to dilatation of the extra- and the intrahepatic bile ducts as well as the gallbladder. Ultrasound can establish the level of obstruction and rule out the presence of bile duct stones as the cause of the obstructive jaundice (Fig. 32-27). It is usually difficult to visualize the tumor itself on ultrasound or on a standard CT scan. Either ultrasound or spiral CT can be used to determine portal vein patency. The biliary anatomy is defined by cholangiography. PTC defines the proximal extent of the tumor, which is the most

important factor in determining resectability. ERC is used, particularly in the evaluation of distal bile duct tumors. For the evaluation of vascular involvement, celiac angiography may be necessary. With the newer types of MRI, a single noninvasive test has the potential of evaluating the biliary anatomy, lymph nodes, and vascular involvement, as well as the tumor growth itself.⁹⁴

A. An endoscopic retrograde cholangiography from a patient with cancer of the common hepatic duct (*arrowheads*). The common bile duct is of normal size as is the cystic duct (*arrow*), but the proximal biliary tree is dilated. The gallbladder is not visualized because of tumor obstructing its neck. **B.** An ultrasound from the same patient showing dilated ducts and tumor obstructing the common hepatic duct (*arrow*). The walls of the bile ducts adjacent to the obstruction are thickened by tumor infiltration (*arrowheads*).

Tissue diagnosis may be difficult to obtain nonoperatively except in advanced cases. Percutaneous fine-needle aspiration biopsy, biliary brush or scrape biopsy, and cytologic examination have a low sensitivity in detecting malignancy. Patients with potentially resectable disease should, therefore, be offered surgical exploration based on radiographic findings and clinical suspicion.⁹⁵

TREATMENT

Surgical excision is the only potentially curative treatment for cholangiocarcinoma. In the past one to two decades, improvements in surgical techniques have resulted in lower mortality and better outcome for patients undergoing aggressive surgical excision for cholangiocarcinoma.⁹⁶

Patients should undergo surgical exploration if they have no signs of metastasis or locally unresectable disease. However, despite improvements in ultrasonography, CT scanning, and MRI, more than one half of patients who are explored are found to have peritoneal implants, nodal or hepatic metastasis, or locally advanced disease that precludes resection. For these patients, surgical bypass for biliary decompression and cholecystectomy to prevent the occurrence of acute cholecystitis should be performed.⁹⁷

For unresectable perihilar cholangiocarcinoma, Roux-en-Y cholangiojejunostomy to either segment II or III bile ducts or to the right hepatic duct can be performed.

For curative resection, the location and local extension of the tumor dictates the extent of the resection. Perihilar tumors involving the bifurcation or proximal common hepatic duct (Bismuth-Corlette type I or II) with no signs of vascular involvement are candidates for local tumor excision with portal lymphadenectomy, cholecystectomy, common bile duct

excision, and bilateral Roux-en-Y hepaticojejunostomies. If the tumor involves the right or left hepatic duct (Bismuth-Corlette type IIIa or IIIb), right or left hepatic lobectomy, respectively, should also be performed. Frequently, resection of the adjacent caudate lobe is required because of direct extension into caudate biliary radicals or parenchyma.⁹⁵

Distal bile duct tumors are more often resectable. They are treated with pylorus-preserving pancreatoduodenectomy (Whipple procedure). For patients with distal bile duct cancer found to be unresectable on surgical exploration, Roux-en-Y hepaticojejunostomy, cholecystectomy, and gastrojejunostomy to prevent gastric outlet obstruction should be performed.

Nonoperative biliary decompression is performed for patients with unresectable disease on diagnostic evaluation.

Percutaneous placement of expandable metal stents or drainage catheters is usually the appropriate approach for proximal tumors. However, for distal bile duct tumors, endoscopic placement is often the preferred approach (Fig. 32-28). There is a significant risk of cholangitis with internal and external drainage, and stent occlusion is not uncommon. However, although surgical bypass offers improved patency and fewer episodes of cholangitis, an operative intervention is not warranted in patients with metastatic disease.⁹⁸

A through F. Percutaneous transhepatic cholangiography and placement of a biliary drainage catheter. The catheter has been passed through the tumor area (distal cholangiocarcinoma) that is obstructing the distal common bile duct and into the duodenum.

There is no proven role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. Adjuvant radiation therapy has also not been shown to increase either quality of life or survival in resected patients. Patients with unresectable disease often are offered treatment with 5-fluorouracil alone or in combination with mitomycin C and doxorubicin, but the response rates are low, <10% and <30%, respectively. The combination of radiation and chemotherapy may be more effective than either treatment alone for unresectable disease, but no data from randomized trials are available. Giving chemoradiation to these patients can be difficult because of the high incidence of cholangitis. External beam radiation has not been shown to be an effective treatment for unresected disease. The use of interstitial (intraoperative) radiation, brachytherapy with iridium 192 via percutaneous or endoscopic stents, and combined interstitial and external beam radiation for unresectable cholangiocarcinoma has been reported with some encouraging results. However, no randomized, prospective trials have been reported.⁹⁵ A palliative measure that has been shown effective in a multicenter randomized trial is photodynamic therapy. In this trial, patients with a diagnosis of unresectable cholangiocarcinoma were randomized to biliary stenting with photodynamic therapy or stenting alone. The authors found that photodynamic therapy prolonged survival by approximately 400 days and improved quality of life on standardized questionnaire.⁹⁹

PROGNOSIS

Most patients with perihilar cholangiocarcinoma present with advanced, unresectable disease. Patients with unresectable disease have a median survival between 5 and 8 months. The most common causes of death are hepatic failure and cholangitis. The overall 5-year survival rate for patients with resectable perihilar cholangiocarcinoma is between 10 and 30%, but for patients with negative margins, it may be as high as 40%. The operative mortality for perihilar cholangiocarcinoma is 6 to 8%. Patients with distal cholangiocarcinoma are more likely to have resectable disease and improved prognosis compared to perihilar cholangiocarcinoma. The overall 5-year survival rate for resectable disease is 30 to 50%, and the median survival is 32 to 38 months.

The greatest risk factors for recurrence after resection are the presence of positive margins and lymph node–positive tumors. Therapy for recurrent disease is palliation of symptoms. Surgery is not recommended for patients with recurrent disease.⁹⁴

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 33. Pancreas >

KEY POINTS

1. Incomplete fusion of the dorsal and ventral pancreatic ducts results in pancreas divisum, but a variety of ductal anomalies can be seen. Magnetic resonance cholangiopancreatography as well as endoscopic retrograde cholangiopancreatography can identify these ductal anomalies, and clarification of the ductal pattern of the pancreas is important before attempts at interventions.
2. The "replaced right hepatic artery" occurs in 15% of patients and needs to be identified preoperatively to prevent inadvertent injury with resulting hepatic necrosis. Anomalous hepatic arterial anatomy can result in hepatic ischemia during dissection of the porta hepatis as well. "Thin cut" multidetector computed tomographic images are usually able to identify the relevant arterial and venous patterns around the pancreas.
3. Regardless of the etiology, the management of the early phase of acute pancreatitis is critical to achieve a successful outcome. "Resting the pancreas" means eliminating oral nutrients, and resumption of diet should be limited to liquids and low-fat/low-protein foods. Patients who do not improve spontaneously within 24 to 48 hours are at risk for developing severe disease with its risk of life-threatening sepsis.
4. Surgical intervention in acute pancreatitis is reserved for patients with infected collections or infected necrosis only, or to relieve an impacted gallstone in the ampulla if endoscopic or radiologic treatments are unavailable or unsuccessful. Infection is usually confirmed by a pattern of air in the retroperitoneum on computed tomographic scan, or by documentation of bacteria on Gram's stain or culture from fine-needle aspiration of a suspected infected fluid collection. Fine-needle aspiration of suspicious fluid collections should not be converted to percutaneous drainage unless infection is confirmed, and the consensus decision has been made that percutaneous drainage is appropriate for the individual patient.
5. The appearance of chronic pancreatitis on computed tomographic scan varies dramatically, and multiple diagnostic studies are usually needed to establish the extent of disease. Calcific pancreatitis is not a marker of alcoholic pancreatitis alone, and rarely indicates autoimmune pancreatitis. Endoscopic ultrasound provides a better assessment of the disease than computed tomography and is useful to disclose indolent or unsuspected cancer, which can occur in up to 10% of patients.
6. The nidus of inflammation in chronic pancreatitis due to any cause is the head of the gland. Therefore, treatment approaches that address the disease in the head have the best long-term results. The Whipple procedure, the Beger procedure, and the Frey procedure, with or without longitudinal duct drainage, are the best surgical options, as all three approaches remove all or most of the disease in the head of the gland.
7. The precursor lesion that probably leads to most cases of ductular adenocarcinoma is the ductal epithelial hyperplasia/dysplasia process described by the pancreatic intraepithelial neoplasia classification system. Pancreatic intraepithelial neoplasia 2 and pancreatic intraepithelial neoplasia 3 lesions may be associated with other, nonspecific changes in pancreatic morphology seen on imaging studies, or may only be seen histologically. Resection margins for pancreatic neoplasms should be examined for advanced pancreatic intraepithelial neoplasia stage patterns of ductal hyperplasia to ensure adequate resection status.
8. Intraductal papillary mucinous neoplasms are small macroscopic polypoid or plaque-like adenomas that develop in the main pancreatic duct or in side-branch ducts, and secrete mucin. They are often silent symptomatically, but cause characteristic appearances of small cyst-like collections of mucus, or diffuse dilatation of the main pancreatic duct with mucus. These premalignant lesions may be multifocal or single and can evolve into invasive adenocarcinoma in a similar pattern as with other adenomatous polypoid lesions of the gastrointestinal tract. They have been diagnosed with increasing frequency, and account for more than one third of pancreatic resections at some centers. Main-duct intraductal papillary mucinous neoplasms are an indication for resection; side-branch intraductal papillary mucinous neoplasms have a lower incidence of malignancy and are sometimes followed with serial imaging surveillance.

ANATOMY AND PHYSIOLOGY

The pancreas is perhaps the most unforgiving organ in the human body, leading most surgeons to avoid even palpating it unless necessary. Situated deep in the center of the abdomen, the pancreas is surrounded by numerous important structures and major blood vessels. Seemingly

minor trauma to the pancreas can result in the release of pancreatic enzymes and cause life-threatening pancreatitis. Surgeons that choose to undertake surgery on the pancreas require a thorough knowledge of its anatomy. However, knowledge of the relationships of the pancreas and surrounding structures is also critically important for all surgeons to ensure that pancreatic injury is avoided during surgery on other structures.

Gross Anatomy

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum (Fig. 33-1). In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20 cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents. Patients with pancreatic cancer without bile duct obstruction usually present after months of vague upper abdominal discomfort, or no antecedent symptoms at all. Due to its retroperitoneal location, pain associated with pancreatitis often is characterized as penetrating through to the back.

Fig. 33-1.

Pancreatic anatomy as seen on computed tomography. Knowledge of the relationship of the pancreas with surrounding structures is important to ensure that injury is avoided during abdominal surgery. IMV = inferior mesenteric vein; SMA = superior mesenteric artery; SMV = superior mesenteric vein.

REGIONS OF THE PANCREAS

Surgeons typically describe the location of pathology within the pancreas in relation to four regions: the head, neck, body, and tail. The head of the

pancreas is nestled in the C-loop of the duodenum and is posterior to the transverse mesocolon. Just behind the head of the pancreas lie the vena cava, the right renal artery, and both renal veins. The neck of the pancreas lies directly over the portal vein. At the inferior border of the neck of the pancreas, the superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein. Sometimes, the inferior mesenteric vein joins the superior mesenteric vein or merges with the superior mesenteric portal venous junction to form a trifurcation (Fig. 33-2). The superior mesenteric artery lies parallel to and just to the left of the superior mesenteric vein. The uncinate process and the head of the pancreas wrap around the right side of the portal vein and end posteriorly near the space between the superior mesenteric vein and superior mesenteric artery. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins during pancreatic resection, unless the tumor is invading the vein anteriorly. The common bile duct runs in a deep groove on the posterior aspect of the pancreatic head until it passes through the pancreatic parenchyma to join the main pancreatic duct at the ampulla of Vater. The body and tail of the pancreas lie just anterior to the splenic artery and vein. The vein runs in a groove on the back of the pancreas and is fed by multiple fragile venous branches from the pancreatic parenchyma. These branches must be ligated to perform a spleen-sparing distal pancreatectomy. The splenic artery runs parallel and just superior to the vein along the posterior superior edge of the body and tail of the pancreas. The splenic artery often is tortuous. The anterior surface of the body of the pancreas is covered by peritoneum. Once the gastrocolic omentum is divided, the body and tail of the pancreas can be seen along the floor of the lesser sac, just posterior to the stomach.

Fig. 33-2.

Variations in portal venous anatomy. The superior mesenteric vein joins the splenic vein and then continues toward the porta hepatis as the portal vein. The inferior mesenteric vein often joins the splenic vein near its junction with the portal vein, but sometimes joins the superior mesenteric vein; or the three veins merge as a trifurcation to form the portal vein.

Pancreatic pseudocysts commonly develop in this area, and the posterior aspect of the stomach can form the anterior wall of the pseudocyst, allowing drainage into the stomach. The base of the transverse mesocolon attaches to the inferior margin of the body and tail of the pancreas. The transverse mesocolon often forms the inferior wall of pancreatic pseudocysts or inflammatory processes, allowing surgical drainage through the transverse mesocolon. The body of the pancreas overlies the aorta at the origin of the superior mesenteric artery. The neck of the pancreas overlies the vertebral body of L1 and L2, and blunt anteroposterior trauma can compress the neck of the pancreas against the spine, causing parenchymal and, sometimes, ductal injury. The neck divides the pancreas into approximately two equal halves. The small portion of the pancreas anterior to the left kidney is referred to as the *tail* and is nestled in the hilum of the spleen near the splenic flexure of the left colon. Awareness of these anatomic relationships is important to avoid injury to the pancreatic tail during left colectomy or splenectomy.

PANCREATIC DUCT ANATOMY

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion

of a ventral and dorsal bud. The duct from the smaller ventral bud, which arises from the hepatic diverticulum, connects directly to the common bile duct. The duct from the larger dorsal bud, which arises from the duodenum, drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct, into the common channel formed from the bile duct and pancreatic duct. The length of the common channel is variable. In about one third of patients, the bile duct and pancreatic duct remain distinct to the end of the papilla, the two ducts merge at the end of the papilla in another one third, and in the remaining one third, a true common channel is present for a distance of several millimeters. Commonly, the duct from the dorsal anlage, the duct of Santorini, persists as the lesser pancreatic duct, and sometimes drains directly into the duodenum through the lesser papilla just proximal to the major papilla. In approximately 30% of patients, the duct of Santorini ends as a blind accessory duct and does not empty into the duodenum. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse.¹ This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as *pancreas divisum* (Fig. 33-3). In a minority of these patients, the minor papilla can be inadequate to handle the flow of pancreatic juices from the majority of the gland. This relative outflow obstruction can result in pancreatitis and is sometimes treated by sphincteroplasty of the minor papilla.

Fig. 33-3.

Embryology of pancreas and duct variations. The duct of Wirsung from the ventral bud connects to the bile duct, while the duct of Santorini from the larger dorsal bud connects to the duodenum. With gut rotation, the two ducts fuse in most cases such that the majority of the pancreas drains through the duct of Wirsung to the major papilla. The duct of Santorini can persist as a blind accessory duct or drain through the lesser papilla. In a minority of patients, the ducts remain separate, and the majority of the pancreas drains through the duct of Santorini, a condition referred to as *pancreas divisum*.

The main pancreatic duct is usually only 2 to 3 mm in diameter and runs midway between the superior and inferior borders of the pancreas, usually closer to the posterior than to the anterior surface. Pressure inside the pancreatic duct is about twice that in the common bile duct, which is thought to prevent reflux of bile into the pancreatic duct. The main pancreatic duct joins with the common bile duct and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. The muscle fibers around the ampulla form the sphincter of Oddi, which controls the flow of pancreatic and biliary secretions into the duodenum. Contraction and relaxation of the sphincter is regulated by complex neural and hormonal factors. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2 cm proximal to the ampulla of Vater.

VASCULAR AND LYMPHATIC ANATOMY

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (Fig. 33-4). The common hepatic artery gives rise to the gastroduodenal artery before continuing toward the porta hepatis as the proper hepatic artery. The gastroduodenal artery becomes the superior pancreaticoduodenal artery as it passes behind the first portion of the duodenum and branches into the anterior and posterior superior pancreaticoduodenal arteries. As the superior mesenteric artery passes behind the neck of the pancreas, it gives off the inferior pancreaticoduodenal artery at the inferior margin of the neck of the pancreas. This vessel quickly divides into the anterior and posterior inferior pancreaticoduodenal arteries. The superior and inferior pancreaticoduodenal arteries join together within the parenchyma of the anterior and posterior sides of the head of the pancreas along the medial aspect of the C-loop of the duodenum to form arcades that give off numerous branches to the duodenum and head of the pancreas. Therefore, it is impossible to resect the head of the pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, common hepatic artery, or gastroduodenal arteries can arise from the superior mesenteric artery. In 15 to 20% of patients, the right hepatic artery will arise from the superior mesenteric artery and travel upwards toward the liver along the posterior aspect of the head of the pancreas (referred to as a *replaced right hepatic artery*). It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the replaced hepatic artery is recognized and injury is avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the superior mesenteric artery and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery. Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas, and account for the rich blood supply of the organ.

Arterial supply to the pancreas. Multiple arcades in the head and body of the pancreas provide a rich blood supply. The head of the pancreas cannot be resected without devascularizing the duodenum unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved.

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply. The veins are usually superficial to the arteries within the parenchyma of the pancreas. There is an anterior and posterior venous arcade within the head of the pancreas. The superior veins drain directly into the portal vein just above the neck of the pancreas. The posterior inferior arcade drains directly into the inferior mesenteric vein at the inferior

border of the neck of the pancreas. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein. Traction on the transverse colon during colectomy can tear these fragile veins, which then retract into the parenchyma of the pancreas, making control tedious. There also are numerous small venous branches coming from the pancreatic parenchyma directly into the lateral and posterior aspect of the portal vein. Venous return from the body and tail of the pancreas drains into the splenic vein (Fig. 33-5).

Fig. 33-5.

Venous drainage from the pancreas. The venous drainage of the pancreas follows a pattern similar to the arterial supply, with the veins usually superficial to the arteries. Anterior traction on the transverse colon can tear fragile branches along the inferior border of the pancreas, which then retract into the parenchyma of the pancreas. Venous branches draining the pancreatic head and uncinate process enter along the right lateral and posterior sides of the portal vein. There are usually no anterior venous tributaries, and a plane can usually be developed between the neck of the pancreas and the portal and superior mesenteric veins.

The lymphatic drainage from the pancreas is diffuse and widespread. The profuse network of lymphatic vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas. This diffuse lymphatic drainage contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. Lymph nodes can be palpated along the posterior aspect of the head of the pancreas in the pancreaticoduodenal groove, where the mesenteric vein passes under the neck of the pancreas, along the inferior border of the body, along the hepatic artery ascending into the porta hepatis, and along the splenic artery and vein. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas often metastasize to these nodes and lymph nodes along the splenic vein and in the hilum of the spleen (Fig. 33-6).

Fig. 33-6.

Lymphatic supply to the pancreas. The lymphatic drainage from the pancreas is diffuse and widespread, which explains the high incidence of lymph node metastases and local recurrence of pancreatic cancer. The pancreatic lymphatics also communicate with lymph nodes in the transverse mesocolon and mesentery of the proximal jejunum. Tumors in the body and tail of the pancreas are often unresectable because they metastasize to these lymph nodes.

NEUROANATOMY

The pancreas is innervated by the sympathetic and parasympathetic nervous systems. The acinar cells responsible for exocrine secretion, the islet cells responsible for endocrine secretion, and the islet vasculature are innervated by both systems. The parasympathetic system stimulates endocrine and exocrine secretion and the sympathetic system inhibits secretion.² The pancreas is also innervated by neurons that secrete amines and peptides, such as somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. The exact role of these neurons in pancreatic physiology is uncertain, but they do appear to affect both exocrine and endocrine function. The pancreas also has a rich supply of afferent sensory fibers, which are responsible for the intense pain associated with advanced pancreatic cancer, as well as acute and chronic pancreatitis. These somatic fibers travel superiorly to the celiac ganglia. Interruption of these somatic fibers can stop transmission of pain sensation (Fig. 33-7).

HISTOLOGY AND PHYSIOLOGY

The exocrine pancreas accounts for about 85% of the pancreatic mass; 10% of the gland is accounted for by extracellular matrix, and 4% by blood vessels and the major ducts, whereas only 2% of the gland is comprised of endocrine tissue. The endocrine and exocrine pancreas are sometimes thought of as functionally separate, but these different components of the organ are coordinated to allow an elegant regulatory feedback system for digestive enzyme and hormone secretion. This complex system regulates the type of digestion, its rate, and the processing and distribution of absorbed nutrients. This coordination is facilitated by the physical approximation of the islets and the exocrine pancreas, the presence of specific islet hormone receptors on the plasma membranes of pancreatic acinar cells, and the existence of an islet-acinar portal blood system.

Although patients can live without a pancreas when insulin and digestive enzyme replacement are administered, the loss of this islet-acinar coordination leads to impairments in digestive function. Although only approximately 20% of the normal pancreas is required to prevent insufficiency, in many patients undergoing pancreatic resection, the remaining pancreas is not normal, and pancreatic endocrine and exocrine insufficiency can develop with removal of smaller portions of the gland.

Exocrine Pancreas

The pancreas secretes approximately 500 to 800 mL per day of colorless, odorless, alkaline, isosmotic pancreatic juice. Pancreatic juice is a combination of acinar cell and duct cell secretions. The acinar cells secrete amylase, proteases, and lipases, enzymes responsible for the digestion of all three food types: carbohydrate, protein, and fat. The acinar cells are pyramid-shaped, with their apices facing the lumen of the acinus. Near the apex of each cell are numerous enzyme-containing zymogen granules that fuse with the apical cell membrane (Fig. 33-8). Unlike the endocrine pancreas, where islet cells specialize in the secretion of one hormone type, individual acinar cells secrete all types of enzymes. However, the ratio of the different enzymes released is adjusted to the composition of digested food through nonparallel regulation of secretion.

Pancreatic amylase is secreted in its active form and completes the digestive process already begun by salivary amylase. Amylase is the only pancreatic enzyme secreted in its active form, and it hydrolyzes starch and glycogen to glucose, maltose, maltotriose, and dextrins. These simple sugars are transported across the brush border of the intestinal epithelial cells by active transport mechanisms. Gastric hydrolysis of protein yields peptides that enter the intestine and stimulate intestinal endocrine cells to release cholecystokinin (CCK)-releasing peptide, CCK, and secretin, which then stimulate the pancreas to secrete enzymes and bicarbonate into the intestine.

The proteolytic enzymes are secreted as proenzymes that require activation. Trypsinogen is converted to its active form, trypsin, by another enzyme, enterokinase, which is produced by the duodenal mucosal cells. Trypsin, in turn, activates the other proteolytic enzymes. Trypsinogen activation within the pancreas is prevented by the presence of inhibitors that are also secreted by the acinar cells. A failure to express a normal trypsinogen inhibitor, pancreatic secretory trypsin inhibitor (PSTI) or *SPINK1*, is a cause of familial pancreatitis. Inhibition of trypsinogen activation ensures that the enzymes within the pancreas remain in an inactive precursor state and are activated only within the duodenum. Trypsinogen is expressed in several isoforms, and a missense mutation on the cationic trypsinogen, or *PRSS1*, results in premature, intrapancreatic activation of trypsinogen. This accounts for about two-thirds of cases of hereditary pancreatitis. Chymotrypsinogen is activated to form chymotrypsin. Elastase, carboxypeptidase A and B, and phospholipase are also activated by trypsin. Trypsin, chymotrypsin, and elastase cleave bonds between amino acids within a target peptide chain, and carboxypeptidase A and B cleave amino acids at the end of peptide chains. Individual amino acids and small dipeptides are then actively transported into the intestinal epithelial cells. Pancreatic lipase hydrolyzes triglycerides to 2-monoglyceride and fatty acid. Pancreatic lipase is secreted in an active form. Colipase is also secreted by the pancreas and binds to lipase, changing its molecular configuration and increasing its activity. Phospholipase A2 is secreted by the pancreas as a proenzyme that becomes activated by trypsin. Phospholipase A2 hydrolyzes phospholipids and, as with all lipases, requires bile salts for its action. Carboxylic ester hydrolase and cholesterol

esterase hydrolyze neutral lipid substrates like esters of cholesterol, fat-soluble vitamins, and triglycerides. The hydrolyzed fat is then packaged into micelles for transport into the intestinal epithelial cells, where the fatty acids are reassembled and packaged inside chylomicrons for transport through the lymphatic system into the bloodstream (Table 33-1).

Table 33-1 Pancreatic Enzymes		
Enzyme	Substrate	Product
Carbohydrate		
Amylase (active)	Starch, glycogen	Glucose, maltose, maltotriose, dextrins
Protein		
Endopeptidases	Cleave bonds between amino acids	Amino acids, dipeptides
Trypsinogen (inactive) $\xrightarrow{\text{Enterokinase}}$ Trypsin (active)		
Chymotrypsinogen (inactive) $\xrightarrow[\text{Trypsin}]{\text{Enterokinase}}$ Chymotrypsin (active)		
Proelastase (inactive) $\xrightarrow[\text{Trypsin}]{\text{Enterokinase}}$ Elastase (active)		
Exopeptidases	Cleave amino acids from end of peptide chains	—
Procarboxy peptidase A&B (inactive) $\xrightarrow{\text{Enterokinase}}$ Carboxypeptidase A&B (active)		
Fat		
Pancreatic lipase (active)	Triglycerides	2-Monoglycerides fatty acids
Phospholipase A2 (inactive) $\xrightarrow{\text{Trypsin}}$ Phospholipase A2 (active)	Phospholipase	—
Cholesterol esterase	Neutral lipids	—

The centroacinar and intercalated duct cells secrete the water and electrolytes present in the pancreatic juice. About 40 acinar cells are arranged into a spherical unit called an *acinus*. Centroacinar cells are located near the center of the acinus and are responsible for fluid and electrolyte secretion. These cells contain the enzyme carbonic anhydrase, which is needed for bicarbonate secretion. The amount of bicarbonate secreted varies with the pancreatic secretory rate, with greater concentrations of bicarbonate being secreted as the pancreatic secretory rate increases. Chloride secretion varies inversely with bicarbonate secretion such that the sum of these two remains constant. In contrast, sodium and potassium concentrations are kept constant throughout the spectrum of secretory rates³ (Fig. 33-9). The hormone secretin is released from cells in the duodenal mucosa in response to acidic chyme passing through the pylorus into the duodenum. Secretin is the major stimulant for bicarbonate secretion, which buffers the acidic fluid entering the duodenum from the stomach. CCK also stimulates bicarbonate secretion, but to a much lesser extent than secretin. CCK potentiates secretin-stimulated bicarbonate secretion. Gastrin and acetylcholine, both stimulants of gastric acid secretion, are also weak stimulants of pancreatic bicarbonate secretion.⁴ Truncal vagotomy produces a myriad of complex effects on the downstream digestive tract, but the sum effect on the exocrine pancreas is a reduction in bicarbonate and fluid secretion.⁵ The endocrine pancreas also influences the adjacent exocrine pancreatic secretions. Somatostatin, pancreatic polypeptide (PP), and glucagon are all thought to inhibit exocrine secretion.

Fig. 33-9.

Composition of pancreatic exocrine secretions. Greater concentrations of bicarbonate are secreted at higher secretory rates, and chloride secretion varies inversely with bicarbonate secretion. In contrast, sodium and potassium concentrations are independent of the secretory rate.

(Reproduced with permission from Bro-Rasmussen F et al: The composition of pancreatic juice as compared to sweat, parotid saliva, and tears. *Acta Phys Scandinav* 37:97–113, 1956.)

The acinar cells release pancreatic enzymes from their zymogen granules into the lumen of the acinus, and these proteins combine with the water and bicarbonate secretions of the centroacinar cells. The pancreatic juice then travels into small intercalated ducts. Several small intercalated ducts join to form an interlobular duct. Cells in the interlobular ducts continue to contribute fluid and electrolytes to adjust the final concentrations of the pancreatic fluid. Interlobular ducts then join to form about 20 secondary ducts that empty into the main pancreatic duct. Destruction of the branching ductal tree from recurrent inflammation, scarring, and deposition of stones eventually contributes to destruction of the exocrine pancreas and exocrine pancreatic insufficiency.

Endocrine Pancreas

There are nearly 1 million islets of Langerhans in the normal adult pancreas. They vary greatly in size from 40 to 900 μm . Larger islets are located closer to the major arterioles and smaller islets are embedded more deeply in the parenchyma of the pancreas. Most islets contain 3000 to 4000 cells of five major types: alpha cells that secrete glucagon, β -cells that secrete insulin, delta cells that secrete somatostatin, epsilon cells that secrete ghrelin, and PP cells that secrete PP (Table 33-2).

Table 33-2 Pancreatic Islet Peptide Products		
Hormones	Islet Cell	Functions
Insulin	β (beta cell)	Decreased gluconeogenesis, glycogenolysis, fatty acid breakdown, and ketogenesis Increased glycogenesis, protein synthesis
Glucagon	α (alpha cell)	Opposite effects of insulin; increased hepatic glycogenolysis and gluconeogenesis
Somatostatin	γ (delta cell)	Inhibits GI secretion Inhibits secretion and action of all GI endocrine peptides Inhibits cell growth
Pancreatic polypeptide	PP (PP cell)	Inhibits pancreatic exocrine secretion and secretion of insulin
Amylin (IAPP)	β (beta cell)	Facilitates hepatic effect of insulin Counterregulates insulin secretion and function
Pancreastatin	β (beta cell)	Decreases insulin and somatostatin release Increases glucagon release Decreases pancreatic exocrine secretion
Ghrelin	ϵ (epsilon cell)	Decreases insulin release and insulin action

IAPP = islet amyloid polypeptide.

Insulin is the best-studied pancreatic hormone. The discovery of insulin in 1920 by Frederick Banting, an orthopedic surgeon, and Charles Best, a medical student, was recognized with the awarding of the Nobel Prize in Physiology or Medicine. They produced diabetes in dogs by performing total pancreatectomy and then treated them with crude pancreatic extracts from dog and calf pancreata using techniques to prevent the breakdown of insulin by the proteolytic enzymes of the exocrine pancreas. Insulin was subsequently purified and found to be a 56-amino acid peptide with two chains, an α and a β chain, joined by two disulfide bridges and a connecting peptide, or C-peptide. Proinsulin is made in the endoplasmic reticulum and then is transported to the Golgi complex, where it is packaged into granules and the C-peptide is cleaved off. There are two phases of insulin secretion. In the first phase, stored insulin is released. This phase lasts about 5 minutes after a glucose challenge. The second phase of insulin secretion is a longer, sustained release due to ongoing production of new insulin. β -cell synthesis of insulin is regulated by plasma glucose levels, neural signals, and the paracrine influence of other islet cells. The diagnosis of diabetes is made by using glucose tolerance tests. Oral glucose tolerance tests and IV glucose tolerance tests are commonly used. Oral glucose not only enters the bloodstream but also stimulates the release of enteric hormones such as gastric inhibitory peptide (also known as *glucose-dependent insulinotropic polypeptide* or *GIP*), glucagon-like peptide-1 (GLP-1), and CCK, that augment the secretion of insulin, and are therefore referred to as *incretins*. Therefore oral glucose is a more vigorous stimulus to insulin secretion than IV glucose. In the oral glucose tolerance test, the patient is fasted overnight, and a basal glucose value is determined. Forty g/m² of glucose is given orally over 10 minutes. Blood samples are taken every 30 minutes for 2 hours. Normal values and criteria for diabetes vary by age, but essentially all values should be <200 mg/dL, and the 120-minute value should be <140 mg/dL.

Insulin secretion by the β -cell is also influenced by plasma levels of amino acids such as arginine, lysine, leucine, and free fatty acids. Glucagon, GIP, GLP-1, and CCK stimulate insulin release, while somatostatin, amylin, and pancreastatin inhibit insulin release.⁶ Cholinergic fibers and beta sympathetic fibers stimulate insulin release, while alpha sympathetic fibers inhibit insulin secretion.

Insulin's function is to inhibit endogenous (hepatic) glucose production and to facilitate glucose transport into cells, thus lowering plasma glucose levels. Insulin also inhibits glycogenolysis, fatty acid breakdown, and ketone formation, and stimulates protein synthesis. There is a considerable amount of functional reserve in insulin secretory capacity. If the remaining portion of the pancreas is healthy, about 80% of the pancreas can be resected without the patient becoming diabetic.⁷ In patients with chronic pancreatitis, or other conditions in which much of the gland is diseased, resection of a smaller fraction of the pancreas can result in diabetes. Insulin receptors are dimeric, tyrosine kinase-containing transmembrane proteins that are located on all cells. Insulin deficiency (type I diabetes) results in an overexpression or upregulation of insulin receptors, which causes an enhanced sensitivity to insulin. Type II diabetes is associated with a downregulation of insulin receptors and relative hyperinsulinemia, with resulting insulin resistance. Some forms of diabetes are associated with selected impairments of hepatic or peripheral insulin receptors, such as pancreatogenic diabetes or maturity-onset diabetes of the young.

Glucagon is a 29-amino-acid, single-chain peptide that promotes hepatic glycogenolysis and gluconeogenesis and counteracts the effects of insulin through its hyperglycemic action. Glucose is the primary regulator of glucagon secretion, as it is with insulin, but it has an inhibitory rather than stimulatory effect. Glucagon release is stimulated by the amino acids arginine and alanine. Gastric inhibitory peptide stimulates glucagon secretion at least in vitro, and GLP-1 inhibits glucagon secretion in vivo. Insulin and somatostatin inhibit glucagon secretion in a paracrine fashion within the islet. The same neural impulses that regulate insulin secretion also regulate glucagon secretion, so that the two hormones work together in a balance of actions to maintain glucose levels. Cholinergic and beta sympathetic fibers stimulate glucagon release, while alpha sympathetic fibers inhibit glucagon release.⁸

Although originally isolated from the hypothalamus, somatostatin is a peptide that is now known to have a wide anatomic distribution, not only in neurons but also in the pancreas, gut, and other tissues. It is a highly conserved peptide hormone, as it is found in lower vertebrates, and is now realized to be of fundamental importance in regulatory processes throughout the body. One gene encodes for a common precursor that is differentially processed to generate tissue-specific amounts of two bioactive products, somatostatin-14 and somatostatin-28. These peptides inhibit endocrine and exocrine secretion and affect neurotransmission, GI and biliary motility, intestinal absorption, vascular tone, and cell proliferation.

Five different somatostatin receptors (SSTRs) have been cloned and the biologic properties of each are being unraveled.⁹ All five are G-protein-coupled receptors with seven highly conserved transmembrane domains and unique amino and carboxy termini. Phosphorylation sites located within the second and third intracellular loops and in the cytoplasmic C-terminal segment are thought to mediate receptor regulation. Although the naturally occurring peptides bind to all five receptors, somatostatin-28 is relatively selective for SSTR5. The hexapeptide and octapeptide analogues such as octreotide bind only to SSTR2, SSTR3, and SSTR5. These analogues have a longer serum half-life, and their potent inhibitory effect has

been used clinically to treat both endocrine and exocrine disorders. For example, octreotide has been shown to decrease fistula output and speed the time it takes for enteric and pancreatic fistulas to close.¹⁰

Endocrine release of somatostatin occurs during a meal. The major stimulant is probably intraluminal fat. Acidification of the gastric and duodenal mucosa also releases somatostatin in isolated perfused organ preparations. Acetylcholine from the cholinergic neurons inhibits somatostatin release.

Pancreatic polypeptide (PP) is a 36-amino-acid, straight-chain peptide discovered by Kimmel in 1968 during the process of insulin purification. Protein is the most potent enteral stimulator of PP release, closely followed by fat, whereas glucose has a weaker effect.^{11,12} Hypoglycemia, whether or not it is insulin induced, strongly stimulates PP secretion through cholinergic stimulation.¹³ Phenylalanine, tryptophan, and fatty acids in the duodenum stimulate PP release, probably by inducing CCK and secretin release. In the isolated perfused pancreas, insulin and gastric inhibitory peptide stimulate PP release, while glucagon and somatostatin inhibit it. Vagal stimulation of the pancreas is the most important regulator of PP secretion. In fact, vagotomy eliminates the rise in PP levels usually seen after a meal. This can be used as a test for the completeness of a surgical vagotomy or for the presence of diabetic autonomic neuropathy.

PP is known to inhibit bile secretion, gallbladder contraction, and secretion by the exocrine pancreas. A number of studies suggest that PP's most important role is in glucose regulation through its regulation of hepatic insulin receptor gene expression. Deficiencies in PP secretion due to proximal pancreatectomy or severe chronic pancreatitis, are associated with diminished hepatic insulin sensitivity due to reduced hepatic insulin receptors.¹⁴ These effects are reversed by PP administration.

Recent studies have shown that a fifth islet peptide, ghrelin, is secreted from a distinct population of islet cells, called *epsilon cells*.^{15,16} Ghrelin also is present in the gastric fundus in large amounts and stimulates growth hormone secretion via growth hormone releasing hormone release from the pituitary. It is an orexigenic, or appetite-stimulating, peptide the plasma levels of which are increased in obesity. Ghrelin has also been shown to block insulin effects on the liver, and inhibits the β -cell response to incretin hormones and glucose.¹⁷ Therefore, ghrelin secretion from and within the islet may modulate the responses of other islet cells to nutrient and hormonal stimuli.

In addition to the five main peptides secreted by the pancreas, there are a number of other peptide products of the islet cells, including amylin and pancreastatin, as well as neuropeptides such as VIP, galanin, and serotonin. Amylin or islet amyloid polypeptide (IAPP) is a 37-amino-acid polypeptide that was discovered in 1988. IAPP is predominantly expressed by the pancreatic β -cells, where it is stored along with insulin in secretory granules.¹⁸ The function of IAPP seems to be the modulation or counterregulation of insulin secretion and function. Pancreastatin is a recently discovered pancreatic islet peptide product that inhibits insulin, and possibly somatostatin release, and augments glucagon release.^{19,20} In addition to this effect on the endocrine pancreas, pancreastatin inhibits pancreatic exocrine secretion.²¹

INTRAISLET REGULATION

The β -cells are located in the central portion of each islet and make up about 70% of the total islet cell mass. The other cell types are located predominantly in the periphery. The delta cells are least plentiful, making up only 5%; the α -cells make up 10%, and the PP cells make up 15%.²² In contrast to the acinar cells that secrete the full gamut of exocrine enzymes, the islet cells seem to specialize in the secretion of predominantly one hormone. However, individual islet cells can secrete multiple hormones. For example, the β -cells secrete both insulin and amylin, which counterregulates the actions of insulin. In reality, >20 different hormones are secreted by the islets, and the exact functions of this milieu are very complex. There is diversity among the islets depending on their location within the pancreas. In general, islets located closer to major arterioles are larger than islets located more deeply in the parenchyma of the pancreas. The β - and δ -cells are evenly distributed throughout the pancreas, but islets in the head and uncinate process (ventral anlage) have a higher percentage of PP cells and fewer α -cells, whereas islets in the body and tail (dorsal anlage) contain the majority of α -cells and few PP cells. This is clinically significant because pancreatoduodenectomy removes 95% of the PP cells in the pancreas. This may partially explain the higher incidence of glucose intolerance after the Whipple procedure than after distal pancreatectomy. In addition, chronic pancreatitis, which disproportionately affects the pancreatic head, is associated with PP deficiency and pancreatogenic diabetes.²³

Control of islet secretion is complex and involves an interplay of neural signals, blood flow patterns, and autocrine, paracrine, and hormonal feedback loops. Although the pancreatic islets account for only 2% of the pancreatic mass, they receive about 20 to 30% of the pancreatic arteriolar flow. The manner in which the blood flows through an individual islet can affect islet function because the β -cells are located in the center and the other islet cells are located mostly in the periphery. Blood can flow into the center of the islet and then to the periphery, from the periphery to the center, or from one pole of the islet to the other. In rodents, in vivo microscopy has demonstrated blood flow from one pole to the other. In addition, sphincters at the feeding arteriole were observed regulating blood flow to the periphery or center of the islet as it passed from pole to

pole. The sphincters are actually bulging endothelial cells of the afferent capillary. These sphincters seemed to be regulated by blood glucose concentrations, neural impulses, and nitric oxide. The predominant pattern of blood flow through the islets in the human pancreas is still conjectural. However, the peptide products of individual islet cells affect neighboring islet cells in a paracrine fashion. Experiments using isolated perfused pancreas and monoclonal antibodies to specific islet peptides have demonstrated that somatostatin from the δ -cells inhibits insulin secretion from the β -cells, glucagon secretion from the α -cells, and PP secretion from the PP cells. Somatostatin may have an important role in intraislet control of islet cell secretions²⁴ (Fig. 33-10). Islet hormone secretion also is regulated by endocrine feedback mechanisms. Insulin secretion, for example, is exquisitely sensitive to small increments in the arterial insulin concentration.

δ - to β -cell axis. Somatostatin from the δ -cells may play an important role in intraislet paracrine control of insulin secretion from the β -cells.

Although most of the blood supply to the exocrine pancreas comes directly from the pancreatic arterial flow, blood draining from the islet capillaries goes on to perfuse the exocrine pancreas. Perfusion of the acinar cells with venous blood from the islets allows the endocrine pancreas to influence the exocrine pancreas. For example, insulin release, stimulated by high levels of carbohydrates in the ingested meal, is thought to promote an amylase-rich exocrine secretion, which preferentially provides for digestion of starches and sugars.

ACUTE PANCREATITIS

Definition and Incidence

Acute pancreatitis is an inflammatory disease of the pancreas that is associated with little or no fibrosis of the gland. It can be initiated by several factors, including gallstones, alcohol, trauma, and infections, and, in some cases, it is hereditary. Very often, patients with acute pancreatitis develop additional complications such as sepsis, shock, and respiratory and renal failure, resulting in considerable morbidity and mortality.²⁵ Approximately 300,000 cases occur in the United States each year, 10 to 20% of which are severe, leading to over 3000 deaths. Pancreatitis is a contributing factor in an additional 4000 deaths annually and inflicts a heavy economic burden, accounting for more than \$2 billion in health costs annually in the United States.²⁶ Despite the considerable amount of research under way relating to this disease, its pathophysiologic mechanisms remain incompletely understood. This can be attributed, in part, to the relative inaccessibility of clinical material for experimental studies, which has led to the development of several models of experimental pancreatitis with which its etiology, pathophysiology, and treatment regimens are being explored.

Etiology

The etiology of acute pancreatitis is a complex subject because many different factors have been implicated in the causation of this disease, and sometimes there are no identifiable causes (Table 33-3). Two factors, biliary tract stone disease and alcoholism, account for 80 to 90% of the cases. The remaining 10 to 20 % is accounted for either by idiopathic disease or by a variety of miscellaneous causes including trauma, surgery, drugs, heredity, infection and toxins.

BILIARY TRACT DISEASE

Although acute pancreatitis is documented in association with acalculous biliary tract disease, bile duct stones (choledocholithiasis) represent the most common form of associated biliary abnormality. The mechanism by which a gallstone may cause pancreatitis is not entirely clear, although gallstones have been implicated ever since Opie made the seminal observation in 1901 of two patients who died of acute pancreatitis with stones impacted in their ampulla of Vater.²⁷ This led him to propose the "common-channel hypothesis," in which a blockage below the junction of the biliary and pancreatic ducts would cause bile to flow into the pancreas, which could then be damaged by the detergent action of bile salts.

Important objections to this theory include the anatomic reality that the majority of individuals have such a short common channel that a stone located there would block both the pancreatic and biliary ducts, effectively isolating the two systems. Furthermore, hydrostatic pressure in the biliary tract is lower than in the pancreas, a condition that would favor abnormal flow of pancreatic juice into the bile duct rather than in the opposite direction. These reservations are bolstered by the observation that, in experimental animals, the flow of normal bile through an unobstructed pancreatic duct does not result in acute pancreatitis (although *forceful* retrograde injection of bile into the pancreas causes injury similar to that of acute pancreatitis).

Another proposed mechanism of causation postulates that passage of a gallstone through the sphincter of Oddi renders it momentarily incompetent, permitting the reflux of duodenal juice containing activated digestive enzymes into the pancreatic ductal system. However, it is questionable whether the transit time through the sphincter of Oddi is long enough to cause sufficient incompetence. Finally, the observation remains that procedures designed to render the sphincter incompetent, such as sphincterotomy, do not routinely cause pancreatitis.

Therefore, although it is reasonable to dismiss an incompetent sphincter of Oddi as an etiologic factor in acute pancreatitis, it is not as simple to dismiss the role of gallstones. A clinical study showed that 88% of patients with acute pancreatitis passed gallstones in their feces within 10 days of the attack. This is in contrast to only 11% of gallstone patients who did not have pancreatitis, suggesting that the process of passing a gallstone may be linked to the development of acute pancreatitis.

This information justifies searching for a more likely causative factor than abnormal bile or duodenal juice backflow into the pancreas. A common phenomenon shared by gallstone disease and other conditions causing acute pancreatitis, such as helminthic infestation of the pancreatic duct or its blockage by tumors, is ductal hypertension resulting from ongoing exocrine secretion into an obstructed pancreatic duct. A simple mechanical explanation has been proposed whereby elevated intraductal pressure causes rupture of the smaller ductules and leakage of pancreatic juice into the parenchyma. Although the pancreatic duct fluid pH is maintained in the range of 8 to 9 by the secretion of bicarbonate, the interstitial pH of 7 within the pancreatic tissue favors activation of proteases when transductal extravasation of fluid occurs. Although pancreatic ductal obstruction and hypertension are likely initiating factors in the etiology of acute pancreatitis, the mechanism by which ductal hypertension initiates pancreatic injury remains under investigation.²⁷ Although the mechanical factors that initiate the process are unclear, the *colocalization theory* of Steer and Saluja has gained acceptance as the cellular mechanism of acute pancreatitis.²⁸ In the normal pancreas, the inactive digestive zymogens and the lysosomal hydrolases are found separately in discrete organelles. However, in response to ductal obstruction, hypersecretion, or a cellular insult, these two classes of substances become improperly colocalized in a vacuolar structure within the pancreatic acinar cell. A cascade has been postulated in which trypsinogen colocalizes with cathepsin B to produce activated trypsin, which, in turn, activates the other digestive zymogens. These active digestive enzymes then begin autodigestion within the pancreatic acinar cells, leading to pancreatitis.

ALCOHOL

Although some patients show the symptoms of acute pancreatitis after little use or even a single exposure to alcohol, the disease commonly occurs in patients who have consumed alcohol for at least 2 years, and often much longer, up to 10 years. In a patient with an exposure history to ethanol and the total absence of other possible causative factors, a first attack of pancreatitis is considered alcohol-related acute pancreatitis. However, it is possible that a first attack of alcohol-related pancreatitis in the typical longstanding alcohol user is really the first manifestation of chronic pancreatitis. The disease can become recurrent with continued alcohol abuse. The nature of alcohol consumed (i.e., beer, wine, or hard liquor) is less significant than a daily intake of between 100 and 150 g of ethanol. Between 10 and 15% of individuals with this degree of alcohol intake go on to develop pancreatitis, while a similar proportion develop cirrhosis of the liver.

Ethanol can induce pancreatitis by several methods. The "secretion with blockage" mechanism is possible because ethanol causes spasm of the sphincter of Oddi, and, more important, ethanol is a metabolic toxin to pancreatic acinar cells, where it can interfere with enzyme synthesis and secretion. The initial effect of ethanol is a brief secretory increase followed by inhibition. This can lead to elevation of enzyme proteins that can precipitate within the pancreatic duct. Calcium then can precipitate within this protein matrix, causing multiple ductal obstructions, while continued secretion can cause pressure buildup. Ethanol also increases ductal permeability, making it possible for improperly activated enzymes to leak out of the pancreatic duct into the surrounding tissue. The inappropriate activation of trypsin by ethanol has been demonstrated in vitro. Ethanol also transiently decreases pancreatic blood flow, possibly causing focal ischemic injury to the gland.^{29,30}

There is evidence that alcoholics who develop pancreatitis have a diet richer in protein and fat than those who do not. Ethanol can alter lipid metabolism, and a transient hyperlipidemic state is sometimes seen during an attack of alcoholic pancreatitis, although the etiologic significance of this observation remains uncertain.

TUMORS

A tumor should be considered in a nonalcoholic patient with acute pancreatitis who has no demonstrable biliary tract disease. Approximately 1 to 2% of patients with acute pancreatitis have pancreatic carcinoma, and an episode of acute pancreatitis can be the first clinical manifestation of a periampullary tumor. In both conditions, the pancreatitis possibly results from blockage of secreted juice and its upstream consequences.

IATROGENIC PANCREATITIS

Acute pancreatitis can be associated with a number of surgical procedures, most commonly those performed on or close to the pancreas, such as pancreatic biopsy, biliary duct exploration, distal gastrectomy, and splenectomy. Acute pancreatitis is associated postoperatively with Billroth II gastrectomy and jejunostomy, in which increased intraduodenal pressure can cause backflow of activated enzymes into the pancreas. However, pancreatitis also can occur in association with surgery that uses low systemic perfusion, such as cardiopulmonary bypass and cardiac transplantation. Acute pancreatitis has been reported to be associated with severe hypothermia, and the hypothermia associated with cardiopulmonary bypass may be similarly causative. It also is possible that atheromatous emboli or ischemia may cause pancreatic injury. Most commonly, endoscopic retrograde cholangiopancreatography (ERCP) results in pancreatitis in 2 to 10% of patients, due to direct injury and/or intraductal hypertension.

DRUGS

For practical reasons, it often is difficult to implicate a drug as the cause of pancreatitis. Many drugs can produce hyperamylasemia and/or abdominal pain, and a drug is considered suspect if the pancreatitis-like illness resolves with its discontinuation. Ethical considerations generally rule out rechallenge with the suspect drug, so the connection often remains vague. However, despite these limitations, certain drugs are known to be capable of causing acute pancreatitis. These include the thiazide diuretics, furosemide, estrogens, azathioprine, L-asparaginase, 6-mercaptopurine, methyl dopa, the sulfonamides, tetracycline, pentamidine, procainamide, nitrofurantoin, dideoxyinosine, valproic acid, and acetylcholinesterase inhibitors.

INFECTIONS

Though mumps, coxsackievirus, and *Mycoplasma pneumoniae* are believed to be capable of inducing acute pancreatitis by infecting the acinar cells, none of these agents has been isolated from a diseased pancreas. The belief may have arisen from the observation that antibody titers to mumps and coxsackievirus are elevated in approximately 30% of patients with acute pancreatitis with no other identified cause. However, this elevation may be an anamnestic or nonspecific response to pancreatitis.

HYPERLIPIDEMIA

It has been suggested that lipase can liberate large amounts of toxic fatty acids into the pancreatic microcirculation. This could lead to endothelial injury, sludging of blood cells, and consequent ischemic states. Patients with types I and V hyperlipoproteinemia often experience attacks of abdominal pain that are thought to indicate episodes of acute pancreatitis. These episodes are frequently associated with marked hypertriglyceridemia and lactescent serum and can be prevented by dietary modifications that restrict serum triglycerides.

MISCELLANEOUS CAUSES

An episode of acute pancreatitis may be precipitated by several other factors. Hypercalcemic states arising from hyperparathyroidism can result in both acute and chronic pancreatitis; the mechanism most likely involves hypersecretion and the formation of calcified stones intraductally. Also implicated are infestations by *Ascaris lumbricoides* and the liver fluke *Clonorchis sinensis*, which is endemic to China, Japan, and Southeast Asia. These cause Oriental cholangitis, which is associated with cholangiocarcinoma obstructing the pancreatic duct. A dominant gene mutation following Mendelian inheritance is known to result in hereditary pancreatitis.³¹ Whitcomb and associates described several families from various parts of the world who have mutations in their cationic trypsinogen gene *PRSS1*, which results in pancreatitis.³² Additionally, 20 to 45% of patients with pancreas divisum (unfused ducts of Wirsung and Santorini) develop pancreatitis, but the failure of procedures to improve drainage of the lesser papilla in reducing attacks of pancreatitis, as well as the observed lack of ductal dilatation in such patients, argues against pancreas divisum as an etiologic factor, rendering the role of this condition as yet unclear. Other implicated factors include azotemia, vasculitis, and the sting of the Trinidadian scorpion *Tityus trinitatis*. This scorpion's venom has been shown to cause neurotransmitter discharge from cholinergic nerve terminals, leading to massive production of pancreatic juice. Poisoning with antiacetylcholinesterase insecticides has a similar effect. Finally, no apparent cause can be ascribed to some episodes of acute pancreatitis, and these constitute the group referred to as *idiopathic pancreatitis*. Some of these patients are eventually found to have gallstone-related pancreatitis, which calls for caution in labeling any episode "idiopathic."

Pathophysiology

Acute pancreatitis occurs in varying degrees of severity, the determinants of which are multifactorial. The generally prevalent belief today is that pancreatitis begins with the activation of digestive zymogens inside acinar cells, which cause acinar cell injury. Studies suggest that the ultimate severity of the resulting pancreatitis may be determined by the events that occur subsequent to acinar cell injury.³³ These include inflammatory cell recruitment and activation, as well as generation and release of cytokines and other chemical mediators of inflammation (Fig. 33-11).

Pathophysiology of acute pancreatitis.

INITIAL EVENTS LEADING TO THE ONSET OF PANCREATITIS

Under physiologic conditions, the pancreas synthesizes a large amount of protein. A majority of these proteins consist of digestive enzymes. Because the exocrine pancreas produces several enzymes that are potentially injurious to itself, it prevents autodigestion by intracellularly assembling the inactive precursors of these enzymes, called *proenzymes* or *zymogens*, which are then transported and secreted outside of the gland. Their activation occurs safely in the duodenum, where the brush-border enzyme enteropeptidase (or enterokinase) activates the trypsinogen, and the resulting trypsin then activates the other zymogens in a cascade reaction.

To further protect the pancreas from these potentially harmful digestive enzymes, they are segregated from the cytoplasmic space within acinar

cells by being enclosed within membrane-bound organelles, referred to as *zymogen granules*. Another layer of protection is provided by the synthesis of trypsin inhibitors, which are transported and stored along with the digestive enzyme zymogens. These are available to inhibit small amounts of prematurely activated trypsinogen within pancreatic acinar cells. It is generally theorized that acute pancreatitis occurs when this process goes awry and the gland is injured by the erroneously activated enzymes that it produces. There are three reasons for this theory: (a) the pancreas is digestible by the activated enzymes of the duodenum; (b) activated digestive enzymes are found within the pancreas during pancreatitis, and (c) the histology of pancreatitis is suggestive of a coagulative necrosis. However, the mechanism(s) of erroneous activation are not fully understood.

Using several different models, recent research has focused intensively on the etiology of the activation mechanism. It was seen that the synthesis and intracellular transport of digestive enzymes are not affected during the development of pancreatitis, but that the secretory output of enzymes of the pancreas is markedly reduced.³⁴ Very early in the development of the disease (shortly after the onset, but before morphologic or biochemical changes are apparent), digestive enzymes are localized in cytoplasmic vacuoles that also contain the lysosomal hydrolase cathepsin B, which is known to activate trypsinogen. Furthermore, intracellular trypsinogen activation was found synchronously with the colocalization phenomenon. Further support for this hypothesis is provided by findings that inhibition of cathepsin B activity by the highly specific inhibitor, CA-074me, protects against intra-acinar cell trypsinogen activation and pancreatitis in two different models of experimental pancreatitis.³⁵ These studies strongly suggest that trypsinogen is activated because it erroneously colocalizes in cytoplasmic vacuoles with cathepsin B. The opportunity is therefore created for autodigestion, however, the mechanism by which the prematurely activated trypsin causes acinar cell injury and death is not well understood. Recent studies suggest that trypsin, once activated inside the colocalized vacuoles (which appear to be similar to those recently described as autophagic vacuoles,³⁶ mediates the permeability of these organelles, and causes them to release their contents into the cytosol. Cathepsin B is one of the enzymes released into the cytosol during pancreatitis. Once in the cytosol, it initiates apoptotic cell death by permeabilizing mitochondrial membranes, which allows cytochrome C to be released into the cytosol. This initiates the apoptotic cascade and results in the apoptotic death of the acinar cells (Fig. 33-12).³⁷

Schematic representation of the overall pancreatitis hypothesis. When acinar cells are pathologically stimulated, their lysosomal and zymogen contents colocalize, whereupon trypsinogen is activated to trypsin by cathepsin B. Increased cytosolic calcium is required for colocalization. The active trypsin mediates the permeability of these colocalized organelles. Once trypsin has permeabilized the cells, cathepsin B and other contents of these colocalized organelles are released into the cytosol. Once in the cytosol, cathepsin B activates apoptosis by causing cytochrome c to be released from the mitochondria. Cathepsin B-induced activation of the Bcl-2 family of proteins may help release cytochrome c from the mitochondria. Heat shock protein 70 (HSP70) overexpression attenuates cytosolic calcium (Ca_i^{2+}), thus preventing colocalization and the subsequent events that lead to acinar cell injury and death.

FACTORS DETERMINING THE SEVERITY OF PANCREATITIS

Clinically, the severity of acute pancreatitis varies significantly. Some patients experience a mild form of the disease that is self-limiting, while others suffer a more severe and sometimes lethal attack. The factors determining the severity of pancreatitis are multifactorial, but their identification is of considerable therapeutic importance, because their manipulation may decrease the morbidity and mortality associated with the disease. It generally is believed that pancreatitis begins with the intrapancreatic activation of digestive enzyme zymogens, acinar cell injury, and activation of transcription factors such as nuclear factor- κB (NF- κB) and activator protein 1.³⁸ This, in turn, leads to the production of proinflammatory factors, acinar cell necrosis, systemic inflammatory response syndrome, and distant organ dysfunction, including lung injury that frequently manifests as the acute respiratory distress syndrome (ARDS). The ultimate severity of acute pancreatitis depends on the extent of the systemic inflammatory response, as well as several cytokines and chemokines and their receptors that play a critical role in the activation and migration of inflammatory cells to the affected site.³⁹

In addition to the cells of the immune system such as the neutrophils, the pancreatic acinar cells are also a source of inflammatory mediators during pancreatitis. Over the past few years, the list of factors associated with pancreatitis and associated lung injury has grown rapidly to include tumor necrosis factor alpha, monocyte chemotactic protein-1, Mip1, interleukin-1 β (IL-1 β), platelet activating factor (PAF), substance P, adhesion molecules [intercellular adhesion molecule-1 (ICAM-1) and selectins], IL-6, IL-8, IL-10, C5a, the CCR1 receptor and its ligands, granulocyte-macrophage colony-stimulating factor, macrophage migration inhibitory factor, COX-2, prostaglandin E1, nitric oxide, and reactive oxygen species.⁴⁰ In addition, several studies have focused on the protective role played by heat shock proteins in pancreatitis.⁴¹ The ultimate severity of

pancreatitis and associated lung injury depends on the balance between the pro- and anti-inflammatory factors. Several therapeutic regimens aimed at reducing the inflammatory response have been tested and include anti-tumor necrosis factor alpha antibody, IL-1 receptor antagonist, anti-ICAM-1 and anti-CD3 antibodies, IL-10, recombinant PAF acetylhydrolase, and the calcineurin antagonist FK506. Recent studies also indicate that Toll-like receptor 4 (TLR4) is significant in determining the severity of acute pancreatitis. The TLR4 initiates a complex signaling pathway when it interacts with lipopolysaccharides that result in a proinflammatory response. Mice in which TLR4 is genetically deleted have significantly reduced pancreatitis; this suggests that TLR4 is a significant promoter of proinflammation. However, this effect appears independently of lipopolysaccharides and is probably mediated by a hitherto unknown TLR4 agonist. It is likely that TLR4 antagonists would be a good therapy against pancreatitis.⁴²

An alternate approach to prevent or reduce the severity of pancreatitis is to inhibit the two early events in pancreatitis, intrapancreatic trypsinogen and NF- κ B activation. Agents that specifically prevent an increase in trypsin activity, either by inhibiting trypsinogen activation and colocalization (e.g., low doses of wortmannin, water immersion, and thermal stress), or inhibiting the cathepsin B activity (E64d or CA074me), have been successful in reducing the severity of pancreatitis in experimental rodent models. Prior thermal (and arsenite) stress and water immersion stress, which upregulate heat shock proteins 70 and 60, respectively, not only prevent cerulein-induced trypsinogen activation, but also inhibit cerulein-induced NF- κ B activation in the pancreas and protect against pancreatitis.⁴³ These studies await verification in a clinical setting.

Diagnosis

The clinical diagnosis of pancreatitis is one of exclusion. The other upper abdominal conditions that can be confused with acute pancreatitis include perforated peptic ulcer, a gangrenous small bowel obstruction, and acute cholecystitis. Because these conditions often have a fatal outcome without surgery, urgent intervention is indicated in the small number of cases in which doubt persists.

All episodes of acute pancreatitis begin with severe pain, generally following a substantial meal. The pain is usually epigastric, but can occur anywhere in the abdomen or lower chest. It has been described as "knifing" or "boring through" to the back, and may be relieved by the patient leaning forward. It precedes the onset of nausea and vomiting, with retching often continuing after the stomach has emptied. Vomiting does not relieve the pain, which is more intense in necrotizing than in edematous pancreatitis. An episode of acute pancreatic inflammation in a patient with known chronic pancreatitis has the same findings.

On examination, the patient may show tachycardia, tachypnea, hypotension, and hyperthermia. The temperature is usually only mildly elevated in uncomplicated pancreatitis. Voluntary and involuntary guarding can be seen over the epigastric region. The bowel sounds are decreased or absent. There are usually no palpable masses. The abdomen may be distended with intraperitoneal fluid. There may be pleural effusion, particularly on the left side.

With increasing severity of disease, the intravascular fluid loss may become life-threatening as a result of sequestration of edematous fluid in the retroperitoneum. Hemoconcentration then results in an elevated hematocrit. However, there also may be bleeding into the retroperitoneum or the peritoneal cavity. In some patients (about 1%), the blood from necrotizing pancreatitis may dissect through the soft tissues and manifest as a bluish discoloration around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign). The severe fluid loss may lead to prerenal azotemia with elevated blood urea nitrogen and creatinine levels. There also may be hyperglycemia, hypoalbuminemia, and hypocalcemia sufficient in some cases to produce tetany.

SERUM MARKERS

Because pancreatic acinar cells synthesize, store, and secrete a large number of digestive enzymes (e.g., amylase, lipase, trypsinogen, and elastase), the levels of these enzymes are elevated in the serum of most pancreatitis patients. Because of the ease of measurement, serum amylase levels are measured most often. Serum amylase concentration increases almost immediately with the onset of disease and peaks within several hours. It remains elevated for 3 to 5 days before returning to normal. There is no significant correlation between the magnitude of serum amylase elevation and severity of pancreatitis; in fact, a milder form of acute pancreatitis is often associated with higher levels of serum amylase as compared with that in a more severe form of the disease.

It is important to note that hyperamylasemia can also occur as a result of conditions not involving pancreatitis. For example, hyperamylasemia can occur in a patient with small bowel obstruction, perforated duodenal ulcer, or other intra-abdominal inflammatory conditions. In contrast, a patient with acute pancreatitis may have a normal serum amylase level, which could be due to several reasons. In patients with hyperlipidemia, values might appear to be normal because of interference by lipids with chemical determination of serum amylase. In many cases, urinary clearance of pancreatic enzymes from the circulation increases during pancreatitis; therefore, urinary levels may be more sensitive than serum levels. For these

reasons, it is recommended that amylase concentrations also be measured in the urine. Urinary amylase levels usually remain elevated for several days after serum levels have returned to normal. In patients with severe pancreatitis associated with significant necrotic damage, the pancreas may not release large amounts of enzymes into the circulation. It is important to recognize that, in patients with severe pancreatitis, frequent measurement of serum enzymes is not needed. Patients with alcoholic pancreatitis, in general, have a smaller increase in serum amylase levels.

Because hyperamylasemia can be observed in many extrapancreatic diseases, measuring pancreatic-specific amylase (p-amylase) rather than total amylase, which also includes salivary amylase, makes the diagnosis more specific (88 to 93%).

Other pancreatic enzymes also have been evaluated to improve the diagnostic accuracy of serum measurements. Specificity of these markers ranges from 77 to 96%, the highest being for lipase. Measurements of many digestive enzymes also have methodologic limitations and cannot be easily adapted for quantitation in emergency labs. Because serum levels of lipase remain elevated for a longer time than total or p-amylase, it is the serum indicator of highest probability of the disease.

ULTRASOUND

Abdominal ultrasound (US) examination is the best way to confirm the presence of gallstones in suspected biliary pancreatitis. It also can detect extrapancreatic ductal dilations and reveal pancreatic edema, swelling, and peripancreatic fluid collections (PFCs). However, in about 20% of patients, the US examination does not provide satisfactory results because of the presence of bowel gas, which may obscure sonographic imaging of the pancreas. A CT scan of the pancreas is more commonly used to diagnose pancreatitis (Fig. 33-13). CT scanning is used to distinguish milder (nonnecrotic) forms of the disease from more severe necrotizing or infected pancreatitis in patients whose clinical presentation raises the suspicion of advanced disease.⁴⁴

Nonnecrotizing acute pancreatitis. The computed tomographic image reveals edema (*large arrow*) and fluid (*small arrow*) but intact vascularization of the pancreas overall.

ASSESSMENT OF SEVERITY

An early discrimination between mild edematous and severe necrotizing forms of the disease is of the utmost importance to provide optimal care to the patient. Several predictors of severity, including early prognostic signs, serum markers, and CT scans, are commonly used for this purpose.⁴⁵

EARLY PROGNOSTIC SIGNS

In 1974, Ranson identified a series of prognostic signs for early identification of patients with severe pancreatitis.⁴⁶ Out of these 11 objective parameters, five are measured at the time of admission, whereas the remaining six are measured within 48 hours of admission (Table 33-4).

Morbidity and mortality of the disease are directly related to the number of signs present. If the number of positive Ranson signs is less than two, the mortality is generally zero; with three to five positive signs, mortality is increased to 10 to 20%. The mortality rate increases to >50% when there are more than seven positive Ranson signs. Although prognostic signs are useful in determining the severity of pancreatitis, there are several limitations to the value of these signs. One has to measure all 11 signs to achieve the best predictability of prognosis, and two full days are needed to complete the profile. A delay of 48 hours after admission merely for assessment may squander a valuable opportunity to prevent a complication during this time. It is important to realize that Ranson's prognostic signs are best used within the initial 48 hours of hospitalization and have not been validated for later time intervals. Although several investigators (Imrie, Banks, Agarwal-Pitchumoni, and others) have proposed modifications to simplify these prognostic criteria throughout the years since their inception, Ranson's original 11 signs are still the most commonly used.

Table 33-4 Ranson's Prognostic Signs of Pancreatitis	
Criteria for acute pancreatitis not due to gallstones	
At admission	During the initial 48 h
Age >55 y	Hematocrit fall >10 points
WBC >16,000/mm ³	BUN elevation >5 mg/dL
Blood glucose >200 mg/dL	Serum calcium <8 mg/dL
Serum LDH >350 IU/L	Arterial PO ₂ <60 mm Hg
Serum AST >250 U/dL	Base deficit >4 mEq/L
	Estimated fluid sequestration >6 L
Criteria for acute gallstone pancreatitis	
At admission	During the initial 48 h
Age >70 y	Hematocrit fall >10 points
WBC >18,000/mm ³	BUN elevation >2 mg/dL
Blood glucose >220 mg/dL	Serum calcium <8 mg/dL
Serum LDH >400 IU/L	Base deficit >5 mEq/L
Serum AST >250 U/dL	Estimated fluid sequestration >4 L

AST = aspartate transaminase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; PO₂ = partial pressure of oxygen; WBC = white blood cell count.

Source: Data from Ranson JHC: Etiological and prognostic factors in human acute pancreatitis: A review. *Am J Gastroenterol* 77:633, 1982. From Macmillan Publishers Ltd. Ranson JH, Rifkind KM, Roses DF, et al: Prognostic signs and the role of operative management in acute pancreatitis. *Surg Gynecol Obstet* 139:69, 1974.

Another set of criteria often used to assess the severity of pancreatitis is the *acute physiology and chronic health evaluation* (APACHE-II) score. This grading system assesses severity on the basis of quantitative measures of abnormalities of multiple variables, including vital signs and specific laboratory parameters, coupled with the age and chronic health status of the patient. The main advantage of the APACHE-II scoring system is the immediate assessment of the severity of pancreatitis. A score of eight or more at admission is usually considered indicative of severe disease.⁴⁷

BIOCHEMICAL MARKERS

The ideal biochemical marker for prognosis of acute pancreatitis should not only have high specificity and sensitivity but also should be able to discriminate between mild (edematous) and severe (necrotic) disease on admission. Although serum enzymes such as amylase and lipase are helpful in the diagnosis of pancreatitis, these have no prognostic value. Several recent research studies have suggested additional markers that may have prognostic value, including acute phase proteins such as C-reactive protein (CRP), alpha₂-macroglobulin, polymorphonuclear neutrophil-elastase, alpha1-antitrypsin, and phospholipase A2. Although CRP measurement is commonly available, many of the others are not. Therefore, at this time, CRP seems to be the marker of choice in clinical settings. The measurement of IL-6 has recently been shown to distinguish patients with mild or severe forms of the disease. However, these tests have to undergo large-scale evaluations before they can be recommended for routine use. Another prognostic marker under evaluation is urinary-trypsinogen activation peptide (TAP). TAP is a five- to seven-amino acid peptide that is released from the N-terminus of trypsinogen during its activation. In studies, Neoptolemos and colleagues have shown a good correlation between

the severity of pancreatitis and concentrations of TAP in urine.⁴⁸ However, further testing and methodologic developments are needed before TAP can be used as a routine prognostic marker.

COMPUTED TOMOGRAPHY SCAN

CT scanning with bolus IV contrast has become the gold standard for detecting and assessing the severity of pancreatitis. Although clinically mild pancreatitis is usually associated with interstitial edema, severe pancreatitis is associated with necrosis. In interstitial pancreatitis, the microcirculation of the pancreas remains intact, and the gland shows uniform enhancement on IV contrast-enhanced CT scan (see Fig. 33-13). In necrotizing pancreatitis, however, the microcirculation is disrupted; therefore, the enhancement of the gland on contrast-enhanced CT scan is considerably decreased. The presence of air bubbles on a CT scan is an indication of infected necrosis or pancreatic abscess (Fig. 33-14). Currently, IV (bolus) contrast-enhanced CT scanning is routinely performed on patients who are suspected of harboring severe pancreatitis, regardless of their Ranson's or APACHE scores.⁴⁹

Necrotizing (infected) acute pancreatitis. The computed tomographic image reveals areas of nonperfusion and the presence of gas in the region of severe necrosis, which indicates infection.

Treatment

The severity of acute pancreatitis covers a broad spectrum of illness, ranging from the mild and self-limiting to the life-threatening necrotizing variety. Regardless of severity, hospitalization of the patient with suspected acute pancreatitis for observation and diagnostic study is usually mandatory. Upon confirmation of the diagnosis, patients with moderate to severe disease should be transferred to the intensive care unit for observation and maximal support. The most important initial treatment is conservative intensive care with the goals of oral food and fluid restriction, replacement of fluids and electrolytes parenterally as assessed by central venous pressure and urinary excretion, and control of pain. In severe acute pancreatitis, or when signs of infection are present, most experts recommend broad-spectrum antibiotics (e.g., imipenem) and careful surveillance for complications of the disease (Table 33-5).⁴⁹

Table 33-5 Complications of Acute Pancreatitis
I. Local
A. Pancreatic phlegmon
B. Pancreatic abscess
C. Pancreatic pseudocyst
D. Pancreatic ascites
E. Involvement of adjacent organs, with hemorrhage, thrombosis, bowel infarction, obstructive jaundice, fistula formation, or mechanical

obstruction
II. Systemic
A. Pulmonary
1. Pneumonia, atelectasis
2. Acute respiratory distress syndrome
3. Pleural effusion
B. Cardiovascular
1. Hypotension
2. Hypovolemia
3. Sudden death
4. Nonspecific ST-T wave changes
5. Pericardial effusion
C. Hematologic
1. Hemoconcentration
2. Disseminated intravascular coagulopathy
D. GI hemorrhage
1. Peptic ulcer
2. Erosive gastritis
3. Portal vein or splenic vein thrombosis with varices
E. Renal
1. Oliguria
2. Azotemia
3. Renal artery/vein thrombosis
F. Metabolic
1. Hyperglycemia
2. Hypocalcemia
3. Hypertriglyceridemia
4. Encephalopathy
5. Sudden blindness (Purtscher's retinopathy)
G. Central nervous system
1. Psychosis
2. Fat emboli
3. Alcohol withdrawal syndrome
H. Fat necrosis
1. Intra-abdominal saponification
2. Subcutaneous tissue necrosis

MILD PANCREATITIS

Pancreatitis is classified as mild when the patient has no systemic complications, low APACHE-II scores and Ranson's signs, sustained clinical improvement, and when a CT scan rules out necrotizing pancreatitis. The treatment then is mostly supportive and has the important aim of *resting the pancreas* through restriction of oral food and fluids. Nasogastric suction and H₂-blockers have routinely been used in this connection, based on the reasoning that even the smallest amount of gastric acid reaching the duodenum could stimulate pancreatic secretion. However, these measures are of little value. The following secretion-inhibiting drugs have also been tried without notable success: atropine, calcitonin, somatostatin, glucagon, and fluorouracil.⁵⁰

Pancreatitis is also an autodigestive process, and various protease-inhibiting drugs, including aprotinin, gabexate mesylate, camostate, and

phospholipase A2 inhibitors, as well as fresh frozen plasma, have been tested to prevent proteolysis, but with little success. Because a significant component of the patient's distress arises from the inflammatory aspect of pancreatitis, various methods have been tried to alleviate inflammation, including indomethacin and the prostaglandin inhibitors; but again, these have not proved to be of much value. Some recent studies examined a different strategy, namely the use of PAF antagonists such as PAF acetylhydrolase and Lexipafant. These showed promising results in experimental animals and in initial clinical studies, but did not live up to their promise in larger-scale clinical trials.⁵¹

The current principles of treatment are physiologic monitoring, metabolic support, and maintenance of fluid balance, which can become dangerously disturbed even in mild acute pancreatitis because of fluid sequestration, vomiting, and sudoresis. Because hypovolemia can result in pancreatic and other visceral ischemia, fluid balance should be assessed at least every 8 hours initially.

The severe pain of acute pancreatitis prevents the patient from resting, and results in ongoing cholinergic discharge, which stimulates gastric and pancreatic secretion. Therefore, pain management is of great importance. Administration of buprenorphine, pentazocine, procaine hydrochloride, and meperidine are all of value in controlling abdominal pain. Morphine is to be avoided, due to its potential to cause sphincter of Oddi spasm. Antibiotic therapy has not proved to be of value in the absence of signs or documented sources of infection.

Cautious resumption of oral feeding consisting of small and slowly increasing meals is permissible after the abdominal pain and tenderness have subsided, serum amylase has returned to normal, and the patient experiences hunger. This usually occurs within a week of the onset of an attack of mild acute pancreatitis. A low-fat, low-protein diet is advocated as the initial form of nutrition following an attack of acute pancreatitis.

SEVERE PANCREATITIS

Pancreatitis can be classified as severe based on predictors such as APACHE-II scores and Ranson's signs, and any evidence that the condition is severe mandates care of the patient in the intensive care unit. Such evidence may take various forms, such as the onset of encephalopathy, a hematocrit >50%, urine output <50 mL/h, hypotension, fever, or peritonitis. Elderly patients with three or more Ranson's criteria should also be monitored carefully despite the absence of severe pain.⁵²

Patients may develop ARDS, and many patients who die during the early stages of severe acute pancreatitis have this complication. Until recently, the lung injury has been thought to be caused by the systemic release of phospholipase A2 and other enzymes that directly damage alveolar tissue and pulmonary capillaries. In addition, recent evidence implicates the cell adhesion molecule ICAM-1, neutrophils, PAF, substance P, and certain chemokines. The presence of ARDS usually requires assisted ventilation with positive end-expiratory pressure. The value of peritoneal lavage in removing enzyme-rich ascites remains unclear. It has been advocated in patients with deteriorating respiratory function and/or shock that is refractory to maximal management, but its effectiveness in reducing the mortality risk of severe acute pancreatitis remains unproven.

Acute pancreatitis may be accompanied by cardiovascular events such as cardiac arrhythmia, myocardial infarction, cardiogenic shock, and congestive heart failure. The conventional modalities of treatment apply in these cases in addition to the support described above.

INFECTIONS

Infection is a serious complication of acute pancreatitis and is the most common cause of death. It is caused most often by translocated enteric bacteria and is seen commonly in necrotizing rather than interstitial pancreatitis. If there is an indication of infection (e.g., retroperitoneal air on CT scan), then a CT- or US-guided fine-needle aspiration (FNA) should be performed for Gram's stain and culture of the fluid or tissue, and the indicated antibiotic therapy initiated. However, antibiotics alone may not be effective in infected necrosis, which has a mortality of nearly 50% unless débrided surgically (Fig. 33-15). The long-held opinion that antibiotic prophylaxis in necrotizing pancreatitis is of little use has been altered by studies showing a beneficial prophylactic effect with antibiotics such as metronidazole, imipenem, and third-generation cephalosporins.^{53–55} Because *Candida* species are common inhabitants of the upper GI tract, *Candida* sepsis and secondary fungal infection of pancreatic necrosis is a risk in severe disease, and many surgeons advocate the use of empiric therapy with fluconazole in cases of severe acute pancreatitis.

Operative view of infected acute pancreatitis. Peripancreatic infection, characterized by mucopurulent exudate, extends far beyond the boundaries of the pancreas in the retroperitoneum.

STERILE NECROSIS

Patients with sterile necrosis have a far better prognosis than those with infected necrosis, with a reported mortality of near zero in the absence of systemic complications. However, others report mortality rates as high as 38% in patients with a single systemic complication.

Treatment of sterile necrotic pancreatitis falls into three degrees of aggressiveness. At one end of the scale is the patient with no systemic complications and no concerns about secondary infections, who can be managed with the supportive care (see Mild Pancreatitis) and be cautiously brought back to refeeding. The area of sterile necrosis may evolve into a chronic pseudocyst or may resolve. An intermediate course is demonstrated by the patient who develops systemic complications, and in whom a secondary infection is suspected. A CT-guided, FNA then confirms or disproves infection, and in the latter instance, the patient can be managed medically. The last and most serious condition is that of the patient who appears to be very ill, has high APACHE-II and Ranson's scores, and shows evidence of systemic toxicity, including shock. Patients in this category have a poor chance of survival without aggressive débridement, and a decision may be made to proceed with exploration simply due to a relentless course of deterioration despite maximal medical therapy.⁵⁰ It must be emphasized that current opinion is against débridement in sterile necrosis unless it is accompanied by life-threatening systemic complications (Fig. 33-16).

Algorithm for managing acute pancreatitis. CRP = C-reactive protein; CT = computed tomography; FNA = fine-needle aspiration; ICU = intensive care unit; IL-6 = interleukin 6; LDH = lactate dehydrogenase; TAP = trypsinogen activation peptide.

PANCREATIC ABSCESS

A pancreatic abscess occurs 2 to 6 weeks after the initial attack, in contrast to infected necrosis, which occurs in the first few hours or days. The mechanism of delayed infection is not clear, but the treatment consists of external drainage, whether established by surgical or by percutaneous catheter-based methods.

NUTRITIONAL SUPPORT

The guiding principle of resting the pancreas dictates that patients with acute pancreatitis not be fed orally until their clinical condition improves. This generally occurs in 3 to 7 days in patients with mild pancreatitis, but the situation in patients with severe pancreatitis is more complicated, requiring nutritional support for several weeks. This can be provided by total parenteral nutrition (TPN) or by enteral nutrition through a jejunal tube.⁵⁶ There is some debate regarding the preferred route, because TPN is known to result in early atrophy of the gut mucosa, a condition that favors transmigration of luminal bacteria, and intrajejunal feeding still stimulates pancreatic exocrine secretion through the release of enteric hormones. Recent animal studies and preliminary clinical trials on humans suggest that, on balance, jejunal feeding may be superior to TPN, and a recent review of nasogastric feeding in acute pancreatitis indicated the safety of this technique even in patients with severe pancreatitis.⁵⁷

Treatment of Biliary Pancreatitis

Gallstones are the most common cause of acute pancreatitis worldwide. Most patients pass the offending gallstone(s) during the early hours of acute pancreatitis, but have additional stones capable of inducing future episodes. This raises the question of the timing of surgical or endoscopic clearance of gallstones. The issue of when to intervene is controversial. Several studies have been aimed at resolving this controversy, but the issue is clouded by the fact that each position is open to some theoretical objection. Additional points of contention include varying inclusion criteria, years of observation of the studied groups, and a lack of uniformity regarding definitions. General consensus favors either urgent intervention (cholecystectomy) within the first 48 to 72 hours of admission, or briefly delayed intervention (after 72 hours, but during the initial hospitalization) to give an inflamed pancreas time to recover. Cholecystectomy and operative common duct clearance is probably the best treatment for otherwise healthy patients with obstructive pancreatitis. However, patients who are at high risk for surgical intervention are best treated by endoscopic sphincterotomy, with clearance of stones by ERCP.

In the case of acute biliary pancreatitis in which chemical studies suggest that the obstruction persists after 24 hours of observation, emergency endoscopic sphincterotomy and stone extraction is indicated. Routine ERCP for examination of the bile duct is discouraged in cases of biliary pancreatitis, as the probability of finding residual stones is low, and the risk of ERCP-induced pancreatitis is significant. Patients who are suspected of harboring a persistent impacted stone in the distal common bile duct or ampulla should have confirmation by radiologic imaging (CT, magnetic resonance cholangiopancreatography, or endoscopic ultrasonography) before intervention.

CHRONIC PANCREATITIS

Definition, Incidence, and Prevalence

Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Autopsy studies indicate the prevalence to be as high as 5% in Scandinavia,⁵⁸ although population studies suggest a prevalence that ranges from 5 to 27 persons per 100,000 population, with considerable geographic variation.^{59,60} Differences in diagnostic criteria, regional nutrition, alcohol consumption, and medical access account for variations in the frequency of the diagnosis, but the overall incidence of the disease has risen progressively over the past 50 years⁶¹ (Fig. 33-17).

Fig. 33-17.

Incidence of chronic pancreatitis. The reported incidence of chronic pancreatitis has increased steadily over the past 50 years.

(Reproduced with permission from Worning.⁶¹)

Autopsy data are difficult to interpret because a number of changes associated with chronic pancreatitis, such as fibrosis, duct ectasia, and acinar atrophy, are also present in asymptomatic elderly patients.⁶² Although the prevalence of chronic pancreatitis in patients with alcoholic cirrhosis and fatty liver ranges from 9 to 34%, the prevalence of chronic pancreatitis among known alcoholics is only 5 to 15%.^{61,63,64}

Etiology

Worldwide, alcohol consumption and abuse is associated with chronic pancreatitis in up to 70% of cases (Table 33-6). In 1878, Friedreich proposed that "a general chronic interstitial pancreatitis may result from excessive alcoholism (drunkard's pancreas).⁶⁵ Since that observation, numerous

studies have shown that a causal relationship exists between alcohol and chronic pancreatitis, but the prevalence of this etiology of the disease in Western countries ranges widely, from 38 to 94%.⁶¹ Other major causes worldwide include tropical (nutritional) and idiopathic disease, as well as hereditary causes.

Table 33-6 Etiology of Chronic Pancreatitis
Alcohol, 70%
Idiopathic (including tropical), 20%
Other, 10%
Hereditary
Hyperparathyroidism
Hypertriglyceridemia
Autoimmune pancreatitis
Obstruction
Trauma
Pancreas divisum

ALCOHOL

There is a linear relationship between exposure to alcohol and the development of chronic pancreatitis.⁶⁶ The risk of disease is present in patients with even a low or occasional exposure to alcohol (1 to 20 g/d), so there is no threshold level of alcohol exposure below which there is no risk of developing chronic pancreatitis. Furthermore, although the risk of disease is dose related, and highest in heavy (150 g/d) drinkers, <15% of confirmed alcohol abusers suffer from chronic pancreatitis.^{67,68} In a study of 247 patients with fatal acute alcoholic pancreatitis, 53% of patients had no autopsy evidence of chronic pancreatitis.⁶⁹ However, the duration of alcohol consumption is definitely associated with the development of pancreatic disease. The onset of disease typically occurs between ages 35 to 40, after 16 to 20 years of heavy alcohol consumption. Recurrent episodes of acute pancreatitis are typically followed by chronic symptoms after 4 or 5 years.^{30,70}

Although the pattern of disease presentation is well known in those alcohol users who develop pancreatic disease, the pathophysiology of alcohol-induced pancreatic disease is still an area of active investigation. In their 1946 classic study, Comfort, Gambrill, and Baggenstoss proposed that chronic pancreatitis was the result of multiple episodes of acute inflammation, with residual and progressively increasing chronic inflammation.⁷¹ Subsequently, other investigators proposed that initial acute inflammation was not necessarily linked to chronic changes in the pancreas,⁷² and Kondo and associates showed that other, additional factors were necessary for repeated exposure to alcohol to cause chronic pancreatitis.⁷³ Regardless of the requirement for other predisposing or facilitative factors, the concept that multiple episodes (or a prolonged course) of pancreatic injury ultimately leads to chronic disease is widely accepted as the pathophysiologic sequence³⁰ (Fig. 33-18). Laboratory studies in rodents reveal that repeated episodes of acute non-alcohol-induced pancreatitis results in findings of chronic pancreatitis,^{74,75} and the induction of severe acute pancreatitis by a single intraductal infusion of oleic acid reproducibly results in chronic pancreatitis in rats.⁷⁶

"Multiple hit" theory of the etiology of acute pancreatitis. Multiple episodes of acute pancreatitis cause progressively more organized inflammatory changes that ultimately result in chronic inflammation and scarring.

(Reproduced with permission from Apte et al.³⁰ Copyright Elsevier.)

Alcohol-associated chronic pancreatitis is less common in Japan and India, where there is a lower per capita consumption of alcohol, and its incidence is otherwise quite variable with regard to geography, nutrition, and race.⁷² Although alcohol exposure to the pancreatic ductal system, or elevated levels of alcohol in the bloodstream, has been shown to alter the integrity and function of pancreatic ducts and acini directly,^{77,78} most investigators believe that alcohol metabolites such as acetaldehyde, combined with oxidant injury, result in local parenchymal injury that is preferentially targeted to the pancreas in predisposed individuals. Repeated or severe episodes of toxin-induced injury activate a cascade of cytokines, which, in turn, induces pancreatic stellate cells (PSCs) to produce collagen and cause fibrosis (Fig. 33-19). It remains to be determined whether alcohol sensitizes the pancreas of susceptible individuals to another cause of acute inflammation, or whether genetic or other factors predispose to direct alcohol-related injury.³⁰

Fig. 33-19.

The sentinel acute pancreatitis event (SAPE) hypothesis for the development of chronic pancreatitis. A critical episode of acute pancreatitis activates cytokine-induced transformation of pancreatic stellate cells, which results in collagen production and fibrosis. ETOH = ethyl alcohol.

(Reproduced with permission from Schneider et al.¹²⁷ Copyright Elsevier.)

Since the discovery of specific genetic mutations and deletions associated with hereditary pancreatitis (see Hereditary Pancreatitis), many studies have been undertaken to determine whether specific genetic abnormalities are associated with alcoholic chronic pancreatitis.⁷⁹ No mutations of the major genetic abnormality associated with hereditary pancreatitis, the cationic trypsinogen gene or *PRSS1*,³¹ have been identified in patients with

alcoholic chronic pancreatitis. A second genetic marker for hereditary pancreatitis, the PSTI, or *SPINK1* gene, has also been studied. Mutations in *SPINK1* are observed in the general population, and Witt and colleagues found a 5.8% rate of *SPINK1* mutations in patients with alcoholic pancreatitis, compared to a 0.8% rate in the control population.⁸⁰ Studies that have examined some of the known polymorphisms and mutations of the cystic fibrosis transmembrane receptor (*CFTR*) gene have thus far failed to demonstrate an association with alcoholic chronic pancreatitis. Therefore, a dominant hereditary cofactor for alcoholic pancreatitis remains to be elucidated.

Alcohol may interfere with the intracellular transport and discharge of digestive enzymes, and may contribute to the colocalization of digestive enzymes and lysosomal hydrolase within acinar cells, leading to autodigestion^{81,82} (see section on Acute Pancreatitis). A high-protein, low-bicarbonate, low-volume secretory output is seen after chronic alcohol exposure⁸³ which may contribute to the precipitation of proteins in secondary ducts in the early stages of chronic pancreatitis.⁸⁴ Lithostathine, a protein found in pancreatic juice, inhibits the formation of calcium carbonate crystals,⁸⁵ and has been found to be decreased in the pancreatic duct fluid in alcoholic and nonalcoholic chronic pancreatitis patients⁸⁶ (see section on Stone Formation below). The zymogen membrane-associated protein GP2 is also found in protein precipitates within small ducts and may contribute to small duct obstruction in chronic pancreatitis.⁸⁷ Calcium is complexed to protein plugs in small ductules, secondary ducts, and, eventually, in the main ductal system, which causes ductal cell injury and obstruction of the secretory system, which further promotes an inflammatory response.

Cigarette smoking has been strongly associated with chronic pancreatitis and with the development of calcific pancreatitis.⁸⁸ Studies on the role of smoking in the development of alcoholic pancreatitis have been conflicting, although the risk of cancer in chronic pancreatitis is increased significantly by smoking. In hereditary pancreatitis, smoking has been found to lower the age of onset of carcinoma by about 20 years.⁸⁹ Smoking would therefore appear to be a definite risk factor for the late complications of alcoholic pancreatitis, if not an early cofactor.

HYPERPARATHYROIDISM

Hypercalcemia is a known cause of pancreatic hypersecretion,⁹⁰ and chronic hypercalcemia caused by untreated hyperparathyroidism is associated with chronic calcific pancreatitis.⁹¹ Hypercalcemia is also a stimulant for pancreatic calcium secretion, which contributes to calculus formation and obstructive pancreatopathy. The treatment is correction of the hyperparathyroidism and assessment of any additional endocrinopathies.

HYPERLIPIDEMIA

In addition to the risk of acute pancreatitis, hyperlipidemia and hypertriglyceridemia predispose women to chronic pancreatitis when they receive estrogen replacement therapy.⁹² Fasting triglyceride levels <300 mg/dL are below the threshold for this to occur, and the mechanism of estrogen potentiation of hyperlipidemia-induced chronic pancreatitis is unknown. It is assumed that chronic changes occur after repeated subclinical episodes of acute inflammation. Aggressive therapy of hyperlipidemia is therefore important in peri- or postmenopausal patients who are candidates for estrogen therapy.

Classification

A major impediment to an accurate accounting of the frequency and severity of chronic pancreatitis has been the difficulty with which investigators and clinicians have struggled to identify a useful classification system. Multiple classification systems have been proposed. In 1963, Henri Sarles organized a symposium in Marseille, France, and subsequent symposia were held in Cambridge (1983), Marseille (1984), and Rome (1998). A current classification system, as delineated by Singer and Chari, is shown in Table 33-7.⁹³

Table 33-7 Classification of Chronic Pancreatitis				
Chronic Calcific Pancreatitis	Chronic Obstructive Pancreatitis	Chronic Inflammatory Pancreatitis	Chronic Autoimmune Pancreatitis	Asymptomatic Pancreatic Fibrosis
Alcohol	Pancreatic tumors	Unknown	Associated with autoimmune disorders (e.g., primary sclerosing cholangitis)	Chronic alcoholic
Hereditary	Ductal stricture			Endemic in asymptomatic residents in tropical climates
Tropical	Gallstone- or trauma-induced pancreas divisum			
Hyperlipidemia			Sjögren's syndrome	
Hypercalcemia			Primary biliary cirrhosis	
Drug-induced				
Idiopathic

CHRONIC CALCIFYING (LITHOGENIC) PANCREATITIS

This type is the largest subgroup in the current classification scheme and includes patients with calcific pancreatitis of most etiologies. Although the majority of patients with calcific pancreatitis have a history of alcohol abuse, stone formation and parenchymal calcification can develop in a variety of etiologic subgroups; hereditary pancreatitis and tropical pancreatitis are particularly noteworthy for the formation of stone disease. The clinician should therefore avoid the assumption that calcific pancreatitis confirms the diagnosis of alcohol abuse.

CHRONIC OBSTRUCTIVE PANCREATITIS

This refers to chronic inflammatory changes that are caused by the compression or occlusion of the proximal ductal system by tumor, gallstone, posttraumatic scar, or inadequate duct caliber (as in pancreas divisum). Obstruction of the main pancreatic duct by inflammatory (posttraumatic) or neoplastic processes can result in diffuse fibrosis, dilated main and secondary pancreatic ducts, and acinar atrophy. The patient may have little in the way of pain symptoms or may present with signs of exocrine insufficiency. Intraductal stone formation is rare, and both functional and structural abnormalities may improve when the obstructive process is relieved or removed. Trauma to the pancreas frequently results in duct injury and leakage, which may result in pseudocyst formation as well as local scar formation. Inadequately treated pancreatic trauma may result in persistent inflammatory changes in the distal gland.⁹⁴

Pancreas divisum represents a special case of obstructive pancreatitis. It is the most common congenital anomaly involving the pancreas and occurs in up to 10% of children. It is thought to predispose the pancreas to recurrent acute pancreatitis and chronic pancreatitis, due to functional obstruction of a diminutive duct of Santorini that fails to communicate with Wirsung's duct (Fig. 33-20). However, the classic picture of obstructive pancreatopathy with a dilated dorsal duct is unusual in pancreas divisum, so a decompressive operation or a lesser papilla sphincteroplasty is frequently not feasible or unsuccessful. Endoscopic stenting through the lesser papilla may result in temporary relief of symptoms, and this response would increase the possibility that a permanent surgical or endoscopic intervention will be successful. Although some authors emphasize the pathologic implications of pancreas divisum,^{95,96} others express skepticism that it represents a true risk to pancreatic secretory capacity or contributes to the development of chronic pancreatitis.^{97,98}

CHRONIC INFLAMMATORY PANCREATITIS

Chronic inflammatory pancreatitis is characterized by diffuse fibrosis and a loss of acinar elements with a predominant mononuclear cell infiltration throughout the gland.

CHRONIC AUTOIMMUNE PANCREATITIS

A variant of chronic pancreatitis is a nonobstructive, diffusely infiltrative disease associated with fibrosis, a mononuclear cell (lymphocyte, plasma cell, or eosinophil) infiltrate, and an increased titer of one or more autoantibodies.⁹⁹ This type is associated with a variety of illnesses with suspected or proven autoimmune etiology, such as Sjögren's syndrome, rheumatoid arthritis, and type 1 diabetes mellitus.

Compressive stenosis of the intrapancreatic portion of the common bile duct is frequently seen, along with symptoms of obstructive jaundice.

Increased levels of serum β -globulin or immunoglobulin G4 are also present. Steroid therapy is uniformly successful in ameliorating the disease, including any associated bile duct compression.¹⁰⁰ The differential diagnosis includes lymphoma, plasmacytoma ("pseudotumor" of the pancreas), and diffuse infiltrative carcinoma. Although the diagnosis is confirmed on pancreatic biopsy, presumptive treatment with steroids is usually undertaken, especially when clinical and laboratory findings support the diagnosis. Failure to obtain a cytologic specimen may lead to an unnecessary resectional procedure, and an untreated inflammatory component may cause sclerosis of the extrahepatic or intrahepatic bile ducts, with eventual liver failure.¹⁰¹

TROPICAL (NUTRITIONAL) PANCREATITIS

Tropical chronic pancreatitis is highly prevalent among adolescents and young adults raised in Indonesia, southern India, and tropical Africa.¹⁰² Abdominal pain develops in adolescence, followed by the development of a brittle form of pancreatogenic diabetes. Parenchymal and intraductal calcifications are seen, and the pancreatic duct stones may be quite large.¹⁰³ Many of the patients appear malnourished, some present with extreme emaciation, and a characteristic cyanotic coloration of the lips may be seen.¹⁰⁴ In addition to protein-caloric malnutrition, toxic products of some indigenous foodstuffs may also contribute to the disease. Cassava root is a starch (the origin of tapioca), which is a staple in the diet throughout the Afro-Asian region where tropical pancreatitis is prevalent. Cassava contains toxic glycosides, which form hydrocyanic acid when mixed with (gastric) hydrochloric acid.¹⁰⁵ Hydrocyanic acid is reduced to thiocyanate, which blocks a variety of enzymes, including superoxide dismutase. The simultaneous deficiency of dietary trace elements such as zinc, copper, and selenium could retard the detoxification of cyanogens and result in an increased susceptibility to free radical injury of the pancreas.

Clinically, tropical pancreatitis presents much like hereditary pancreatitis, and a familial pattern among cases is not unusual. An association with mutations of the PSTI or *SPINK1* gene in patients with tropical pancreatitis has been reported.^{106,107} The accelerated deterioration of endocrine and exocrine function, the chronic pain due to obstructive disease, and the recurrence of symptoms despite decompressive procedures characterize the course of disease.¹⁰⁴ As immigrants from the tropical regions increasingly find their way to all parts of the world, an awareness of this severe form of chronic pancreatitis is helpful for those who treat patients with pancreatic disease.

HEREDITARY PANCREATITIS

In 1952, Comfort and Steinberg reported a kindred of "hereditary chronic relapsing pancreatitis" after treating the proband, a 24-year-old woman, at the Mayo Clinic.¹⁰⁸ Subsequently, familial patterns of chronic, nonalcoholic pancreatitis have been described worldwide, and a familial pattern has emerged. Typically, patients first present in childhood or adolescence with abdominal pain and are found to have chronic calcific pancreatitis on imaging studies. Progressive pancreatic dysfunction is common, and many patients present with symptoms due to pancreatic duct obstruction. The risk of subsequent carcinoma formation is increased, reaching a prevalence, in some series, of 40%, but the age of onset for carcinoma is typically >50 years old.^{109,110} The disorder is characterized by an autosomal dominant pattern of inheritance, with 80% penetrance and variable expression. The incidence is equal in both sexes. Whitcomb and colleagues,¹¹¹ and separately LeBodic and associates,¹¹² performed gene linkage analysis and identified a linkage for hereditary pancreatitis to chromosome 7q35. Subsequently, the region was sequenced and revealed eight trypsinogen genes. Mutational analysis revealed a missense mutation resulting in an Arg to His substitution at position 117 of the cationic trypsinogen gene, or *PRSS1*, one of the primary sites for proteolysis of trypsin. This mutation prevents trypsin from being inactivated by itself or other proteases and results in persistent and uncontrolled proteolytic activity and autodestruction within the pancreas.¹¹³ The position 117 mutation of *PRSS1* and an additional mutation, now known collectively as the R122H and N291 mutations of *PRSS1*, account for about two-thirds of cases of hereditary pancreatitis. Recently, Masson and associates described a mutation in the anionic trypsinogen gene that may also be present in some cases.¹¹⁴ Thus, hereditary pancreatitis results from one or more mutational defects that incapacitate an autoprotective process that normally prevents proteolysis within the pancreas.

Similarly, PSTI, also known as *SPINK1*, has been found to have a role in hereditary pancreatitis. *SPINK1* specifically inhibits trypsin action by competitively blocking the active site of the enzyme. Witt and colleagues investigated 96 unrelated children with chronic pancreatitis in Germany and found a variety of *SPINK1* mutations in 23% of the patients.⁸⁰ Several studies have now confirmed an association of *SPINK1* mutations with familial and idiopathic forms of chronic pancreatitis, as well as tropical pancreatitis.^{106,108,115,116} *SPINK1* mutations are common in the general population as well, and the frequency of these mutations varies in different cohorts of idiopathic chronic pancreatitis, from 6.4% in France¹⁰¹ to 25.8% in the United States.¹¹⁵

The *CFTR* gene contains over 4300 nucleotides, divided into 24 exons, which encode for a 1480-amino acid protein. Over 1000 polymorphisms have been reported, and many are common.⁷⁹ The severe *CFTR* mutation associated with the classic disease, F508, is rarely observed in chronic

pancreatitis. But other minor *CFTR* mutations have been noted to be associated with chronic idiopathic pancreatitis in which the pulmonary, intestinal, and cutaneous manifestations of the disease are silent.^{117,118} It is likely that many of the "idiopathic" forms of chronic pancreatitis, as well as some patients with the more common forms of the disease, will be found to have a genetic linkage or predisposition. The goal of this active area of research is to elucidate specific molecular abnormalities and provide strategies for treatment and prevention.

ASYMPTOMATIC PANCREATIC FIBROSIS

Asymptomatic pancreatic fibrosis is seen in some asymptomatic elderly patients, in tropical populations, or in asymptomatic alcohol users. There is diffuse perilobar fibrosis and a loss of acinar cell mass, but without a main ductular component.

A shortcoming of these clinical classification systems is the lack of histologic criteria of chronic inflammation due to the usual absence of a biopsy specimen. The differentiation of recurrent acute pancreatitis from chronic pancreatitis with exacerbations of pain can be difficult to establish and is not facilitated by the current system. Similarly, cystic fibrosis is known to cause fibrosis and acinar dysfunction but is not included in the classification despite increasing evidence for its possible role in idiopathic chronic pancreatitis.¹¹⁹ Therefore, further refinements in the classification system for chronic pancreatitis are needed to allow a better prediction of its clinical course and a more accurate diagnosis of a likely etiologic agent.

IDIOPATHIC PANCREATITIS

When a definable cause for chronic pancreatitis is lacking, the term *idiopathic* is used to categorize the illness. Not surprisingly, as diagnostic methods and clinical awareness of disease improve, fewer patients fall into the idiopathic category. Classically, the idiopathic group includes young adults and adolescents who lack a family history of pancreatitis but who may represent individuals with spontaneous gene mutations encoding for regulatory proteins in the pancreas. In addition, the idiopathic group has included a large number of older patients for whom no obvious cause of recurrent or chronic pancreatitis can be found.¹²⁰ However, because the prevalence of biliary calculi increases steadily with age, it is not surprising that, as methods to detect biliary stone disease and microlithiasis have improved, a larger proportion of elderly "idiopathic" pancreatitis patients are found to have biliary tract disease.¹²¹

As noted in the section on Hereditary Pancreatitis above, an increasing number of mutations of the *CFTR* and *SPINK1* genes have been identified in association with idiopathic pancreatitis.^{117,118,122} However, the role of genetic analysis in the management of these patients remains unclear, as guidelines have yet to be developed to allow physicians to use the data consistently. The clinical management of patients who harbor a minor *CFTR* mutation and chronic pancreatitis, for example, is still dictated by the manifestations of the pancreatitis. Any genetic counseling for the patient and his or her family has yet to be defined.¹¹⁹

Pathology

HISTOLOGY

In early chronic pancreatitis, the histologic changes are unevenly distributed and are characterized by induration, nodular scarring, and lobular regions of fibrosis (Fig. 33-21). As the disease progresses, there is a loss of normal lobulation, with thicker sheets of fibrosis surrounding a reduced acinar cell mass, and dilatation of ductular structures (Fig. 33-22). The ductular epithelium is usually atypical and may display features of dysplasia, as evidenced by cuboidal cells with hyperplastic features, accompanied by areas of mononuclear cell infiltrates or patchy areas of necrosis. Cystic changes may be seen, but areas of relatively intact acinar elements and normal-appearing islets persist. In severe chronic pancreatitis, there is considerable replacement of acinar tissue by broad, coalescing areas of fibrosis, and the islet size and number are reduced (Fig. 33-23). Small arteries appear thickened and neural trunks become prominent.¹²³

Tropical pancreatitis and hereditary pancreatitis are histologically indistinguishable from chronic alcoholic pancreatitis. In obstructive chronic pancreatitis, calculi are absent, although periacinar fibrosis and dilated ductular structures are prominent. In pancreatic lobular fibrosis seen in elderly subjects, small ducts are dilated, sometimes with small calculi trapped within. Hypertrophy of ductular epithelia is thought to cause this small-duct disease, which is accompanied by perilobular fibrosis.¹²⁴

FIBROSIS

A common feature of all forms of chronic pancreatitis is the perilobular fibrosis that forms surrounding individual acini, then propagates to surround small lobules, and eventually coalesces to replace larger areas of acinar tissue. The pathogenesis of this process involves the activation of PSCs that are found adjacent to acini and small arteries.¹²⁵ The extended cytoplasmic processes of PSCs encircle the acini but appear quiescent in the normal gland, where they contain lipid vacuoles and cytoskeletal proteins. In response to pancreatic injury, the PSCs become activated and proliferate (similarly to hepatic stellate cells), lose their lipid vesicles, and transform into myofibroblast-like cells. These cells respond to proliferative factors such as transforming growth factor beta, platelet-derived growth factor, and proinflammatory cytokines and synthesize and secrete type I and III collagen and fibronectin. Studies indicate that vitamin A metabolites, similar to those present in quiescent PSCs, can inhibit the collagen production of activated cultured PSCs.¹²⁶ This raises the possibility that early intervention may be possible to interrupt or prevent the fibrosis resulting from ongoing activation of PSCs.

The overall pathogenic sequence proposed by Schneider and Whitcomb¹²⁷ whereby alcohol induces acute pancreatitis and, with ongoing exposure, promotes the development of chronic fibrosis, is summarized in Fig. 33-19. Stellate cells surrounding the acinus are activated in acute pancreatitis but may be inactivated by anti-inflammatory cytokines and, in the absence of further injury, may revert to a quiescent state. The role of proinflammatory macrophages, cytokines, and stellate cells in models of acute and chronic pancreatitis represents an important area of current research.

STONE FORMATION

Pancreatic stones are composed largely of calcium carbonate crystals trapped in a matrix of fibrillar and other material.¹²⁸ The fibrillar center of most stones contains no calcium but rather a mixture of other metals. This suggests that stones form from an initial noncalcified protein precipitate, which serves as a focus for layered calcium carbonate precipitation. The same low-molecular-weight protein is present in stones and protein plugs and was initially named *pancreatic stone protein*, or PSP.¹²⁹ PSP comprises up to 14% of the protein content of mammalian pancreatic juice, and is secreted in four isoforms (PSP-S2, S3, S4, and S5), with molecular weights ranging from 16 to 20 kDa. PSP was found to be a potent inhibitor of calcium carbonate crystal growth and has subsequently been renamed *lithostathine*.¹³⁰ Independently, a 15-kDa fibrillar protein isolated from the pancreas was named *pancreatic thread protein*, and it has been shown to be homologous with lithostathine. Finally, a protein product of the *reg* gene, so named because it is expressed in association with regenerating islets in models of pancreatic injury, was isolated and called *reg* protein.¹³¹

This also has been found to be homologous with lithostathine.¹³² No overall homology has been found between lithostathine and other pancreatic proteins. The PSP/pancreatic thread protein/reg/lithostathine gene encodes for a 166-amino acid product that undergoes posttranslational modification to the S2 through S5 isoforms present in pancreatic juice. The protein is expressed in all rodents and mammals, both in the pancreas as well as in brain tissue, where it is found in particularly high concentrations in pyramidal neurons in Alzheimer's disease and Down syndrome. It is also found in the renal tubules, which is consistent with its biologic action of preventing calcium carbonate precipitation.¹³²

Calcium and bicarbonate ions are normally present in pancreatic juice in high concentrations, and the solubility product of calcium carbonate is greatly exceeded under normal conditions. Microcrystals of calcium carbonate can be seen in normal pancreatic juice but are usually clinically silent. Lithostathine is a potent inhibitor of calcium carbonate crystal formation, at a concentration of only 0.1 $\mu\text{mol/L}$. However, lithostathine concentrations in normal pancreatic juice are in the range of 20 to 25 $\mu\text{mol/L}$, so a constant suppression of calcium carbonate crystal formation is present in the normal pancreas.

In alcoholics and in patients with alcoholic chronic pancreatitis, lithostathine expression and secretion are dramatically inhibited^{132–134} (Fig. 33-24). In addition, elevated levels of precipitated lithostathine in the duct fluid in chronic pancreatitis patients suggests that the availability of the protein may be further reduced by the action of increased proteases and other proteins present in the duct fluid of alcoholic patients. Increased pancreatic juice protein levels in alcoholic men are reversible by abstinence from alcohol,¹³⁵ so the availability and effectiveness of lithostathine may be restored in patients with early-stage disease by timely intervention. Nevertheless, calcific stone formation represents an advanced stage of disease, which can further promote injury or symptoms due to mechanical damage to duct epithelium or obstruction of the ductular network.

DUCT DISTORTION

Although calcific stone disease is normally a marker for an advanced stage of disease, parenchymal and ductular calcifications do not always correlate with symptoms. Obstructing main duct stones are commonly observed and are thought to be an indication for endoscopic or surgical removal. The ball-valve effect of a stone in a secreting system produces inevitable episodes of duct obstruction, usually accompanied by pain. But some patients with complete duct obstruction have prolonged periods of painlessness. Ductular hypertension has been documented in patients with proximal stenosis of the main pancreatic duct, and prolonged ductular distention after secretin administration is taken as a sign of ductular obstruction.¹³⁶ Although calculus disease and duct enlargement appear together as late stages of chronic pancreatitis, controversy persists over

whether they are associated, are independent events, or are causally related.

RADIOLOGY

Radiologic imaging of chronic pancreatitis assists in four areas: (a) diagnosis, (b) the evaluation of severity of disease, (c) detection of complications, and (d) assistance in determining treatment options.¹³⁷ With the advent of cross-sectional imaging techniques such as CT and magnetic resonance imaging (MRI), the contour, content, ductal pattern, calcifications, calculi, and cystic disease of the pancreas are all readily discernible. Transabdominal ultrasonography is frequently used as a screening method for patients with abdominal symptoms or trauma, and the extension of ultrasonic imaging to include endoscopic ultrasound (EUS) and laparoscopic US have resulted in the highest-resolution images that are capable of detecting very small (<1 cm) abnormalities in the pancreas. EUS is now frequently used as a preliminary step in the evaluation of patients with pancreatic disease, and magnetic resonance cholangiopancreatography (MRCP) is increasingly being used to select patients who are candidates for the most invasive imaging method, ERCP. The staging of disease is important in the care of patients, and a combination of imaging methods is usually used (Table 33-8).

Table 33-8 Cambridge Classification of Pancreatic Morphology in Chronic Pancreatitis		
Classification	ERCP Findings	CT and US Findings
Normal	No abnormal SBDs	Normal gland size, shape; homogeneous parenchyma
Equivocal	MPD normal	One of the following: less than three abnormal SBDs; MPD 2–4 mm; gland enlarged more than two times normal size; heterogeneous parenchyma
Mild	MPD normal	Two or more of the following: less than three abnormal SBDs; MPD 2–4 mm; slight gland enlargement; heterogeneous parenchyma
Moderate	MPD changes	Small cysts <10 mm; MPD irregularity
	SBD changes	Focal acute pancreatitis; increased echogenicity of MPD walls; gland-contour irregularity
Severe	Any of the above changes plus one or more of the following: Cysts <10 mm; intraductal filling defects; calculi; MPD obstruction or stricture; severe MPD irregularity; contiguous organ invasion	—

CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; MPD = main pancreatic duct; SBD = side-branch duct; US = ultrasound.

Ultrasonography is frequently used as an initial imaging method in patients with abdominal symptoms, and changes consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes, and a heterogeneous texture are seen in chronic pancreatitis (Fig. 33-25). The sensitivity of transabdominal ultrasonography ranges from 48 to 96%, and is operator dependent.¹³⁸ However, the contour, texture, and ductal pattern are usually quite discernible, and it is a reliable method for periodic re-examination to determine the efficacy of treatment.

Sonography in chronic pancreatitis. Transabdominal sonogram of patient with chronic pancreatitis demonstrates heterogeneity of the pancreatic parenchyma, dilated ductal systems, and cyst formation.

(Reproduced with permission from Bolondi et al.¹³⁸)

EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent and less widely available than transabdominal ultrasonography, EUS provides not only imaging capability but adds the capacity to obtain cytologic and chemical samples of tissue and fluid aspirated with linear array monitoring (Fig. 33-26). EUS images obtained through a high-frequency (7.5- to 12.5-mHz) transducer are able to evaluate subtle changes in 2- to 3-mm structures within the pancreas and can detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions, intraductal mucus, cystic lesions, and subtle ductular abnormalities are recognizable by EUS (Table 33-9). This allows ERCP to be reserved for these patients who require therapeutic maneuvers, or for the evaluation of more complex problems. EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis¹³⁹ and may be more sensitive than ERCP in the detection of mild disease.¹⁴⁰

Table 33-9 Endoscopic Ultrasound Features of Chronic Pancreatitis

Endoscopic Ultrasound Feature	Implication
Ductal changes	
Duct size >3 mm	Ductal dilation
Tortuous pancreatic duct	Ductal irregularity
Intraductal echogenic foci	Stones or calcification
Echogenic duct wall	Ductal fibrosis
Side-branch ectasia	Periductal fibrosis
Parenchymal changes	
Inhomogeneous echo pattern	Edema
Reduced echogenic foci (1–3 mm)	Edema
Enhanced echogenic foci	Calcifications
Prominent interlobular septae	Fibrosis
Lobular outer gland margin	Fibrosis, glandular atrophy
Large, echo-poor cavities (>5 mm)	Pseudocyst

CT scanning has affected the diagnosis of pancreatic disease more broadly than any other method. Before its widespread introduction in the early 1970s, pancreatic imaging was largely a matter of detecting the displacement of adjacent, contrast-filled viscera by mass lesions of the pancreas. Since the introduction of cross-sectional techniques, and with the advent of faster helical CT scanning and CT angiography, visualization of the nature, extent, location, and relative relationships of pancreatic structures and lesions is possible with great clarity. Duct dilatation, calculous disease, cystic changes, inflammatory events, and anomalies are all detectable with a resolution of 3 to 4 mm (Fig. 33-27). CT scanning has a false-negative rate of <10% for chronic pancreatitis, but early or mild chronic disease may go undetected by CT imaging. The earliest changes are dilatation of secondary ducts and heterogeneous parenchymal changes, which are detectable by EUS and ERCP. Another drawback of CT scanning is its lower sensitivity for detecting small neoplasms, which are seen with increased frequency in chronic pancreatitis and may be invisible to all modalities except EUS.

Computed tomographic imaging of chronic pancreatitis. A dilated pancreatic duct is seen, with evidence of intraductal stones and parenchymal calcification.

MRI, in both the cross-sectional mode and the coronally oriented heavily weighted T2 or high spin ratio imaging (MRCP) that can disclose fluid-filled ducts and cystic lesions, has added greatly to the imaging options for chronic pancreatitis (Fig. 33-28). The resolution of cross-sectional MRI scanning is now approaching that of CT scanning, although the availability of MRI scanners and the complexity of the images produced have limited their large-scale use for routine imaging of the pancreas. MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities that correlates closely with the contrast-filled ducts imaged by ERCP.¹⁴¹ The advantages of MRCP include its noninvasive methodology and its ability to image obstructed ducts that are not opacified by ERCP injection. It is therefore a useful screening study to detect duct abnormalities and to confirm the need for interventional procedures. Oral, IV, and intraductal contrast are unnecessary for MRCP, and its lack of ionizing radiation makes this the safest method to image the ductal system in high-risk patients.

Magnetic resonance cholangiopancreatography in chronic pancreatitis. A dilated pancreatic duct suggests obstructive pancreatopathy due to proximal scarring.

ERCP is considered to be the gold standard for the diagnosis and staging of chronic pancreatitis. It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers, such as biopsy or brushing for cytology, or the use of stents to relieve obstruction or drain a pseudocyst (Fig. 33-29). Unfortunately, ERCP also carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients.¹⁴² Patients at increased risk include those with sphincter of Oddi dysfunction and those with a previous history of post-ERCP pancreatitis. Post-ERCP pancreatitis occurs after uncomplicated procedures, as well as after those that require prolonged manipulation. Severe pancreatitis and deaths have occurred after ERCP. This method should be reserved for patients in whom the diagnosis is unclear despite the use of other imaging methods, or in whom a diagnostic or therapeutic maneuver is specifically indicated.

Pancreatic duct stenting. At endoscopic retrograde cholangiopancreatography, a stent is placed in the proximal pancreatic duct to relieve obstruction and reduce symptoms of pain. Pancreatic duct stents are left in place for only a limited time to avoid further inflammation.

Newer imaging methods are being evaluated that detect changes in metabolic activity, instead of radiologic behavior, as a means to analyze abnormal tissue. The positron emission tomographic scan measures focal changes in nutrient (e.g., glucose) metabolism to detect focal changes in tissue behavior. This method has shown usefulness in the detection of occult neoplasms of the brain and lung, and evaluations are currently ongoing to assess its role in pancreatic imaging.

Presentation, Natural History, and Complications

PRESENTING SIGNS AND SYMPTOMS

Pain is the most common symptom of chronic pancreatitis. It is usually midepigastria in location but may localize or involve either the left or right upper quadrant of the abdomen. Occasionally, it is perceived in the lower midabdomen but is frequently described as penetrating through to the back (Fig. 33-30). The pain is typically steady and boring, but not colicky. It persists for hours or days and may be chronic with exacerbations caused by eating or drinking alcohol. Chronic alcoholics also describe a steady, constant pain that is temporarily relieved by alcohol, followed by a more severe recurrence hours later.^{143,144}

Fig. 33-30.

Pain location in chronic pancreatitis.

(Reproduced with permission from Murayama et al.¹⁴⁴)

Patients with chronic pancreatic pain typically flex their abdomen and either sit or lie with their hips flexed, or lie on their side in a fetal position. Unlike ureteral stone pain or biliary colic, the pain causes the patient to be still. Nausea or vomiting may accompany the pain, but anorexia is the most common associated symptom.

Pain from chronic pancreatitis has been ascribed to three possible etiologies. Ductal hypertension, due to strictures or stones, may predispose to pain that is initiated or exacerbated by eating. Chronic pain without exacerbation may be related to parenchymal disease or retroperitoneal inflammation with persistent neural involvement. Acute exacerbations of pain in the setting of chronic pain may be due to acute increases in duct pressure or recurrent episodes of acute inflammation in the setting of chronic parenchymal disease. Nealon and Matin have described these various pain syndromes as being predictive of the response to various surgical procedures.¹⁴⁵ Pain that is found in association with ductal hypertension is most readily relieved by pancreatic duct decompression, through endoscopic stenting or surgical decompression.¹⁴³

Ammann and colleagues also studied the pain patterns of patients with chronic pancreatitis and observed that the pain was commonly of relatively short (<10 days) duration, after which it was absent for long periods, or relentless or frequent, in which case it lasted for months.¹⁴⁶ Patients in the latter category frequently had other complications of pancreatitis, such as pseudocyst or duodenal compression.

The pain of chronic pancreatitis may decrease or disappear completely over a period of years, as symptoms of exocrine and endocrine deficiency become apparent.^{147,148} This is referred to as *burned out* pancreatitis and correlates with the progression of disease from a mild or moderate stage to severe destruction of the pancreas.¹⁴⁹ Non-interventional approaches to the treatment of chronic pancreatitis are accompanied by the development of narcotic addiction, inability to work, and the sequelae of chronic illness.

Although increased ductal pressure, and therefore parenchymal pressure, is thought to be the cause of pain in chronic obstructive pancreatitis,¹⁵⁰ the role of chronic inflammation per se, and the development of actual nerve damage in the diseased gland, are also thought to contribute to pain.¹⁵¹ Chronic inflammation results in the infiltration of tissue by macrophages, which secrete prostaglandins and other nociceptive agents that cause chronic stimulation of afferent neural fibers. Inflammatory damage to the perineurial layers surrounding the unmyelinated pancreatic nerves and a focal infiltration of inflammatory cells around nerves suggest that neural fibers are a target for the cellular response to inflammation in the pancreas.¹⁵²

Strategies to relieve pain are therefore based on three approaches: (a) reducing secretion and/or decompress the secretory compartment, (b) resecting the focus of chronic inflammatory change, or (c) interrupting the transmission of afferent neural impulses through neural ablative procedures. A trial of antisecretory therapy or endoscopic duct drainage may select those patients who will benefit preferentially from a decompressive procedure.

MALABSORPTION AND WEIGHT LOSS

When pancreatic exocrine capacity falls below 10% of normal, diarrhea and steatorrhea develop¹⁵³ (Fig. 33-31). Patients describe a bulky, foul-

smelling, loose (but not watery) stool that may be pale in color and float on the surface of toilet water. Frequently, patients will describe a greasy or oily appearance to the stool, or may describe an "oil slick" on the water's surface. In severe steatorrhea, an orange, oily stool is often reported.⁵⁸ As exocrine deficiency increases, symptoms of steatorrhea are often accompanied by weight loss. Patients may describe a good appetite despite weight loss, or diminished food intake due to abdominal pain.

Relationship of lipase output to fat malabsorption. Excess fecal fat appears when the pancreatic lipase output falls below 10% of normal secretory values.

(Reproduced with permission from DiMagno et al.¹⁵³)

In severe symptomatic chronic pancreatitis, anorexia or nausea may occur with or separate from abdominal pain. The combination of decreased food intake and malabsorption of nutrients usually results in chronic weight loss. As a result, many patients with severe chronic pancreatitis are below ideal body weight.

Lipase deficiency tends to manifest itself before trypsin deficiency,¹⁵⁴ so the presence of steatorrhea may be the first functional sign of pancreatic insufficiency. As pancreatic exocrine function deteriorates further, the secretion of bicarbonate into the duodenum is reduced, which causes duodenal acidification and further impairs nutrient absorption.¹⁵⁵

APANCREATIC DIABETES

The islets comprise only 2% of the mass of the pancreas, but they are preferentially conserved when pancreatic inflammation occurs. In chronic pancreatitis, acinar tissue loss and replacement by fibrosis is greater than the degree of loss of islet tissue, although islets are typically smaller than normal and may be isolated from their surrounding vascular network by the fibrosis. With progressive destruction of the gland, endocrine insufficiency commonly occurs. Frank diabetes is seen initially in about 20% of patients with chronic pancreatitis, and impaired glucose metabolism can be detected in up to 70% of patients. In a study of 500 patients with predominantly alcoholic chronic pancreatitis, diabetes developed in 83% within 25 years of the clinical onset of chronic pancreatitis, and more than half of the diabetic patients required insulin treatment.¹⁵⁶ Ketoacidosis and diabetic nephropathy are relatively uncommon in apancreatic (also termed *pancreatogenic*) diabetes (Table 33-10), but retinopathy and neuropathy are seen to occur with a similar frequency as in idiopathic diabetes.¹⁵⁷

Table 33-10 Types of Diabetes Mellitus			
Parameter	Type I IDDM Juvenile Onset	Type II NIDDM Adult Onset	Type III Apancreatic Postoperative Onset
Ketoacidosis	Common	Rare	Rare
Hyperglycemia	Severe	Usually mild	Mild
Hypoglycemia	Common	Rare	Common

Peripheral insulin sensitivity	Normal or increased	Decreased	Increased
Hepatic insulin sensitivity	Normal	Normal or decreased	Decreased
Insulin levels	Low	High	Low
Glucagon levels	Normal or high	Normal or high	Low
Pancreatic polypeptide levels	High	High	Low
Typical age of onset	Childhood or adolescence	Adulthood	Any

IDDM = insulin-dependent diabetes mellitus; NIDDM = non-insulin-dependent diabetes mellitus.

Apancreatic diabetes is more common after surgical resection for chronic pancreatitis.¹⁵⁶ Distal pancreatectomy and Whipple procedures have a higher incidence of diabetes than do drainage procedures, and the severity of diabetes is usually worse after subtotal or total pancreatectomy.¹⁵⁸

The etiology and pathophysiology of apancreatic or type III diabetes is distinct from that of either insulin-dependent (type I) or non-insulin-independent (type II) diabetes. In apancreatic diabetes, due to the loss of functioning pancreatic tissue by disease or surgical removal, there is a global deficiency of all three glucoregulatory islet cell hormones: insulin, glucagon, and PP. In addition, there is a paradoxical combination of enhanced peripheral sensitivity to insulin and decreased hepatic sensitivity to insulin.¹⁵⁹ As a result, insulin therapy is frequently difficult; patients are hyperglycemic when insulin replacement is insufficient (due to unsuppressed hepatic glucose production) or hypoglycemic when insulin replacement is barely excessive (due to enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion to counteract the hypoglycemia). This form of diabetes is referred to as *brittle* diabetes and requires special attention.

Although the primary hormonal deficit is a loss of insulin secretory capacity, the additional deficiencies of glucagon and PP are pathognomonic for apancreatic diabetes. PP has recently been shown to be important in the regulation of insulin action.¹⁶⁰ The expression of the hepatic insulin receptor gene and the subsequent availability and action of insulin receptors on hepatocyte membranes are regulated by PP.¹⁶¹ PP deficiency correlates with the severity of chronic pancreatitis, and impairments in the hepatic action of insulin are reversed in PP-deficient chronic pancreatitis patients by administration of PP¹⁶² (Fig. 33-32).

Because PP cells are predominantly located in the posterior head and uncinate process of the pancreas,¹⁶³ proximal pancreatectomy is invariably associated with profound PP deficiency. Seymour and associates studied a group of nondiabetic young men who had previously undergone various pancreatic resections for trauma, and showed that those who were PP deficient had a measurable loss of hepatic insulin sensitivity, and that this was reversed by PP administration¹⁶⁴ (Fig. 33-33). In addition, Hanazaki and colleagues showed that the addition of PP to insulin delivered via a pump in pancreatectomized dogs resulted in decreased insulin requirements to achieve glucose control.¹⁶⁵ This suggests that the treatment of apancreatic diabetes may be improved by the use of PP or a PP receptor agonist.¹⁶⁶

Laboratory Studies

Unlike chronic liver disease or abnormalities of the upper and lower GI tract, pancreatic disease presents a diagnostic challenge because a tissue biopsy and histologic confirmation of the type and stage of the disease process is almost never obtainable outside of the operating room. As a result, the diagnosis of chronic pancreatitis depends on the clinical presentation, a limited number of indirect measurements that correlate with pancreatic function, and selected imaging studies (Table 33-11).

Table 33-11 Tests for Chronic Pancreatitis
I. Measurement of pancreatic products in blood
A. Enzymes
B. Pancreatic polypeptide
II. Measurement of pancreatic exocrine secretion
A. Direct measurements
1. Enzymes
2. Bicarbonate

B. Indirect measurement
1. Bentiromide test
2. Schilling test
3. Fecal fat, chymotrypsin, or elastase concentration
4. [^{14}C]-olein absorption
III. Imaging techniques
A. Plain film radiography of abdomen
B. Ultrasonography
C. Computed tomography
D. Endoscopic retrograde cholangiopancreatography
E. Magnetic resonance cholangiopancreatography
F. Endoscopic ultrasonography

The direct measurement of pancreatic enzymes (e.g., lipase and amylase) by blood test is highly sensitive and fairly specific in acute pancreatitis but is seldom helpful in the diagnosis of chronic pancreatitis. The pancreatic endocrine product that correlates most strongly with chronic pancreatitis is the PP response to a test meal (Fig. 33-34). Severe chronic pancreatitis is associated with a blunted or absent PP response to feeding but, as with many other tests, a normal PP response does not rule out the presence of early disease.¹⁶⁷

Fig. 33-34.

Pancreatic polypeptide (PP) response to a test meal. Immunoreactive PP (IR-PP) responses in control subjects (NL, $n = 6$) and patients with severe chronic pancreatitis (CP) accompanied by PP deficiency (CP, $n = 5$) are shown. A test meal was administered at 0 minutes. Means \pm standard error of the mean are shown.

(Reproduced with permission from Brunicaudi et al.¹⁶² Copyright 1996 The Endocrine Society.)

The measurement of pancreatic exocrine secretion requires aspiration of pancreatic juice from the duodenum after nutrient (Lundh test meal) or hormonal (CCK or secretin) stimulation.^{168,169} Direct aspiration of pancreatic juice by endoscopic cannulation of the duct has been proposed, but is not risk free, comfortable for the patient, or more sensitive than luminal intubation methods.¹⁷⁰

Indirect tests of pancreatic exocrine function are based on the measurement of metabolites of compounds that are altered ("digested") by pancreatic exocrine products and can be quantified by serum or urine measurements. A commonly used indirect test is the bentiromide test, in which *N*-benzoyl-L-tyrosyl-p-aminobenzoic acid is ingested by the subject, and the urinary excretion of the proteolytic metabolite p-aminobenzoic acid (PABA) is measured. Free PABA is absorbed from the small intestine and excreted by the kidney in a linear correlation with the degree of chymotrypsin degradation of *N*-benzoyl-L-tyrosyl-p-aminobenzoic acid.¹⁷¹ Although the sensitivity of the test is as high as 100% in patients with severe chronic pancreatitis, it identifies only 40 to 50% of patients with mild disease.¹⁷² Furthermore, reduced PABA excretion is found in patients

with a variety of other GI, hepatic, and renal diseases. Therefore, the test is of value not for the diagnosis of chronic pancreatitis but for determining the extent of exocrine pancreatic insufficiency in patients with known disease.

Similarly, the absorption of vitamin B12 is adversely affected by pancreatic exocrine insufficiency, and the recovery of urinary cobalamin correlates with the functional impairment. This method is referred to as the *Schilling test* and has been modified by the addition of cobalamin binding agents such as intrinsic factor and R protein, which are differentially affected by exocrine secretion.¹⁷³ The test also is limited by poor sensitivity in patients with mild disease.

Fecal levels of chymotrypsin¹⁷⁴ and elastase¹⁷⁵ have been proposed as simpler, less expensive tests of exocrine function and correlate well with loss of pancreatic function. As with other test methods, however, these tests lose their sensitivity in patients with mild to moderate chronic pancreatitis and may be more sensitive for other causes of pancreatic dysfunction, including cystic fibrosis.

The quantification of stool fat has also been used as a measure of pancreatic lipase secretion, either through the direct measurement of total fecal fat levels while the subject consumes a diet of known fat content, or by the measurement of exhaled ¹⁴CO₂ after ingestion of [¹⁴C]-triolein or [¹⁴C]-olein. This so-called triolein breath test is less cumbersome than intubation methods, and avoids the necessity of stool collections and analysis, but also has a high false-negative rate.¹⁷⁶

Radiologic imaging has become the principal method of diagnosis of chronic pancreatitis, with the codification of classification systems that correlate with proven disease. ERCP has been considered the most sensitive radiologic test for the diagnosis of chronic pancreatitis, with specific ERCP findings that are highly correlative with the degree or stage of chronic disease¹⁷⁷ (Table 33-12). CT scanning is sensitive for the diagnosis of chronic pancreatitis when calcification, duct dilatation, or cystic disease is present, but is not accurate in the absence of these findings. CT is helpful as a screening study to guide interventional therapy or other diagnostic modalities.¹³⁷ EUS has become a more widely used study for the diagnosis of pancreatic disease and offers the advantage of very-high-resolution images of the pancreatic parenchyma, the main and secondary ductal systems, cystic lesions, and calcific changes.¹⁷⁸ Although operator dependent and invasive, the technique is far safer than ERCP and, in experienced hands, is excellent for the diagnosis in moderate and severe stage disease¹³⁹ (Table 33-13). Most importantly, EUS is highly reliable in ruling out pancreatic carcinoma when EUS findings are normal.¹⁷⁹ Studies suggest that EUS may be more valuable than ERCP for the diagnosis of early chronic pancreatitis.¹⁴¹

Table 33-12 Cambridge Classification of Chronic Pancreatitis by Endoscopic Retrograde Cholangiopancreatography		
Grade	Main Pancreatic Duct	Side Branches
Normal	Normal	Normal
Suggestive	Normal	<3 Abnormal
Mild	Normal	≥3 Abnormal
Moderate	Abnormal	>3 Abnormal
Severe	Abnormal plus at least one of the following:	
	Large cavity	
	Duct obstruction	
	Dilation or duct irregularity	
	Intraductal filling defects

PROGNOSIS AND NATURAL HISTORY

The prognosis for patients with chronic pancreatitis is dependent on the etiology of the disease, the development of complications, and on the age and socioeconomic status of the patient. The influence of treatment is less evident in long-term studies, although the general absence of randomized, prospective trials clouds the issue of whether specific forms of therapy alter the long-term outlook for patients with the disease.¹⁸⁰

Several studies have demonstrated that, although symptoms of pain decrease over time in about half of the patients, this decline is also accompanied by a progression of exocrine and endocrine insufficiency.^{147–149,181} In general, the likelihood of eventual pain relief is dependent upon the stage of disease at diagnosis, and the persistence of alcohol use in patients with alcoholic chronic pancreatitis. Miyake and colleagues found that pain relief was achieved in 60% of alcoholic patients who successfully discontinued drinking, but in only 26% who did not.¹⁸¹

The long-term survival of patients with chronic pancreatitis is less than for patients without pancreatitis. In an international multicenter study of >2000 patients, Lowenfels and colleagues found that the 10- and 20-year survival rates for patients with chronic pancreatitis were 70 and 45%, respectively, compared to 93 and 65% for patients without pancreatitis.¹⁸² The mortality risk was found to be 1.6-fold higher in patients who continued to abuse alcohol, compared to those who did not (Fig. 33-35). Continued alcohol abuse has a similar effect on the response to surgical treatment (Fig. 33-36), and results in a twofold increase in mortality over a 10- to 14-year follow-up period.¹⁸³

Effect of alcohol use on survival after surgical procedures. The cumulative survival of patients with chronic pancreatitis following pancreaticoduodenectomy or distal pancreatectomy is shown for nonalcoholic and alcoholic patients.

(Reproduced with permission from Frey et al.¹⁸³)

In addition to progressive endocrine and exocrine dysfunction, and the risk of the specific complications outlined below and in Table 33-13, the other significant long-term risk for the patient with chronic pancreatitis is the development of pancreatic carcinoma.¹⁸⁴ There is a progressive, cumulative increased risk of carcinoma development in patients with chronic pancreatitis, which continues throughout the subsequent lifetime of the patient (Fig. 33-37). The incidence of carcinoma in patients with chronic pancreatitis ranges from 1.5 to 2.7%,^{148,149} which is at least 10-fold greater than that of patients of similar age seen in a hospital setting. In patients with advanced chronic pancreatitis referred for surgical therapy, the risk of indolent carcinoma can be as high as 10%.¹⁸⁵ The development of carcinoma in the setting of chronic pancreatitis is no doubt related to the dysregulation of cellular proliferation and tissue repair processes in the setting of chronic inflammation, as is seen throughout the alimentary tract and elsewhere. In the setting of chronic pancreatitis, carcinoma development can be especially cryptic, and the diagnosis of early-stage tumors is particularly difficult. Awareness of this risk justifies close surveillance for cancer in patients with chronic pancreatitis. Periodic measurement of tumor markers such as CA19-9, and periodic imaging of the pancreas with CT scan and EUS are necessary to detect the development of carcinoma in the patient with chronic pancreatitis.

Complications

PSEUDOCYST

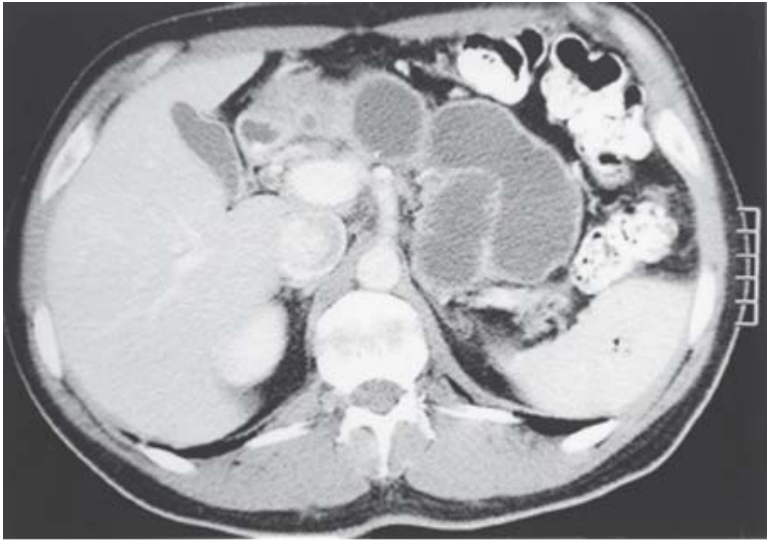

A chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis is referred to as a *pseudocyst*. Pseudocysts occur in up to 10% of patients with acute pancreatitis, and in 20 to 38% of patients with chronic pancreatitis, and thus, they comprise the most common complication of chronic pancreatitis.^{148,186,187} The identification and treatment of pseudocysts requires definition of the various forms of pancreatic fluid collections that occur (Table 33-14). In chronic pancreatitis, a pancreatic duct leak with extravasation of pancreatic juice results in a PFC. Over a period of 3 to 4 weeks, the PFC is sealed by an inflammatory reaction that leads to development of a wall of acute granulation tissue without much fibrosis. This is referred to as an *acute pseudocyst*. Acute pseudocysts may resolve spontaneously in up to 50% of cases, over a course of 6 weeks or longer.^{186,187} Pseudocysts >6 cm resolve less frequently than smaller ones but may regress over a period of weeks to months. Pseudocysts are multiple in 17% of patients,¹⁸⁸ or may be multilobulated. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments (Fig. 33-38).

Table 33-14 Definitions of Pancreatic Fluid Collections	
Term	Definition
Peripancreatic fluid collection	A collection of enzyme-rich pancreatic juice that occurs early in the course of acute pancreatitis, or that forms after a pancreatic duct leak; located in or near the pancreas; it lacks a well-organized wall of granulation or fibrous tissue
Early pancreatic (sterile) necrosis	A focal or diffuse area of nonviable pancreatic parenchyma, typically occupying >30% of the gland and containing liquefied debris and fluid
Late pancreatic (sterile) necrosis	An organized collection of sterile necrotic debris and fluid with a well-defined margin or wall within the normal domain of the pancreas
Acute pseudocyst	A collection of pancreatic juice enclosed within a perimeter of early granulation tissue, usually as a consequence of acute pancreatitis that has occurred within the preceding 3–4 wk
Chronic	A collection of pancreatic fluid surrounded by a wall of normal granulation and fibrous tissue, usually persisting for >6 wk

pseudocyst	
Pancreatic abscess	Any of the above in which gross purulence (pus) is present, with bacterial or fungal organisms documented to be present

Extensive pseudocyst disease. A computed tomographic scan in a patient with alcoholic chronic pancreatitis demonstrates multiloculated pseudocyst disease.

Pseudocysts may become secondarily infected, in which case they become abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric-portal vein thrombosis or splenic vein thrombosis.¹⁸⁹ They can erode into visceral arteries and cause intracystic hemorrhage or pseudoaneurysms (Fig. 33-39). They also can perforate and cause peritonitis or intraperitoneal bleeding.¹⁹⁰

Fig. 33-39.

This contrast-enhanced axial CT scan shows a large, well-defined pseudocyst. Within the pseudocyst, there is a hyperdense area labeled 'B', representing active bleeding. Three black arrows point to the area of hemorrhage, indicating a pseudoaneurysm of the gastroduodenal artery that has eroded into the pseudocyst.

Pseudocysts usually cause symptoms of pain, fullness, or early satiety. Asymptomatic pseudocysts can be managed expectantly and may resolve spontaneously or persist without complication.^{187,191} Symptomatic or enlarging pseudocysts require treatment, and any presumed pseudocyst without a documented antecedent episode of acute pancreatitis requires investigation to determine the etiology of the lesion.¹⁹² Although pseudocysts comprise roughly two thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinoma radiographically. An incidentally discovered cystic lesion should be examined by EUS and aspirated to determine whether it is a true neoplasm or a pseudocyst.

The timing and method of treatment requires careful consideration.^{191,193} Pitfalls in the management of pseudocysts result from the incorrect (presumptive) diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of a pseudocyst that appears to be fluid filled on CT scan, and a failure to document true adherence with an adjacent portion of the stomach before attempting transgastric internal drainage. Therefore, the management of a pseudocyst, as with other treatment decisions regarding chronic pancreatitis, should involve the multidisciplinary evaluation and selection of any given treatment strategy. Surgeons, therapeutic endoscopists, and interventional radiologists together offer all the expertise necessary to obtain the best possible outcome for a patient with pseudocystic disease. The challenge is to select the best approach for each individual patient, and this requires dedicated and experienced representatives from each specialty to participate in the decision making.

If infection is suspected, the pseudocyst should be aspirated (not drained) by CT- or US-guided FNA, and the contents examined for organisms by Gram's stain and culture.¹⁹⁴ If infection is present, and the contents resemble pus, external drainage is employed, using either surgical or percutaneous techniques.

If the pseudocyst has failed to resolve with conservative therapy, and symptoms persist, internal drainage is usually preferred to external drainage, to avoid the complication of a pancreaticocutaneous fistula. Pseudocysts communicate with the pancreatic ductal system in up to 80% of cases,^{188,193} so external drainage creates a pathway for pancreatic duct leakage to and through the catheter exit site. Internal drainage may be performed with either percutaneous catheter-based methods (transgastric puncture and stent placement to create a cystogastrostomy), endoscopic methods (transgastric or transduodenal puncture and multiple stent placements, with or without a nasocystic irrigation catheter), or surgical methods (a true cystoenterostomy, biopsy of cyst wall, and evacuation of all debris and contents). Surgical options include a cystogastrostomy (Fig. 33-40), a Roux-en-Y cystojejunostomy, or a cystoduodenostomy. Cystojejunostomy is the most versatile method, and it can be applied to pseudocysts that penetrate into the transverse mesocolon, the paracolic gutters, or the lesser sac. Cystogastrostomy can be performed endoscopically¹⁹⁵ (Fig. 33-41), laparoscopically,¹⁹⁶ or by a combined laparoscopic-endoscopic method.¹⁹⁷

Because pseudocysts often communicate with the pancreatic ductal system, two newer approaches to pseudocyst management are based on main duct drainage, rather than pseudocyst drainage per se. Transpapillary stents inserted at the time of ERCP may be directed into a pseudocyst through the ductal communication itself (Fig. 33-42), or can be left across the area of suspected duct leakage to facilitate decompression and cyst drainage, analogous to the use of common bile duct stents in the setting of a cystic duct leak.^{195,197} In a surgical series of patients with chronic pancreatitis, ductal dilatation, and a coexisting pseudocyst, Nealon and Walser showed that duct drainage alone, without a separate cystoenteric anastomosis, was as successful as a combined drainage procedure.¹⁹⁸ Furthermore, the "duct drainage only" group enjoyed a shorter hospital stay and fewer complications than the group who underwent a separate cystoenterostomy. These observations suggest that transductal drainage may be a safe and effective approach to the management of pseudocystic disease. The endoscopic approach seems logical in the treatment of postoperative or posttraumatic pseudocysts when duct disruption is documented or in those patients with pseudocysts that communicate with the duct. Whether the technique will be as effective for chronic pseudocysts without demonstrable communication with the pancreatic duct remains open to investigation.

Fig. 33-42.

The complications of endoscopic or radiologic drainage of pseudocysts often require surgical intervention. Bleeding from the cystoenterostomy, and inoculation of a pseudocyst with failure of resolution and persistence of infection, may require surgical treatment. Bleeding risks may be lessened by the routine use of EUS in the selection of the site for transluminal stent placement.¹⁹⁹ Percutaneous and endoscopic treatment of pseudocysts requires large-bore catheters, multiple stents, and an aggressive approach to management for success to be achieved. Failure of nonsurgical therapy, with subsequent salvage procedures to remove infected debris and establish complete drainage, is associated with increased risks for complications and death.^{200,201} The most experienced therapeutic endoscopists report a complication rate of 17 to 19% for the treatment of sterile pseudocysts, and deaths as a result of endoscopic therapy have occurred.¹⁹³ The use of endoscopic methods to treat sterile or infected pancreatic necrosis has a higher complication rate and is limited to specialized centers.¹⁹⁹

Resection of a pseudocyst is sometimes indicated for cysts located in the pancreatic tail, or when a midpancreatic duct disruption has resulted in a distally located pseudocyst. Distal pancreatectomy for removal of a pseudocyst, with or without splenectomy, can be a challenging procedure in the setting of prior pancreatitis. An internal drainage procedure of the communicating duct or of the pseudocyst itself should be considered when distal resection is being contemplated.

PANCREATIC ASCITES

When a disrupted pancreatic duct leads to pancreatic fluid extravasation that does not become sequestered as a pseudocyst, but drains freely into the peritoneal cavity, pancreatic ascites occurs. Occasionally, the pancreatic fluid tracks superiorly into the thorax, and a pancreatic pleural effusion occurs. Referred to as *internal pancreatic fistulae*, both complications are seen more often in patients with chronic pancreatitis rather than after acute pancreatitis. Pancreatic ascites and pleural effusion occur together in 14% of patients, and 18% have a pancreatic pleural effusion alone.^{202–204}

Patients demonstrate the general demographics of chronic pancreatitis and usually present with a subacute or recent history of progressive abdominal swelling despite weight loss. Pain and nausea are rarely present. The abdominal CT scan discloses ascites and the presence of chronic pancreatitis or a partially collapsed pseudocyst (Fig. 33-43). Paracentesis or thoracentesis reveals noninfected fluid with a protein level >25 g/L and a markedly elevated amylase level. Serum amylase may also be elevated, presumably from reabsorption across the parietal membrane. Serum albumin may be low, and patients may have coexisting liver disease. Paracentesis is therefore critical to differentiate pancreatic from hepatic ascites.

Pancreatic ascites. Computed tomographic scan of a patient with a ruptured pancreatic pseudocyst resulting in intraperitoneal pancreatic fluid.
(Reproduced with permission from Lipsett et al.²⁰³)

ERCP is most helpful to delineate the location of the pancreatic duct leak and to elucidate the underlying pancreatic ductal anatomy. Pancreatic duct stenting may be considered at the time of ERCP, but if nonsurgical therapy is undertaken and then abandoned, repeat imaging of the pancreatic duct is appropriate to guide surgical treatment.

Antisecretory therapy with the somatostatin analogue octreotide acetate, together with bowel rest and parenteral nutrition, is successful in more than half of patients.²⁰⁵ Reapposition of serosal surfaces to facilitate closure of the leak is considered a part of therapy, and this is accomplished by complete paracentesis. For pleural effusions, a period of chest tube drainage may facilitate closure of the internal fistula.^{202,205} Surgical therapy is reserved for those who fail to respond to medical treatment. If the leak originates from the central region of the pancreas, a Roux-en-Y pancreaticojejunostomy is performed to the site of duct leakage (Fig. 33-44). If the leak is in the tail, a distal pancreatectomy may be considered, or an internal drainage procedure can be performed. The results of surgical treatment are usually favorable if the ductal anatomy has been carefully delineated preoperatively.

PANCREATIC-ENTERIC FISTULA

The erosion of a pancreatic pseudocyst into an adjacent hollow viscus can result in a pancreatic-enteric fistula. The most common site of communication is the transverse colon or splenic flexure. The fistula usually presents with evidence of GI or colonic bleeding and sepsis. If the fistula communicates with the stomach or duodenum, it may close spontaneously or persist as a pancreatic-enteric fistula. When the fistula involves the colon, operative correction is usually required.²⁰⁶

HEAD-OF-PANCREAS MASS

In up to 30% of patients with advanced chronic pancreatitis, an inflammatory mass develops in the head of the pancreas.²⁰⁷ The clinical presentation includes severe pain, and frequently includes stenosis of the distal common bile duct, duodenal stenosis, compression of the portal vein, and stenosis of the proximal main pancreatic duct (Table 33-15). In a series of 279 patients with chronic pancreatitis treated surgically at the University of Ulm in Germany, patients with pancreatic head enlargement represented half of the total group. The subgroup with pancreatic head enlargement appeared to have a lower incidence of endocrine and exocrine insufficiency, but a higher expression of epidermal growth factor and the c-*erbB*-2 protooncogene.²⁰⁸ Mutations and polymorphisms of p53 were found in 3 and 8% of these patients, respectively, and a focus of ductular carcinoma was found in 3.7% of patients with pancreatic head enlargement. It was concluded that an accelerated transformation from hyperplasia to dysplasia exists in patients with pancreatic head enlargement, although the etiology for this process remains unclear. Treatment in the majority of cases consisted of the duodenum-preserving pancreatic head resection (DPPHR), with good results.

Table 33-15 Signs and Symptoms of Chronic Pancreatitis with and without a Pancreatic Head Mass		
Signs and Symptoms	With Head Enlargement (<i>n</i> = 138) (%)	Without Head Enlargement (<i>n</i> = 141) (%)
Daily severe pain	67	40
Cholestasis	46	11
Slight to frequent pain	33	60
Duodenal obstruction	30	7

Diabetes mellitus	18	30
Vascular involvement	15	8

SPLENIC AND PORTAL VEIN THROMBOSIS

Vascular complications of chronic pancreatitis are fortunately infrequent, because they are difficult to treat successfully. Portal vein compression and occlusion can occur as a consequence of an inflammatory mass in the head of the pancreas, and splenic vein thrombosis occurs in association with chronic pancreatitis in 4 to 8% of cases.²⁰⁹ Variceal formation can occur as a consequence of either portal or splenic venous occlusion, and splenic vein thrombosis with gastric variceal formation is referred to as *left-sided* or *sinistral portal hypertension*. Although bleeding complications are infrequent, the mortality risk of bleeding is >20%. When gastroesophageal varices are caused by splenic vein thrombosis, the addition of splenectomy to prevent variceal hemorrhage is prudent when surgery is otherwise indicated to correct other problems.

Treatment

MEDICAL THERAPY

The medical treatment of chronic or recurrent pain in chronic pancreatitis requires the use of analgesics, a cessation of alcohol use, oral enzyme therapy, and the selective use of antisecretory therapy. Interventional procedures to block visceral afferent nerve conduction or to treat obstructions of the main pancreatic duct are also an adjunct to medical treatment.

ANALGESIA

Oral analgesics are prescribed as needed, alone or with analgesia-enhancing agents such as gabapentin. Adequate pain control usually requires the use of narcotics, but these should be titrated to achieve pain relief with the lowest effective dose. Opioid addiction is common, and the use of long-acting analgesics by transdermal patch together with oral agents for pain exacerbations slightly reduces the sedative effects of high-dose oral narcotics.

It is essential for patients to abstain from alcohol. In addition to removing the causative agent, alcohol abstention results in pain reduction or relief in 60 to 75% of patients with chronic pancreatitis.²¹⁰ Despite this benefit, roughly half of alcoholic chronic pancreatitis patients continue to abuse alcohol.

ENZYME THERAPY

Pancreatic enzyme administration serves to reverse the effects of pancreatic exocrine insufficiency and may reduce or alleviate the pain experienced by patients. The choice of enzyme supplement and the dose should be selected based on whether malabsorption or pain (or both) are the indications for therapy²¹¹ (Table 33-16). Conventional (non–enteric-coated) enzyme preparations are partially degraded by gastric acid but are available within the duodenal and jejunal regions to bind to CCK-releasing peptide, and downregulate the release of CCK. This theoretically reduces the enteric signal for pancreatic exocrine secretion, which reduces the pressure within a partially or completely obstructed pancreatic duct.^{212,213} Enteric-coated preparations result in little to no pain relief, presumably due to their reduced bioavailability in the proximal gut.²¹⁴ Due to the loss of pancreatic enzymes by acid hydrolysis and proteolysis, relatively large doses are required to achieve effective levels of enzyme within the proximal small bowel. Enteric-coated preparations are protected from acid degradation but are presumably not released in the critical proximal gut in sufficient quantity to inhibit the stimulus for endogenous pancreatic enzyme secretion. Nonalcoholic patients may experience more effective pain relief than alcoholic patients,²¹¹ but it is recommended that all patients with chronic pancreatitis pain begin a trial of non–enteric-coated enzyme supplements for 1 month. If pain relief is achieved, therapy is continued. If enzyme therapy fails, further investigation of the pancreatic ductal system by ERCP guides the therapy based on the presence or absence of large duct (obstructive) disease (Fig. 33-45).

Table 33-16 Pancreatic Enzyme Preparations		
Name	Dose ^a	Lipase/Protease (USP Units)
Conventional (non-enteric-coated) compounds ^b		
Viokase	8 tablets each time	8000/30,000

Ku-Zyme HP	8 tablets each time	8000/30,000
Enteric-coated compounds ^c		
Creon 10	2–3 capsules each time	10,000/37,500
Creon 20	2–3 capsules each time	20,000/75,000
Pancrease MT 10	2–3 capsules each time	10,000/30,000
Pancrease MT 16	2–3 capsules each time	16,000/48,000

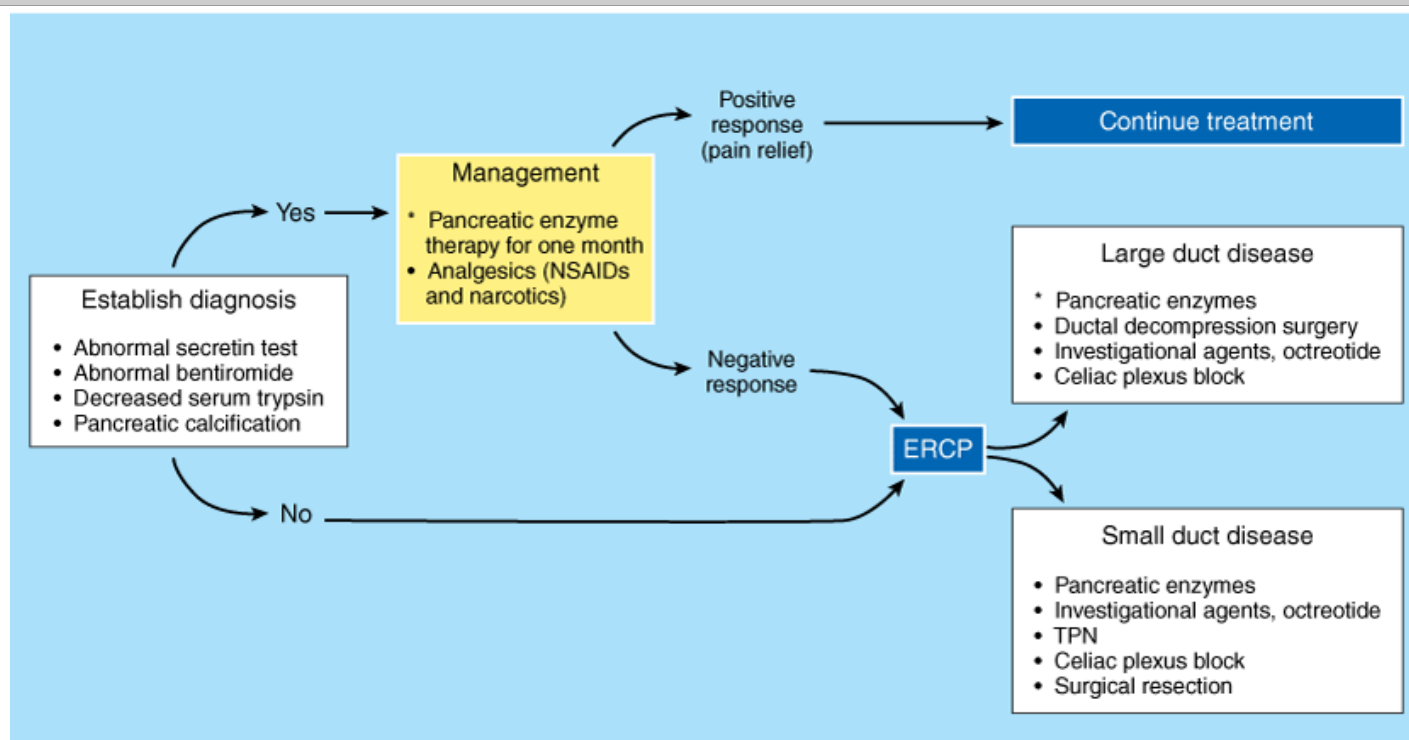

^aThe dosing schedule is before meals; can also take a dose at night if patient experiences pain.

^bConventional enzymes are the treatment of choice for pain relief. If no improvement occurs with conventional enzymes alone, add H₂-blockers or proton pump inhibitors to decrease peptic acid inhibition of the enzymes.

^cEnteric-coated preparations are treatment of choice for steatorrhea. Acid-suppressive therapy should not be given with enteric-coated preparations.

USP = United States Pharmacopeia.

ANTISECRETORY THERAPY

Somatostatin administration has been shown to inhibit pancreatic exocrine secretion and CCK release.²¹⁵ The somatostatin analogue octreotide acetate has therefore been investigated for pain relief in patients with chronic pancreatitis.^{216,217} In a double-blind, prospective, randomized 4-week trial, 65% of patients who received 200 µg of octreotide acetate subcutaneously three times daily reported pain relief, compared with 35% of placebo-treated subjects. Patients who had the best results were patients with chronic abdominal pain, suggestive of obstructive pancreatopathy. However, in another trial that used a 3-day duration of treatment, no significant pain relief was observed.²¹⁸ None of the studies published thus far have examined the sustained-release formulation of octreotide, and it remains unclear what subgroups of patients, or what dose of octreotide,

might be beneficial in the treatment of pain. Anecdotal reports suggest that severe pain exacerbations in chronic pancreatitis can benefit from a combination of octreotide therapy and TPN, and trials are currently underway to assess the effectiveness of the sustained-release form of octreotide that requires only once-monthly administration.

NEUROLYTIC THERAPY

Celiac plexus neurolysis with alcohol injection has been an effective form of analgesic treatment in patients with pancreatic carcinoma. However, the use of radiologically- or endoscopically-guided celiac plexus blockade in chronic pancreatitis has been disappointing. Due to the risk of alcohol injury and the need for repeated injections, celiac plexus blockade in chronic pancreatitis has used short-acting analgesics or other drugs rather than 50% alcohol. A recent trial of EUS-guided celiac plexus blockade revealed successful pain relief in 55% of patients, but the benefit lasted beyond 6 months in only 10% of patients.²¹⁹ The procedure therefore appears safe, but the effect is short lived in those patients who obtain pain relief.

ENDOSCOPIC MANAGEMENT

The techniques of endoscopic treatment of pancreatic duct obstruction, stone disease, pseudocyst formation, pancreatic duct leak, and for the diagnosis and management of associated pancreatic tumors have expanded greatly over the past 10 years. Newer endoscopes with expanded therapeutic capabilities have been introduced, and the role of EUS and EUS-guided needle and catheter insertion has expanded the ability of the therapeutic endoscopist in the diagnosis and treatment of chronic pancreatitis and its complications.²²⁰

Pancreatic duct stenting is used for treatment of proximal pancreatic duct stenosis, decompression of a pancreatic duct leak, and for drainage of pancreatic pseudocysts that can be catheterized through the main pancreatic duct (Fig. 33-46). Pancreatic duct stents can induce an inflammatory response within the duct, so prolonged stenting is usually avoided. Patients with sphincter of Oddi dyskinesia are at high risk for developing post-ERCP pancreatitis after biliary sphincterotomy, and a recent study demonstrated that the prophylactic placement of a pancreatic duct stent reduced the amylase level and development of pancreatitis after biliary sphincterotomy.²²¹ Pancreatic duct leaks were seen in 37% of patients with acute pancreatitis, and pancreatic duct stenting appeared to facilitate the resolution of the leak.²²² Similarly, pancreatic duct stenting has been used to treat postsurgical pancreatic duct leaks and posttraumatic leaks.^{95,223,224}

Endoscopic decompression of a peripancreatic fluid collection through the pancreatic duct. Options for transpapillary placement include placement of the stent (**A**) beyond the point of duct disruption, (**B**) at the point of disruption, or (**C**) proximal to the point of duct disruption. Each of these locations may facilitate decompression of a peripancreatic fluid collection or pseudocyst caused by duct disruption, analogous to this successful treatment of a cystic duct leak by a common bile duct stent.

(Reproduced with permission from Hawes.¹⁹⁹)

Pancreas divisum (see Fig. 33-3) is thought to cause pain and chronic pancreatitis due to functional or mechanical obstruction of the dorsal duct draining exclusively, or predominantly, through the lesser papilla. A recent study from Marseille reported good long-term results in 24 patients after minor papilla sphincterotomy and dorsal duct stenting.²²⁵ The number of patients with chronic pain decreased from 83% before stenting to 29% after stenting, but pancreatitis or recurrent papillary stenosis occurred in 38%. Patients that responded best were those with intermittent pain, and this subset may be preferentially treated with endoscopic therapy.

Idiopathic pancreatitis patients have been treated with endoscopic stenting, pancreatic duct sphincterotomy, and endoscopic stone removal with good results.^{220,226} In a prospective randomized trial, 53% of idiopathic recurrent pancreatitis patients in the control group experienced continued episodes of pancreatitis, although only 11% of the treated patients had continued symptoms.²²⁰

Extracorporeal shock wave lithotripsy (ESWL) has been used for pancreatic duct stones, together with endoscopic stenting and stone removal.²²⁷ A single ESWL session was used in 35 patients with pancreatic duct stones, together with 86 ERCP sessions to complete the stone removal process. After 2.4 years, 80% of patients had significant relief of symptoms (Fig. 33-47). However, due to the tendency for recurrent stone formation, the

use of ESWL for long-term management of calcific pancreatitis remains uncertain.

SURGICAL THERAPY

Indications and History

The traditional approach to surgical treatment of chronic pancreatitis and its complications has maintained that surgery should be considered only when the medical therapy of symptoms has failed. Nealon and Thompson published a landmark study in 1993, however, that showed that the progression of chronic obstructive pancreatitis could be delayed or prevented by pancreatic duct decompression.²²⁸ No other therapy has been shown to prevent the progression of chronic pancreatitis, and this study demonstrated the role of surgery in the early management of the disease (Table 33-17). Small-duct disease or the absence of a clear obstructive component are causes for uncertainty over the choice of operation. Major

resections have a high complication rate, both early and late, in chronic alcoholic pancreatitis, and lesser procedures often result in symptomatic recurrence. So the choice of operation and the timing of surgery are based on each patient's pancreatic anatomy, the likelihood (or lack thereof) that further medical and endoscopic therapy will halt the symptoms of the disease, and the chance that a good result will be obtained with the lowest risk of morbidity and mortality. Finally, preparation for surgery should include restoration of protein-caloric homeostasis, abstinence from alcohol and tobacco, and a detailed review of the risks and likely outcomes to establish a bond of trust and commitment between the patient and the surgeon.

Table 33-17 Effect of Surgical Drainage on Progression of Chronic Pancreatitis	
Treatment Group	24-Month Evaluation
Operated (<i>n</i> = 47)	Mild to moderate 48 (87%); severe 6 (13%)
Nonoperated (<i>n</i> = 36)	Mild to moderate 8 (22%); severe 28 (78%)

Eighty-three patients with chronic pancreatitis were evaluated by exocrine, endocrine, nutritional, and endoscopic retrograde cholangiopancreatography studies, and all had mild to moderate disease and dilated pancreatic ducts. A Puestow-type duct decompression procedure was performed in 47 patients, and all subjects were restaged by the same methods 24 months later.

Source: Reproduced with permission from Nealon et al.²²⁸

Historically, the surgery for chronic pancreatitis before the second half of the twentieth century was a true demonstration of trial and error, with little anatomic information available before operation. Excellent results before CT scans and ERCP were either the result of serendipity or due to the talent and creativity of the surgeon. In 1911, Link described an operation he devised on the spot, when a laparotomy in a young woman with abdominal pain revealed a fluctuant, obstructed pancreatic duct. After performing a dochotomy and evacuating multiple stones, he inserted a rubber tube, and exteriorized the pancreatostomy just above her navel.²²⁹ He later described the operation as having been a success for the next 30 years of the patient's life, during which the patient managed the care of the drainage tube without apparent problems.²³⁰

With the demonstration in 1942 by Priestley that total pancreatectomy was technically feasible,²³¹ and the report in 1946 by Whipple that proximal pancreatic resection was beneficial in (three) patients with chronic pancreatitis,²³² the option of surgical resection as treatment for chronic pancreatitis was established. By the mid-1950s, however, growing disappointment with the high risk of resection and the lack of long-term benefit overshadowed the surgical treatment of chronic pancreatitis. The choice of resection vs. drainage was largely based on surgeon preference until the 1970s, when the widespread adoption of ERCP and CT scans provided the ability to preoperatively diagnose obstructive and sclerotic disease, and this resulted in the rational selection of operative procedures. During this period, the major drawbacks to surgical therapy remained the approximately 20% incidence of recurrent symptoms despite surgery, the corresponding development of an inflammatory (or malignant) mass in the undrained pancreatic head (Fig. 33-48), or the high morbidity and mortality of major resectional procedures that seemed to predispose the patients to a cascade of metabolic problems.

Sphincteroplasty

The sphincter of Oddi and the pancreatic duct sphincter serve as gatekeepers for the passage of pancreatic juice into the duodenum (Fig. 33-49). Stenosis of either sphincter (sclerosing papillitis), due to scarring from pancreatitis or from the passage of gallstones, may result in obstruction of the pancreatic duct and chronic pain.²³³ As gallstone pancreatitis became a popular diagnosis in the 1940s and 1950s, attention was focused on the ampullary region as a possible cause of chronic symptoms, and surgical sphincteroplasty was advocated. Although endoscopic techniques are now used routinely to perform sphincterotomy of either the common bile duct or pancreatic duct, a true (permanent) sphincteroplasty can only be performed surgically. Transduodenal sphincteroplasty with incision of the septum between the pancreatic duct and common bile duct appears to offer significant relief for patients with obstruction and inflammation isolated to this region²³⁴ (Fig. 33-50).

Drainage Procedures

After the early reports of success with pancreaticostomy for the relief of symptoms of chronic pancreatitis,²²⁹ Cattell described pancreaticojejunostomy for relief of pain in unresectable pancreatic carcinoma.²³⁵ Shortly thereafter, Duval,²³⁶ and separately, Zollinger and associates,²³⁷ described the caudal Roux-en-Y pancreaticojejunostomy for the treatment of chronic pancreatitis in 1954 (Fig. 33-51). The so-called Duval procedure was used for decades by some surgeons, but it almost invariably failed due to restenosis and segmental obstruction of the pancreas due to progressive scarring. In 1958, Puestow and Gillesby described these segmental narrowings and dilatations of the ductal system as a "chain of lakes," and proposed a longitudinal decompression of the body and tail of the pancreas into a Roux limb of jejunum²³⁸ (Fig 33-52). Four of Puestow and Gillesby's 21 initial cases were side-to-side anastomoses, and 2 years after their report, Partington and Rochelle described a much simpler version of the longitudinal, or side-to-side Roux-en-Y pancreaticojejunostomy that became universally known as the Puestow procedure²³⁹ (Fig. 33-53).

Longitudinal dochotomy in obstructing calcific pancreatitis. A longitudinal pancreatotomy typically discloses segmental stenosis of the pancreatic duct and the presence of intraductal calculi in a patient with chronic calcific pancreatitis (A). Following mobilization of a Roux limb of jejunum, a longitudinal pancreaticojejunostomy is performed to permit extensive drainage of the pancreatic duct system (B). This technique, described by Partington and Rochelle, is the typical method used for the Puestow procedure.

(Reproduced with permission from Partington et al.²³⁹)

The effectiveness of decompression of the pancreatic duct is dependent on the extent to which ductal hypertension is the etiologic agent for the disease. Thus, the diameter of the pancreatic duct is a surrogate for the degree of ductal hypertension, and the Puestow procedure has been shown to be effective for pain relief when the maximum duct diameter is 6 mm. Results are less impressive in glands with smaller caliber ducts, although Izbicki and associates have described good results with a conization method that allows a longitudinal decompression of more normal caliber ducts.²⁴⁰ Successful pain relief after the Puestow-type decompression procedure has been reported in 75 to 85% of patients for the first few years after surgery, but pain recurs in >20% of patients after 5 years,¹⁴⁹ even in patients who are abstinent from alcohol.

With the advent of therapeutic endoscopy and techniques for transluminal stone removal and lithotripsy, modern clinical series have reported the successful endoscopic treatment of pancreatic duct calculi, although the long-term outcomes of these efforts has been uneven.^{241–244} Endoscopic removal of pancreatic duct stones is usually coupled to prolonged pancreatic duct stenting, which carries the risk of further inflammation.^{245,246} Despite the risk of perioperative complications, the surgical management of pancreatic duct stones and stenosis has been shown to be superior to endoscopic treatment in randomized clinical trials in which the long, side-to-side technique of pancreaticojejunostomy is used.^{247,248}

Resectional Procedures

Distal Pancreatectomy

For patients with focal inflammatory changes localized to the body and tail, or in whom no significant ductal dilatation exists, the technique of partial (40 to 80%) distal pancreatectomy has been advocated (Fig. 33-54). Although distal pancreatectomy is less morbid than more extensive resectional procedures, the operation leaves untreated a major portion of the gland, and is therefore associated with a significant risk of symptomatic recurrence.¹⁴⁰ It has been a more popular operation in British centers, where its success seems to be greater, perhaps due to the lower incidence of alcoholic chronic pancreatitis.²⁴⁹ However, long-term outcomes reveal good pain relief in only 60% of patients, with completion pancreatectomy required for pain relief in 13% of patients.

Fig. 33-54.

Distal (spleen-sparing) pancreatectomy. A distal pancreatectomy for chronic pancreatitis is usually performed with en bloc splenectomy. In the presence of minimal inflammation, a spleen-sparing version can be performed, as shown here.

(Reproduced with permission from Bell.¹⁹⁶)

Laparoscopic distal pancreatectomy has been shown to be feasible for the removal of focal lesions of the distal pancreas²⁵⁰ but is more difficult in the setting of chronic pancreatitis.

Ninety-Five Percent Distal Pancreatectomy

In 1965, Fry and Child proposed the more radical 95% distal pancreatectomy, which was intended for patients with sclerotic (small duct) disease, and which attempted to avoid the morbidity of total pancreatectomy by preserving the rim of pancreas in the pancreaticoduodenal groove, along with its associated blood vessels and distal common bile duct.²³³ The operation was found to be associated with pain relief in 60 to 77% of patients long term, but is accompanied by a high risk of brittle diabetes, hypoglycemic coma, and malnutrition.²⁵¹ Although the operation was the first attempt to resect the pancreatic head while preserving the duodenum and distal bile duct, the extensive degree of pancreatic removal led to its failure as viable treatment for the symptoms of pancreatic sclerosis.

Proximal Pancreatectomy

In 1946, Whipple reported a series of five patients treated with either pancreaticoduodenectomy or total pancreatectomy for symptomatic chronic pancreatitis, with one operative death.²³² Subsequently, proximal pancreatectomy or pancreaticoduodenectomy, with or without pylorus preservation (Fig. 33-55), has been widely used for the treatment of chronic pancreatitis.^{145,206,252} In the three largest modern (circa 2000) series of the treatment of chronic pancreatitis by the Whipple procedure, pain relief 4 to 6 years after operation was found in 71 to 89% of patients.

However, mortality ranged from 1.5 to 3%, and major complications occurred in 25 to 38% of patients at the Johns Hopkins Hospital,²⁵³ the Massachusetts General Hospital,²⁵⁴ and the Mayo Clinic.²⁵⁵ In follow-up, 25 to 48% of patients developed diabetes, and about the same percentage required exocrine therapy. Advocates of the Whipple procedure uniformly suggest that the high rate of symptomatic relief outweighs the metabolic consequences and the mortality risk of the procedure.

Fig. 33-55.

The pancreaticoduodenectomy (Whipple procedure) can be performed either with the standard technique, which includes distal gastrectomy (**A**), or with preservation of the pylorus (**B**). The pylorus-sparing version of the procedure is used most commonly.

[Reproduced from Gaw JU, Andersen DK: Pancreatic surgery, in Wu GY, Aziz K, Whalen GF (eds): *An Internist's Illustrated Guide to Gastrointestinal Surgery*. Totowa, NJ: Humana Press, 2003, p 229, with permission.]

Total Pancreatectomy

Priestley and associates first described successful total pancreatectomy in 1944 in a patient with hyperinsulinism,²³¹ and two of Whipple's original five cases of chronic pancreatitis reported in 1946 were treated with total pancreatectomy.²³² Subsequently, surgeons who used total pancreatectomy found that the operation produces no better pain relief for their patients than pancreaticoduodenectomy (about 80% to 85%). Moreover, the metabolic consequences of total pancreatectomy in the absence of islet cell transplantation are profound and life-threatening. The patients have a "brittle" form of diabetes in which avoidance of hyper- and hypoglycemia is problematic.^{158,256–258} In addition, lethal episodes of hypoglycemia are common in severe apanteatic diabetes. These are due to hypoglycemic unresponsiveness, due to the absence of pancreatic glucagon, and to hypoglycemia unawareness, despite an ongoing need to treat with exogenous insulin.²⁵⁹ In a series of >100 patients treated with total pancreatectomy, Gall and colleagues showed that half of all the late deaths after this operation were due to (iatrogenic) hypoglycemia.²⁶⁰ Without adequate insulin treatment, patients with apanteatic diabetes become progressively more hyperglycemic and develop the same incidence of retinal and renal disease as type 1 diabetic patients.¹⁵⁷ Despite newer forms of insulin and insulin delivery systems, severe apanteatic diabetes is an adverse outcome, as complete prevention of the physiologic consequences of total pancreatectomy remains an unfulfilled goal.

Hybrid Procedures

In 1980, Beger and associates described the DPPHR²⁶¹ (Fig. 33-56), and published long-term results with DPPHR for the treatment of chronic pancreatitis in 1985,²⁶² and more recently in 1999.²⁶³ In 388 patients who were followed for an average of 6 years after DPPHR, pain relief was maintained in 91%, mortality was <1%, and diabetes developed in 21%, with 11% demonstrating a reversal of their preoperative diabetic status. These authors also compared the DPPHR procedure with the pylorus-sparing Whipple procedure in a randomized trial in 40 patients with chronic pancreatitis.²⁶⁴ The mortality was zero in both groups, and the morbidity was also comparable. Pain relief (over 6 months) was seen in 94% of DPPHR patients, but in only 67% of Whipple patients. Furthermore, the insulin secretory capacity and glucose tolerance were noted to deteriorate in the Whipple group, but actually improved in the DPPHR patients.

The duodenum-preserving pancreatic head resection described by Beger and colleagues. **A.** The completed resection after transection of the pancreatic neck, and subtotal removal of the pancreatic head, with preservation of the distal common bile duct and duodenum. **B.** Completion of the reconstruction with anastomosis to the distal pancreas and to the proximal pancreatic rim by the same Roux limb of jejunum.

(Reproduced with permission from Bell.¹⁹⁶)

The DPPHR requires the careful dissection of the gastroduodenal artery and the creation of two anastomoses (Fig. 33-57), and carries a similar complication risk as the Whipple procedure due to the risk of pancreatic leakage and intra-abdominal fluid collections.

Fig. 33-57.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Intraoperative view of the Beger procedure. The gastroduodenal artery is encircled by a vessel loop. Just below, the intrapancreatic portion of the common bile duct is exposed as it courses toward the ampulla. A rim of well-vascularized pancreatic tissue remains in the duodenal C-loop. Preservation of the posterior branch of the gastroduodenal artery is essential to preserve viability of these structures.

In 1987, Frey and Smith described the local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ), which included excavation of the pancreatic head including the ductal structures in continuity with a long dichotomy of the dorsal duct²⁶⁵ (Fig. 33-58). The Frey procedure provides thorough decompression of the pancreatic head as well as the body and tail of the gland, and a long-term follow-up suggested that improved outcomes are associated with this more extensive decompressive procedure. Frey and Amikura reported their results in 50 patients followed for >7 years, and found complete or substantial pain relief in 87% of patients. There was no operative mortality, but 22% of patients developed postoperative complications.²⁶⁶

Fig. 33-58.

Frey procedure. The local resection of the pancreatic head with longitudinal pancreaticojejunostomy (LR-LPJ) provides complete decompression of the entire pancreatic ductal system. Reconstruction is performed with a side-to-side Roux-en-Y pancreaticojejunostomy.

(Reproduced with permission from Bell.¹⁹⁶)

Key steps in the performance of the LR-LPJ include preservation of the pancreatic neck as well as the capsule of the posterior pancreatic head. In the pancreaticoduodenectomy and the DPPHR, the pancreatic neck is freed up from the portal and superior mesenteric vein confluence and divided. In the LR-LPJ, the neck of the pancreas is preserved intact as are the body and tail of the pancreas. Not having to divide the pancreatic neck, as in the pancreaticoduodenectomy or DPPHR, reduces the risk of the operation, as it avoids intraoperative problems with the venous structures lying posterior to the gland. To reduce the risk of penetrating the posterior capsule of the head, Frey recommended in his 1994 report that the posterior limit of resection be the back wall of the opened duct of Wirsung and duct to the uncinate (Fig. 33-59).

Operative view of excavated head of the pancreas during the Frey procedure. The main pancreatic duct is opened widely down to the level of the ampulla, and the head of the pancreas is excavated in a conical fashion so as to allow complete decompression of the chronically obstructed and inflamed pancreatic ducts.

(Reproduced with permission from Aspelund G et al: Improved outcomes for benign disease with limited pancreatic head resection. *J Gastrointest Surg* 9:400, 2005. With kind permission from Springer Science + Business Media.)

Subsequent to Frey's own modification of the technique, other surgeons have described modifications of the extent or technique of the LR-LPJ. Andersen and Topazian advocated performing the LR-LPJ as it was originally described, in which the entirety of the ducts are excised from the head (Fig. 33-60), and described the use of the ultrasonic aspirator and dissector for this purpose.²⁶⁷ The use of this device permits precise removal of the ducts and adjacent tissue with good visualization and without complications. There is little pancreatic tissue behind these ducts and the pancreatic capsule is continuously palpated as the dissection proceeds to ensure a safe margin of resection. The intrapancreatic portion of the common bile duct is usually exposed, and avoiding injury to it is enhanced by the ultrasonic aspirator. The majority of the parenchyma of the uncinate process is spared, and the excavation of the pancreatic head is made contiguous with a generous dochotomy of the dorsal duct. Whether merely unroofing as opposed to removal of the proximal ducts contributes to better pain relief is not known and awaits a randomized trial to compare the two versions of the LR-LPJ. Izbicki and colleagues at the University of Hamburg also recommend a more extensive excavation of the pancreatic head, and use a technique that they refer to as the *Hamburg modification* of the LR-LPJ²⁶⁸ (Fig. 33-61). This wider excavation of the pancreatic head is created in continuity with the dorsal dochotomy, and is followed by a single, side-to-side pancreaticojejunostomy.

Fig. 33-60.

The Hamburg modification of the local resection of the pancreatic head with longitudinal pancreaticojejunostomy.

(From Izbicki JR, Yekebas EE, Mann O: *Shackelford's Surgery of the Alimentary Tract*. New York: Saunders, 2007, p 1310.)

In 2001, Ho and Frey subsequently described merely excavating the core of the pancreatic head, and draining the excavation with a Roux-en-Y pancreaticojejunostomy, but without any effort to include the dorsal duct^{269,270} (Fig. 33-62). In 2003, Farkas and colleagues described a similar

excavation of the central portion of the pancreatic head without any effort to include the duct of the body in the lateral pancreaticojejunostomy,²⁷¹ and reported excellent results of what they termed an *organ-preserving pancreatic head resection* (OPPHR) in a randomized comparison to the pylorus-preserving pancreaticoduodenectomy (PPPD).²⁷²

Excavation of pancreatic head without longitudinal pancreaticojejunostomy.

(From Ho HS, Frey CF: *Arch Surg* 136:1353, 2001.)

This approach was advocated by Gloor and associates in Bern as an alternative to the DPPHR procedure in patients with portal hypertension,²⁷³ and was described as the *Berne modification of the DPPHR* (Fig. 33-63). Most recently, Königer and colleagues in Heidelberg published a randomized, controlled trial of the "Berne" version of the excavation method compared to the "classic" Beger procedure.²⁷⁴ Operative times and length of stay were shorter in the group undergoing excavation of the pancreatic head, while long-term outcomes and quality-of-life scores were identical over 2 years postoperatively.

The Berne modification of the local resection of the pancreatic head with longitudinal pancreaticojejunostomy.

(From Gloor B, Friess H, Uhl W, et al: A modified technique of the Beger and Frey procedure in patients with chronic pancreatitis. *Dig Surg* 18:21, 2001.)

The common element of these variations on the theme of LR-LPJ remains the excavation or "coring out" of the central portion of the pancreatic head. It remains uncertain, however, whether and to what degree the doctotomy needs to be extended into the body and tail. The logical conclusion of all of these efforts is that the head of the pancreas is the nidus of the chronic inflammatory process in chronic pancreatitis, and that removal of the central portion of the head of the gland is the key to the successful resolution of pain long-term.

Complications

Initial and long-term results of the LR-LPJ demonstrate pain relief that is equivalent to that of pancreaticoduodenectomy and the DPPHR.^{275–277} The observed mortality rate has thus far been zero, and therefore, less than with the Whipple procedure. Major complications were less with the LR-LPJ (16%) than with pancreaticoduodenectomy (40%) or DPPHR (25%) in one single-site series, and the incidence of new postoperative diabetes after LR-LPJ was 8% with an average follow-up of 3 years.¹⁸⁵

Comparisons of the Three Operative Procedures: Pancreaticoduodenectomy, DPPHR (Beger Procedure), and LR-LPJ (Frey Procedure)

There has been considerable interest to apply evidence-based methods to the study of the three operations currently advocated for the treatment of chronic pancreatitis. The best studies, or level 1 data by the Strength of Recommendation Taxonomy, are prospective, randomized controlled trials comparing two or more operations from a single or multi-institutional study. Retrospective, cohort-based studies are regarded as level 2 data by the Strength of Recommendation Taxonomy criteria.

To date, six published level 1 studies have examined various comparisons between these three operations, and one level 2 study has examined all three procedures at a single institution. In the level 1 study of 43 patients by Klempa and colleagues,²⁷⁸ DPPHR patients had a shorter hospital stay, greater weight gain, less postoperative diabetes, and exocrine dysfunction than standard Whipple patients over a 3- to 5-year follow-up. Pain control was similar between the two procedures. This was confirmed in a level 1 study of 40 patients by Buchler and associates,²⁷⁹ in which DPPHR patients reported better pain relief, glucose tolerance, and weight gain compared to pylorus-preserving pancreaticoduodenectomy (PPPD) patients, however the follow-up averaged <1 year.

In a level 1 study of 61 patients randomized to PPPD or LR-LPJ, Izbicki and colleagues²⁷⁶ found a lower postoperative complication rate associated with the Frey procedure (19%) compared to the PPPD group (53%), and better global quality-of-life scores (71 vs. 43%, respectively). Both operations were equally effective in controlling pain over a 2-year follow-up. More recently, the level 1 study by Farkas and associates²⁷² examined 40 patients randomized to PPPD or the method of excavation of the pancreatic head that their group described as an *organ-preserving pancreatic head resection* (OPPHR), and found that OPPHR was associated with a shorter operating time, less postoperative morbidity, shorter hospital stay, and better quality of life than PPPD. The degree of pain relief was equal over a 1- to 3-year follow-up. Operation times have been shown to be shorter with the LR-LPJ and DPPHR compared to the PPPD, and intraoperative blood loss and perioperative transfusion requirements are less with LR-LPJ and DPPHR procedures.^{185,274,276,280}

Late Morbidity and Mortality

In 1995, Izbicki and colleagues began a level 1 study of 42 patients randomized to the DPPHR or LR-LPJ. The study was continued and updated in 1997²⁷⁵ to include 74 patients. In 2005, the long-term results of these 74 patients with an average follow-up of 8.5 years were reported.²⁷⁷ There were no significant differences between the groups with regard to global quality of life, pain scores, late mortality, and exocrine or endocrine insufficiency. The level 1 study by Königer, which compared the classic DPPHR with excavation of the pancreatic head, showed identical outcomes at 2 years after an initial reduction in morbidity associated with the excavation procedure.²⁷⁴ These results were echoed in the level 2 study by Aspelund and associates, which demonstrated fewer complications with both the DPPHR and LR-LPJ procedures compared to pancreaticoduodenectomy, a lower incidence of new diabetes (8%) for both DPPHR and LR-LPJ compared to the Whipple procedure (25%), but no significant differences in outcomes or pain relief between DPPHR and LR-LPJ.¹⁸⁵ Finally, level 2 data support the efficacy of both DPPHR and LR-LPJ in patients with dilated as well as nondilated ducts.^{281,282}

Long-term exocrine and/or endocrine insufficiency in chronic pancreatitis patients treated surgically is a product of the surgical intervention as well as the progression of the underlying disease. Although the short-term (3-year) incidence of new diabetes after operation appears less with the LR-LPJ and DPPHR than with the PPPD, the late incidence of diabetes appears similar in all groups. After an average of 7 years of follow-up after LR-LPJ or PPPD, survival, pain relief, and pancreatic function were similar in both groups. The rate of diabetes was slightly lower after LR-LPJ (61%) than after PPPD (65%), but these had both more than doubled from their preoperative status.²⁷⁷ Therefore, although the limited pancreatic procedures of DPPHR and LR-LPJ have a lower initial rate of endocrine dysfunction, the long-term risk of diabetes is more related to the progression of the underlying disease than to the effects of operation.

The decreased incidence of postoperative diabetes in the near-term after the duodenum-sparing operations may be the result of a preserved β -cell mass in the more conservative resections, and may also be due to the conservation of the PP-secreting cells localized to the posterior head and uncinate process.^{158,164} Preservation of near-normal glucose metabolism and the avoidance of pancreatogenic diabetes is therefore a significant but time-limited benefit of the newer operative procedures.

Autotransplantation of Islets

Islet cell transplantation for the treatment of diabetes is an attractive adjunct to pancreatic surgery in the treatment of benign pancreatic disease, but problems due to rejection of allotransplanted islets have plagued this method since its initial clinical application in the early 1970s. However, despite the difficulties in recovering islets from a chronically inflamed gland, Najarian and associates demonstrated the utility of autotransplantation of islets in patients with chronic pancreatitis in 1980.²⁸³ Subsequently, through refinements in the methods of harvesting and gland preservation, and through standardization of the methods by which islets are infused into the portal venous circuit for intrahepatic engraftment, the success of autotransplantation has steadily increased to achieve insulin independence in the majority of patients treated in recent series.^{284,285} Although 2 to 3 million islets are required for successful engraftment in an allogeneic recipient, the autotransplant recipient can usually achieve long-term, insulin-independent status after engraftment of only 300,000 to 400,000 islets.²⁸⁶ However, the ability to recover a sufficient quantity of islets from a sclerotic gland is dependent on the degree of disease present, so the selection of patients as candidates for autologous islet transplantation is

important. As success with autotransplantation increases, patients with nonobstructive, sclerotic pancreatitis may be considered for resection and islet autotransplantation earlier in their course, as end-stage fibrosis bodes poorly for transplant success.²⁸⁷ As the necessary expertise with islet transplantation becomes more widespread, this therapy may become routine in the treatment of chronic pancreatitis.

Denervation Procedures

In patients who have persistent and disabling pain, but who are poor candidates for resection or drainage procedures, a denervation procedure may provide symptomatic relief. As discussed above in "Presenting Signs and Symptoms" and "Neurolytic Therapy," neural ablation is a valid treatment strategy to block afferent sympathetic nociceptive pathways. In addition to direct infiltration of the celiac ganglia with long-acting analgesics or neurolytic agents,²⁸⁸ a variety of true denervation procedures have been described for symptomatic relief in chronic pancreatitis. These include operative celiac ganglionectomy or splanchnicectomy²⁸⁹ transhiatal splanchnicectomy,²⁹⁰ (Fig. 33-64), transthoracic splanchnicectomy with or without vagotomy,²⁹¹ and videoscopic transthoracic splanchnicectomy.²⁹² Mallet-Guy demonstrated long-term pain relief in 83% of 215 patients treated with operative celiac splanchnicectomy,²⁸⁹ and Michotey and associates claimed pain relief in all 14 patients treated with (transabdominal) transhiatal splanchnicectomy of the lower mediastinal sympathetic tracts,²⁹⁰ but both of these approaches represent major abdominal procedures. For the patient who is a poor candidate for an abdominal procedure, the transthoracic ablation of the sympathetic chain, either on the left side alone or bilaterally, has been shown to result in pain relief in 60 to 66% of patients. The application of videoscopic techniques to thoracic splanchnicectomy has further reduced the risks and discomfort of these procedures in chronically ill patients and provides a valuable alternative to a direct attack on the pancreas.

PANCREATIC NEOPLASMS

Neoplasms of the Endocrine Pancreas

Neoplasms of the endocrine pancreas are relatively uncommon but do occur with enough frequency (five cases per million population) that most surgeons will encounter them in an urban practice. The cells of the endocrine pancreas, or islet cells, originate from neural crest cells, also referred to as *amine precursor uptake and decarboxylation cells*. Multiple endocrine neoplasia (MEN) syndromes occur when these cells cause tumors in multiple sites. The MEN1 syndrome involves pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Some pancreatic endocrine neoplasms are functional, secreting peptide products that produce interesting clinical presentations. Neoplasms of the endocrine pancreas that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a pancreatic endocrine tumor. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases. Unfortunately, most pancreatic endocrine tumors are malignant, but the course of the disease is far more favorable than that seen with pancreatic exocrine cancer. The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward. The goals of surgery range from complete resection, often accomplished with insulinomas, to controlling symptoms with debulking procedures. Unresectable disease in the liver is often addressed with chemoembolization.

As with pancreatic exocrine tumors, the initial diagnostic imaging test of choice for pancreatic endocrine tumors is a multidetector CT scan with four phases of contrast and fine cuts through the pancreas and liver. EUS also can be valuable in localizing these tumors, which can produce dramatic symptoms despite their small (<1 cm) size. In contrast to pancreatic exocrine tumors, many of the endocrine tumors have somatostatin receptors (SSTRs) that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning (Fig. 33-65). The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling.

INSULINOMA

Insulinomas are the most common pancreatic endocrine neoplasms and present with a typical clinical syndrome known as Whipple's triad. The triad consists of symptomatic fasting hypoglycemia, a documented serum glucose level <50 mg/dL, and relief of symptoms with the administration of glucose. Patients will often present with a profound syncopal episode and will admit to similar less severe episodes in the recent past. They also may admit to palpitations, trembling, diaphoresis, confusion or obtundation, and seizure, and family members may report that the patient has undergone a personality change.

Routine laboratory studies will uncover a low blood sugar, the cause of all of these symptoms. Serum insulin levels are elevated. C-peptide levels should also be elevated and rule out the unusual case of surreptitious administration of insulin or oral hypoglycemic agents, because excess endogenous insulin production leads to excess C-peptide. The diagnosis can be clinched with a monitored fast in which blood is sampled every 4 to 6 hours for glucose and insulin levels until the patient becomes symptomatic. However, this can be dangerous and must be done with close supervision.

Insulinomas are usually localized with CT scanning and EUS. Technical advances in EUS have led to preoperative identification of $>90\%$ of insulinomas.²⁹³ Visceral angiography with venous sampling is rarely required to accurately localize the tumor. Insulinomas are evenly distributed throughout the head, body, and tail of the pancreas.²⁹⁴

Unlike most endocrine pancreatic tumors, the majority (90%) of insulinomas are benign and solitary, and only 10% are malignant. They are typically cured by simple enucleation. However, tumors located close to the main pancreatic duct and large (>2 cm) tumors may require a distal pancreatectomy or pancreaticoduodenectomy. Intraoperative US is useful to determine the tumor's relation to the main pancreatic duct and guides intraoperative decision making. Enucleation of solitary insulinomas and distal pancreatectomy for insulinoma can sometimes be performed using a minimally invasive technique.

Ninety percent of insulinomas are sporadic, and 10% are associated with the MEN1 syndrome. Insulinomas associated with the MEN1 syndrome are more likely to be multifocal and have a higher rate of recurrence.

GASTRINOMA

Zollinger-Ellison syndrome (ZES) is caused by a *gastrinoma*, an endocrine tumor that secretes gastrin, leading to acid hypersecretion and peptic ulceration. Many patients with ZES present with abdominal pain, peptic ulcer disease, and severe esophagitis. However, in the era of effective antacid therapy, the presentation can be less dramatic. Although most of the ulcers are solitary, multiple ulcers in atypical locations that fail to respond to antacids should raise suspicion for ZES and prompt a work-up. Twenty percent of patients with gastrinoma have diarrhea at the time of diagnosis.

The diagnosis of ZES is made by measuring the serum gastrin level. It is important that patients stop taking proton pump inhibitors for this test. In most patients with gastrinomas, the level is >1000 pg/mL. Gastrin levels can be elevated in conditions other than ZES. Common causes of hypergastrinemia include pernicious anemia, treatment with proton pump inhibitors, renal failure, G-cell hyperplasia, atrophic gastritis, retained or excluded antrum, and gastric outlet obstruction. In equivocal cases, when the gastrin level is not markedly elevated, a secretin stimulation test is helpful.

In 70 to 90% of patients, the primary gastrinoma is found in Passaro's triangle, an area defined by a triangle with points located at the junction of the cystic duct and common bile duct, the second and third portion of the duodenum, and the neck and body of the pancreas (Fig. 33-66). However, because gastrinomas can be found almost anywhere, whole-body imaging is required. The test of choice is SSTR (octreotide) scintigraphy in combination with CT. The octreotide scan is more sensitive than CT, locating about 85% of gastrinomas and detecting tumors <1 cm. With the octreotide scan, the need for tedious and technically demanding selective angiography and measurement of gastrin gradients has declined. EUS is another new modality that assists in the preoperative localization of gastrinomas. It is particularly helpful in localizing tumors in the pancreatic head or duodenal wall, where gastrinomas are usually <1 cm in size. A combination of octreotide scan and EUS detects $>90\%$ of gastrinomas.

Fig. 33-66.

Passaro's triangle. The typical location of a gastrinoma is described by this anatomic region, including the head of the pancreas, duodenum, and the lymphatic bed posterior and superior to the duodenum, as originally described by E. Passaro.

(Reproduced with permission from Bell.¹⁹⁶)

It is important to rule out MEN1 syndrome by checking serum calcium levels before surgery because resection of the gastrinoma(s) in these patients rarely results in normalization of serum gastrin concentrations or a prolongation of survival. Only one fourth of gastrinomas occur in association with the MEN1 syndrome. One half of patients with gastrinomas will have solitary tumors while the remainder will have multiple gastrinomas. Multiple tumors are more common in patients with MEN1 syndrome. Aggressive surgical treatment is justified in patients with sporadic gastrinomas. If patients have MEN1 syndrome, the parathyroid hyperplasia is addressed with total parathyroidectomy and implantation of parathyroid tissue in the

forearm.

Fifty percent of gastrinomas metastasize to lymph nodes or the liver, and are therefore considered malignant. Patients who meet criteria for operability should undergo exploration for possible removal of the tumor. Although the tumors are submucosal, a full-thickness excision of the duodenal wall is performed if a duodenal gastrinoma is found. All lymph nodes in Passaro's triangle are excised for pathologic analysis. If the gastrinoma is found in the pancreas and does not involve the main pancreatic duct, it is enucleated. Pancreatic resection is justified for solitary gastrinomas with no metastases. A highly selective vagotomy can be performed if unresectable disease is identified or if the gastrinoma cannot be localized. This may reduce the amount of expensive proton pump inhibitors required. In cases in which hepatic metastases are identified, resection is justified if the primary gastrinoma is controlled and the metastases can be safely and completely removed. Debulking or incomplete removal of multiple hepatic metastases is probably not helpful, especially in the setting of MEN1. The application of new modalities such as radiofrequency ablation seems reasonable, but data to support this approach are limited.²⁹⁵ Postoperatively, patients are followed with fasting serum gastrin levels, secretin stimulation tests, octreotide scans, and CT scans. In patients found to have inoperable disease, chemotherapy with streptozocin, doxorubicin, and 5-fluorouracil (5-FU) is used. Other approaches such as somatostatin analogues, interferon, and chemoembolization also have been used in gastrinoma with some success.

Unfortunately, a biochemical cure is achieved in only about one-third of the patients operated on for ZES. Despite the lack of success, long-term survival rates are good, even in patients with liver metastases. The 15-year survival rate for patients without liver metastases is about 80%, while the 5-year survival rate for patients with liver metastases is 20 to 50%. Pancreatic tumors are usually larger than tumors arising in the duodenum, and more often have lymph node metastases. In gastrinomas, liver metastases decrease survival rates, but lymph node metastases do not. The best results are seen after complete excision of small sporadic tumors originating in the duodenum. Large tumors associated with liver metastases, located outside of Passaro's triangle, have the worst prognosis.

VASOACTIVE INTESTINAL PEPTIDE-SECRETING TUMOR

In 1958, Verner and Morrison first described the syndrome associated with a pancreatic neoplasm secreting VIP. The classic clinical syndrome associated with this pancreatic endocrine neoplasm consists of severe intermittent watery diarrhea leading to dehydration, and weakness from fluid and electrolyte losses. Large amounts of potassium are lost in the stool. The *vasoactive intestinal peptide-secreting tumor (VIPoma) syndrome* is also called the *WDHA syndrome* due to the presence of *watery diarrhea, hypokalemia, and achlorhydria*. The massive (5 L/d) and episodic nature of the diarrhea associated with the appropriate electrolyte abnormalities should raise suspicion of the diagnosis. Serum VIP levels must be measured on multiple occasions because the excess secretion of VIP is episodic, and single measurements might be normal and misleading. A CT scan localizes most VIPomas, although as with all islet cell tumors, EUS is the most sensitive imaging method. Electrolyte and fluid balance is sometimes difficult to correct preoperatively and must be pursued aggressively. Somatostatin analogues are helpful in controlling the diarrhea and allowing replacement of fluid and electrolytes. VIPomas are more commonly located in the distal pancreas and most have spread outside the pancreas. Palliative debulking operations can sometimes improve symptoms for a period, along with somatostatin analogues. Hepatic artery embolization also has been reported as a potentially beneficial treatment.²⁹⁶

GLUCAGONOMA

Diabetes in association with dermatitis should raise the suspicion of a glucagonoma. The diabetes usually is mild. The classic necrolytic migratory erythema manifests as cyclic migrations of lesions with spreading margins and healing centers typically on the lower abdomen, perineum, perioral area, and feet. The diagnosis is confirmed by measuring serum glucagon levels, which are usually >500 pg/mL. Glucagon is a catabolic hormone, and most patients present with malnutrition. The rash associated with glucagonoma is thought to be caused by low levels of amino acids. Preoperative treatment usually includes control of the diabetes, parenteral nutrition, and octreotide. Like VIPomas, glucagonomas are more often in the body and tail of the pancreas and tend to be large tumors with metastases. Again, debulking operations are recommended in good operative candidates to relieve symptoms.

SOMATOSTATINOMA

Because somatostatin inhibits pancreatic and biliary secretions, patients with a somatostatinoma present with gallstones due to bile stasis, diabetes due to inhibition of insulin secretion, and steatorrhea due to inhibition of pancreatic exocrine secretion and bile secretion. Most somatostatinomas originate in the proximal pancreas or the pancreatoduodenal groove, with the ampulla and periampullary area as the most common site (60%). The most common presentations are abdominal pain (25%), jaundice (25%), and cholelithiasis (19%).²⁹⁷ This rare type of pancreatic endocrine tumor is diagnosed by confirming elevated serum somatostatin levels, which are usually >10 ng/mL. Although most reported cases of somatostatinoma

involve metastatic disease, an attempt at complete excision of the tumor and cholecystectomy is warranted in fit patients.

NONFUNCTIONING ISLET CELL TUMORS

Although some pancreatic endocrine neoplasms secrete one or more hormones and are associated with interesting characteristic clinical syndromes, many are not associated with elevated serum hormone levels. After insulinoma, the most common islet cell tumor is the nonfunctioning islet cell neoplasm. Because it is clinically silent until its size and location produce symptoms, it is usually malignant when first diagnosed. Some presumably nonfunctional pancreatic endocrine neoplasms stain positive for pancreatic polypeptide (PP), and elevated PP levels are therefore a marker for the lesion. Because clinical manifestations are absent, the tumors are usually large and metastatic at the time of diagnosis, unless they are detected serendipitously on CT scan or sonogram. Nonfunctioning islet cell tumors are also seen in association with other multiple neoplasia syndromes, such as von Hippel-Lindau syndrome. The tumors grow slowly and 5-year survival is common, as opposed to pancreatic exocrine tumors, for which 5-year survival is extraordinarily rare.

Neoplasms of the Exocrine Pancreas

EPIDEMIOLOGY AND RISK FACTORS

It is estimated that 37,680 patients were diagnosed with and 34,290 patients died of cancer of the pancreas in the United States in 2008.²⁹⁸ Overall, pancreatic cancer has the worst prognosis of all malignancies with a 5% 5-year survival rate.²⁹⁸ Despite its ubiquity, this disease is extremely difficult to treat, and its exact cause unknown. However, epidemiologic studies linking various environmental and host factors provide some clues. Recent discoveries using modern molecular biologic techniques have also improved our understanding of the causes of pancreatic cancer. The etiology of pancreatic cancer likely involves a complex interaction of genetic and environmental factors. Understanding these factors will become increasingly important as better diagnostic tools such as DNA sequencing become clinically available to screen populations at risk for developing pancreatic cancer.

Pancreatic cancer is more common in the elderly with most patients being >60 years old. Pancreatic cancer is more common in African Americans and slightly more common in men than women. The risk of developing pancreatic cancer is two to three times higher if a parent or sibling had the disease. Another risk factor that is consistently linked to pancreatic cancer is cigarette smoking. Smoking increases the risk of developing pancreatic cancer by at least twofold due to the carcinogens in cigarette smoke.²⁹⁹ Coffee and alcohol consumption have been investigated as possible risk factors, but the data are inconsistent. As in other GI cancers, diets high in fat and low in fiber, fruits, and vegetables are thought to be associated with an increased risk of pancreatic cancer.

Diabetes has been known to be associated with pancreatic cancer for many years. In fact, glucose intolerance is present in 80% of patients with pancreatic cancer, and approximately 20% have overt diabetes, a much greater incidence than would be expected to occur by chance. Pre-existing type II diabetes may increase the risk for development of pancreatic cancer.³⁰⁰ The new onset of diabetes also can be an early manifestation of otherwise occult pancreatic cancer. Thus, the new onset of diabetes or a sudden increase in insulin requirement in an elderly patient with pre-existing diabetes should provoke concern for the presence of pancreatic cancer.

Recent epidemiologic studies have confirmed the fact that patients with chronic pancreatitis, especially familial pancreatitis, have an increased risk of developing pancreatic cancer.¹⁸⁴ Large, retrospective cohort studies of patients with pancreatitis have revealed up to a 20-fold increase in risk for pancreatic cancer. This increased risk seems to be independent of the type of pancreatitis, a finding consistent with the fact that most studies have shown little effect of alcohol ingestion per se on the risk of pancreatic carcinoma. The mechanisms involved in carcinogenesis in patients with pre-existing pancreatitis are unknown. However, the mutated *K-ras* oncogene, which is present in most cases of pancreatic cancer, has been detected in the ductal epithelium of some patients with chronic pancreatitis.

GENETICS OF PANCREATIC CANCER

Pancreatic carcinogenesis probably involves multiple mutations that are inherited and acquired throughout aging. The *K-ras* oncogene is currently thought to be the most commonly mutated gene in pancreatic cancer, with approximately 90% of tumors having a mutation.³⁰¹ This prevalent mutation is present in precursor lesions and is therefore thought to occur early and be essential to pancreatic cancer development. *K-ras* mutations can be detected in DNA from serum, stool, pancreatic juice, and tissue aspirates of patients with pancreatic cancer, suggesting that the presence of this mutation may provide the basis for diagnostic testing in select individuals. The *HER-2/neu* oncogene, homologous to the epidermal growth factor receptor (EGFr), is overexpressed in pancreatic cancers.³⁰¹ This receptor is involved in signal transduction pathways that lead to cellular proliferation. Multiple tumor-suppressor genes are deleted and/or mutated in pancreatic cancer, and include *p53*, *p16*, and *DPC4* (*Smad4*), and in a

minority of cases, *BRCA2*.³⁰¹ Most pancreatic cancers have three or more of the above mutations.

With the completion of the human genome project, comparison of the normal genome and the results of DNA sequencing of pancreatic and other cancers is an active area of research. Discovery of mutations in numerous other genes is likely in the near future and will hopefully lead to better diagnostic and therapeutic approaches.

It is estimated that up to 10% of pancreatic cancers occur as a result of an inherited genetic predisposition. A family history of pancreatic cancer in a first-degree relative increases the risk of pancreatic cancer by about twofold.³⁰¹ Rare familial cancer syndromes that are associated with an increased risk of pancreatic cancer include *BRCA2*, the familial atypical multiple mole–melanoma syndrome, hereditary pancreatitis, familial adenomatous polyposis (FAP), hereditary nonpolyposis colorectal cancer, Peutz-Jeghers syndrome, and ataxia-telangiectasia.³⁰²

In addition to mutations in oncogenes and tumor-suppressor genes, pancreatic cancers also are known to have aberrations in the expression of growth factors and their receptors. These growth factors include epidermal growth factor, fibroblast growth factor, transforming growth factor beta, insulin-like growth factor, hepatocyte growth factor, and vascular endothelial growth factor.³⁰³

The fact that many GI hormones and growth factors affect the growth of the normal exocrine pancreas suggests that these peptides also could affect the growth of pancreatic cancer, and some studies in cell culture and laboratory animals have supported this hypothesis.³⁰³ Newer drugs such as erlotinib (Tarceva) and cetuximab (Erbix), EGFR inhibitors, and bevacizumab (Avastin), a vascular endothelial growth factor inhibitor, and other drugs aimed at manipulation of growth factors, their receptors, and secondary messengers are the subject of ongoing clinical research. However, the combination of these drugs with standard chemotherapy in recent trials has not resulted in dramatic improvements in overall survival in pancreatic cancer.

PATHOLOGY

Pancreatic cancer probably arises through a stepwise progression of cellular changes, just as colon cancer progresses by stages from hyperplastic polyp to invasive cancer. Systematic histologic evaluation of areas surrounding pancreatic cancers has revealed the presence of precursor lesions that have been named *pancreatic intraepithelial neoplasia* (Fig. 33-67). Three stages of pancreatic intraepithelial neoplasia have been defined. These lesions demonstrate the same oncogene mutations and loss of tumor-suppressor genes found in invasive cancers, the frequency of these abnormalities increasing with progressive cellular atypia and architectural disarray.³⁰⁴ The ability to detect these precursor lesions in humans at a stage where the cancer can still be prevented or cured is an important goal of current pancreatic cancer research.

Pancreatic intraepithelial neoplasia (PanIN). Histology (*top panel*) showing grades PanIN-1A (A), PanIN-1B (B), PanIN-2 (C), and PanIN-3 (D), and schema of correlation of histology with mutational events (*bottom panel*) showing cumulative abnormalities of tumor-promoter and tumor-suppressor factors such as kRAS, p53, etc. and their corresponding cellular phenotype.

(From Hruban RH, Takaori K, Klimstra DS, et al: An illustrated consensus on the classification of pancreatic intraepithelial neoplasia and intraductal papillary mucinous neoplasms. *Am J Surg Pathol* 28:977, 2004.)

About two thirds of pancreatic adenocarcinomas arise within the head or uncinate process of the pancreas; 15% are in the body, and 10% in the

tail, with the remaining tumors demonstrating diffuse involvement of the gland. Tumors in the pancreatic body and tail are generally larger at the time of diagnosis, and therefore, less commonly resectable. Tumors in the head of the pancreas are typically diagnosed earlier because they cause obstructive jaundice. Ampullary carcinomas, carcinomas of the distal bile duct, and periampullary duodenal adenocarcinomas present in a similar fashion to pancreatic head cancer but have a slightly better prognosis, probably because early obstruction of the bile duct and jaundice leads to the diagnosis.

In addition to ductal adenocarcinoma, which makes up about 75% of nonendocrine cancers of the pancreas, there are a variety of less common types of pancreatic cancer. Adenosquamous carcinoma is a variant that has both glandular and squamous differentiation. The biologic behavior of this lesion is unfortunately no better than the typical ductal adenocarcinoma.³⁰⁵ Acinar cell carcinoma is an uncommon type of pancreatic cancer that usually presents as a large tumor, often 10 cm in diameter or more, but the prognosis of patients with these tumors may be better than with ductal cancer.

DIAGNOSIS AND STAGING

Exact pathologic staging of pancreatic cancer is important because it allows accurate quantitative assessment of results and comparisons between institutions. The tumor-node-metastasis (TNM) staging of pancreatic cancer is shown in Table 33-18.

Table 33-18 Staging of Pancreatic Cancer				
Tumor (T)				
TX: Primary tumor cannot be assessed				
T0: No evidence of primary tumor				
Tis: Carcinoma in situ				
T1: Tumor is limited to the pancreas and is ≤2 cm in greatest dimension				
T2: Tumor is limited to the pancreas and is >2 cm in greatest dimension				
T3: Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery				
T4: Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)				
Regional lymph nodes (N)				
NX: Regional lymph nodes cannot be assessed				
N0: No regional lymph node metastasis				
N1: Regional lymph node metastasis				
Distant metastasis (M)				
MX: Distant metastasis cannot be assessed				
M0: No distant metastasis				
M1: Distant metastasis				
Stage	T	N	M	Description
IA	1	0	0	Limited to pancreas ≤2 cm
IB	2	0	0	Limited to pancreas >2 cm
IIA	3	0	0	Extends beyond pancreas but does not involve arteries
IIB	1-3	1	0	Any tumor without artery involvement with lymph node involvement
III	4	Any	0	Tumor involves arteries (unresectable)
IV	Any	Any	1	Any tumor with distant metastases

Source: Exocrine pancreas, in: American Joint Committee on Cancer: *AJCC Cancer Staging Manual*, 6th ed. New York: Springer, 2002, p 157. Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Sixth Edition (2002) published by Springer Science and Business Media LLC, www.springerlink.com.

T1 lesions are ≤2 cm in diameter and are limited to the pancreas. T2 lesions also are limited to the pancreas, but are >2 cm. T3 lesions extend beyond the pancreas but do not involve the celiac axis or superior mesenteric artery. T4 lesions involve the celiac axis or superior mesenteric artery and are not resectable. T1 and T2 tumors with no lymph node involvement are considered stage I disease (stage IA and IB). More extensive invasion, such as that associated with T3 tumors, indicates stage IIA disease. Any lymph node involvement indicates stage IIB disease. Locally advanced unresectable tumors (T4) without metastatic disease are considered stage III while patients with metastases to distant sites such as the

liver or lungs are stage IV.

Seven percent of pancreas cancer cases are diagnosed while the cancer is still confined to the primary site (localized stage); 26% are diagnosed after the cancer has spread to regional lymph nodes or directly beyond the primary site; 52% are diagnosed after the cancer has already metastasized (distant stage); and for the remaining 15%, the staging information was unknown. The corresponding 5-year relative survival rates were: 20.3% for localized, 8.0% for regional, 1.7% for distant, and 4.1% for unstaged. The overall 5-year relative survival rate for patients with pancreatic cancer for 1996 to 2003 from 17 Surveillance, Epidemiology and End Results geographic areas was 5%.³⁰⁶

The most critical deficit in the ability to treat pancreatic cancer effectively is the lack of tools for early diagnosis. The pancreas is situated deep within the abdomen, and the early symptoms of pancreatic cancer often are too vague to raise suspicion of the disease. Ultimately, the majority of patients present with pain and jaundice. On physical examination, weight loss is evident and the skin is icteric; a distended gallbladder is palpable in about one-fourth of patients. More fortunate patients have tumors situated such that biliary obstruction and jaundice occurs early and prompts diagnostic tests. Unfortunately, however, the vast majority of patients are not diagnosed until weight loss has occurred—a sign of advanced disease.

Although it is often taught that carcinoma of the pancreas presents with painless jaundice (to help distinguish it from choledocholithiasis), this aphorism is not accurate. Most patients do experience pain as part of the symptom complex of pancreatic cancer, and it is often the first symptom. Therefore, awareness of the way pancreatic pain is perceived may help clinicians suspect pancreatic cancer. The pain associated with pancreatic cancer is usually perceived in the epigastrium but can occur in any part of the abdomen, and often, but not always, penetrates to the back. When questioned in retrospect, patients often recall mild and vague pain for many months before diagnosis. A low threshold for ordering a CT scan with "pancreatic protocol" should be maintained for elderly patients with unexplained, persistent, although vague, abdominal pain. As mentioned above, new-onset diabetes in an elderly patient, especially if combined with vague abdominal pain, should prompt a search for pancreatic cancer.

Unfortunately, at this time there is no sensitive and specific serum marker to assist in the timely diagnosis of pancreatic cancer. With jaundice, direct hyperbilirubinemia and elevated alkaline phosphatase are expected but do not serve much of a diagnostic role other than to confirm the obvious. With long-standing biliary obstruction, the prothrombin time will be prolonged due to a depletion of vitamin K, a fat-soluble vitamin dependent on bile flow for absorption. CA19-9 is a mucin-associated carbohydrate antigen that can be detected in the serum of patients with pancreatic cancer. Serum levels are elevated in about 75% of patients with pancreatic cancer. However, CA19-9 is also elevated in about 10% of patients with benign diseases of the pancreas, liver, and bile ducts.³⁰⁷ CA19-9 is thus neither sufficiently sensitive nor specific to allow an earlier diagnosis of pancreatic cancer. Despite the fact that many tumor markers such as CA19-9 have been studied in an attempt to facilitate early diagnosis, there are still no effective screening tests for pancreatic cancer. Research taking advantage of recent advances in genomics, gene expression analysis, and proteomics has demonstrated thousands of genes and corresponding proteins that are differentially expressed in pancreatic tumors that have potential for early detection of pancreatic cancer.³⁰⁸ Some of these proteins would be expected to be expressed at the cell surface or in pancreatic juice and may become useful as biomarkers for pancreatic cancer in the future.

In patients presenting with jaundice, a reasonable first diagnostic imaging study is abdominal US. If bile duct dilation is not seen, hepatocellular disease is likely. Demonstration of cholelithiasis and bile duct dilation suggests a diagnosis of choledocholithiasis, and the next logical step would be ERCP to clear the bile duct. In the absence of gallstones, malignant obstruction of the bile duct is likely, and a CT scan rather than ERCP would be the next logical step. For patients suspected of having pancreatic cancer who present without jaundice, US is not appropriate, and a CT scan should be the first test.

The current diagnostic and staging test of choice for pancreatic cancer is a multidetector, dynamic, contrast-enhanced CT scan, and techniques are constantly improving (Fig. 33-68). The accuracy of CT scanning for predicting unresectable disease is about 90 to 95%.³⁰⁹ CT findings that indicate a tumor is unresectable include invasion of the hepatic or superior mesenteric artery, enlarged lymph nodes outside the boundaries of resection, ascites, and distant metastases (e.g., liver). Invasion of the superior mesenteric vein or portal vein is not in itself a contraindication to resection as long as the veins are patent. In contrast, CT scanning is less accurate in predicting resectable disease. CT scanning will miss small liver metastases, and predicting arterial involvement is sometimes difficult.

Fig. 33-68.

Computed tomography scan demonstrating resectable pancreatic cancer. SMA = superior mesenteric artery.

Currently, CT is probably the single most versatile and cost-effective tool for the diagnosis of pancreatic cancer. Abdominal MRI is rapidly evolving but currently provides essentially the same information as CT scanning. Positron emission tomography scanning is becoming more widely available and may help distinguish chronic pancreatitis from pancreatic cancer. EUS can be used to detect small pancreatic masses that could be missed by CT scanning and is commonly used when there is a high suspicion for pancreatic cancer but no mass is identified by the CT scan. EUS has the added advantage of providing the opportunity for transluminal biopsy of pancreatic masses, although a tissue diagnosis before pancreaticoduodenectomy is not required. However, in specific patients a histologic diagnosis may be necessary such as for those in a neoadjuvant clinical trial or before chemotherapy in advanced tumors. EUS is a sensitive test for portal/superior mesenteric vein invasion, although it is somewhat less effective at detecting superior mesenteric artery invasion. When all of the current staging modalities are used, their accuracy in predicting resectability is reported to be about 80%, meaning that one in five patients brought to the operating room with the intent of a curative resection will be found at the time of surgery to have unresectable disease.³¹⁰

In an attempt to avoid such futile laparotomies, preliminary laparoscopy has been advocated for patients with disease felt to be resectable by CT imaging (Fig. 33-69). Diagnostic laparoscopy with the use of US is reported to improve the accuracy of predicting resectability to about 98%.³¹⁰ The technique involves more than simple visualization with the scope and requires the placement of multiple ports and manipulation of the tissues. A general exploration of the peritoneal surfaces is carried out. The ligament of Treitz and the base of the transverse mesocolon are examined for tumor. The gastrocolic ligament is incised, and the lesser sac is examined. The US probe is used to examine the liver, porta hepatis, and the portal vein and superior mesenteric artery.

Liver metastases identified at diagnostic laparoscopy.

The percentage of patients in whom a positive laparoscopy helps avoid a nontherapeutic laparotomy varies from 10 to 30% in carcinoma of the head of the pancreas but may be as high as 50% in patients with tumors in the body and tail of the gland. As the quality of CT scanning has improved, the value of routine diagnostic laparoscopy has decreased. However, the morbidity of diagnostic laparoscopy is less than that of laparotomy, and the procedure can be performed on an outpatient basis. Patients who are found to have unresectable disease recover more rapidly from a laparoscopy than a laparotomy and can receive palliative chemotherapy and radiation sooner. The potential immunosuppressive effects of a major surgical procedure also are avoided, as well as the negative psychologic impact of a major painful operation with little benefit.

Biliary obstruction can be relieved with an endoscopic approach in almost all cases. When large (10F) plastic stents are used, most patients do not require replacement for about 3 months. Metallic wall stents last about 5 months on average and usually fail only with tumor ingrowth.³¹¹ Keeping in mind that patients with unresectable pancreatic cancer usually live <1 year, the requirement for numerous stent changes is unlikely.

Diagnostic laparoscopy is possibly best applied to patients with pancreatic cancer on a selective basis. Diagnostic laparoscopy will have a higher yield in patients with large tumors (>4 cm), tumors located in the body or tail, patients with equivocal findings of metastasis or ascites on CT scan, and patients with other indications of advanced disease such as marked weight loss or markedly elevated CA19-9 (>1000 U/mL). An algorithm for the diagnosis, staging, and treatment of pancreatic cancer is shown in Fig. 33-70.

Diagnostic and treatment algorithm for pancreatic cancer. If computed tomography (CT) scan demonstrates a potentially resectable tumor, patients are offered participation in a clinical trial after histologic confirmation by CT or endoscopic ultrasound (EUS)-guided biopsy. If CT scan demonstrates resectable disease, diagnostic laparoscopy is used selectively in patients with tumors in the body/tail, equivocal findings of metastasis or CT scan, ascites, high CA19-9, or marked weight loss. Patients also have diagnostic laparoscopy if they elect to participate in a neoadjuvant clinical trial. In cases where no mass is demonstrated on CT scan, but suspicion of cancer remains, EUS or endoscopic retrograde cholangiopancreatography (ERCP) with brushings are performed, and the CT may be repeated after an interval of observation.

PALLIATIVE SURGERY AND ENDOSCOPY

For the 85 to 90% of patients with pancreatic cancer who have disease that precludes surgical resection, appropriate and effective palliative treatment is critical to the quality of their remaining life. Because of the poor prognosis of the disease, it is not appropriate to use invasive and toxic regimens in patients with extremely advanced disease and poor performance status. When patients do desire antineoplastic therapy, it is important to encourage them to enroll in clinical trials so that therapeutic advances can be made.

In general, there are three clinical problems in advanced pancreatic cancer that require palliation: pain, jaundice, and duodenal obstruction. The mainstay of pain control is oral narcotics. Sustained-release preparations of morphine sulfate are frequently used. Invasion of retroperitoneal nerve trunks accounts for the severe pain experienced by patients with advanced pancreatic cancer. A celiac plexus nerve block can control pain effectively for a period of months, although the procedure sometimes needs to be repeated.

Jaundice is present in the majority of patients with pancreatic cancer, and the most troublesome aspect for the patient is the accompanying pruritus. Biliary obstruction may also lead to cholangitis, coagulopathy, digestive symptoms, and hepatocellular failure. In the past, surgeons traditionally performed a biliary bypass when unresectable disease was found at laparotomy. As many patients today already have a bile duct stent in place by the time of operation, it is not clear that operative biliary bypass is required. If an operative bypass is performed, choledochojejunostomy is the preferred approach. Although an easy procedure to perform, choledochoduodenostomy is felt to be unwise because of the proximity of the duodenum to tumor. Some have discouraged the use of the gallbladder for biliary bypass³¹¹; however, it is suitable as long as the cystic duct clearly enters the common duct well above the tumor.

Duodenal obstruction is usually a late event in pancreatic cancer and occurs in only about 20% of patients.³¹² Therefore, in the absence of signs or symptoms of obstruction, such as a tumor that is already encroaching on the duodenum at the time of surgery, the routine use of prophylactic gastrojejunostomy when exploration reveals unresectable tumor is controversial. Although anastomotic leaks are uncommon, gastrojejunostomy is sometimes associated with delayed gastric emptying, the very symptom the procedure is designed to treat.

Whether performing both a biliary and enteric bypass or just a biliary bypass, the jejunum is brought anterior to the colon, if possible, rather than retrocolic, where the tumor potentially would invade the bowel sooner. Some surgeons use a loop of jejunum with a jejunojejunostomy to divert the enteric stream away from the biliary-enteric anastomosis. Others use a Roux-en-Y limb with the gastrojejunostomy located 50 cm downstream

from the hepaticojejunostomy (Fig. 33-71). Potential advantages of the defunctionalized Roux-en-Y limb include the ease with which it will reach up to the hepatic hilum, probable decreased risk of cholangitis, and easier management of biliary anastomotic leaks. If a gastrojejunostomy is performed, it should be placed dependently and posterior along the greater curvature to improve gastric emptying, and a vagotomy should not be performed. If patients are explored laparoscopically and found to have unresectable disease, palliation of jaundice can be achieved in a minimally invasive fashion with ERCP and placement of a coated, expandable metallic endoscopic biliary stent (Fig. 33-72). Endoscopic stents are definitely not as durable as a surgical bypass. Recurrent obstruction and cholangitis is more common with stents and results in inferior palliation. However, this minimally invasive approach is associated with considerably less initial morbidity and mortality than surgical bypass. Newer, expandable metallic wall stents demonstrate improved patency and provide better palliation than plastic stents.

Expandable metallic biliary stent.

If an initial diagnostic laparoscopy reveals a contraindication to the Whipple procedure, such as liver metastases, it is not appropriate to perform a laparotomy simply to create a biliary bypass. In such a patient, it is better to place an endoscopic stent. In contrast, if a laparotomy has already been performed as part of the assessment of resectability and the Whipple procedure is not possible, a surgical bypass is usually performed. However, if the patient has a functioning endoscopic stent already in place, it may be reasonable to forego surgical bypass.

PALLIATIVE CHEMOTHERAPY AND RADIATION

In patients with unresectable pancreatic cancer, gemcitabine results in symptomatic improvement, improved pain control and performance status, and weight gain.³¹³ However, survival is improved by only 1 to 2 months. Although these results may warrant treatment in patients who understand the benefits and risks, the lack of significant survival advantage should encourage physicians to refer motivated patients for experimental protocols, because it is only through continued clinical research that more meaningful treatments for pancreatic cancer will be developed.

SURGICAL RESECTION: PANCREATICODUODENECTOMY

In a patient with appropriate clinical and/or imaging indications of pancreatic cancer, a tissue diagnosis before performing a pancreaticoduodenectomy is not essential. Although percutaneous CT-guided biopsy is usually safe, complications such as hemorrhage, pancreatitis, fistula, abscess, and even death can occur. Tumor seeding along the subcutaneous tract of the needle is uncommon. Likewise, FNA under EUS guidance is safe and well tolerated. The problem with preoperative or even intraoperative biopsy is that many pancreatic cancers are not very cellular and contain a significant amount of fibrous tissue, so a biopsy may be misinterpreted as showing chronic pancreatitis if it does not contain malignant glandular cells. In the face of clinical and radiologic preoperative indications of pancreatic cancer, a negative biopsy should not preclude resection. In patients who are not candidates for resection because of metastatic disease, biopsy for a tissue diagnosis becomes important because these patients may be candidates for palliative chemotherapy trials. It is especially important to make an aggressive attempt at tissue diagnosis before surgery in patients whose clinical presentation and imaging studies are more suggestive of alternative diagnoses such as pancreatic lymphoma or pancreatic islet cell tumors. These patients might avoid surgery altogether in the case of lymphoma or warrant an aggressive debulking approach in the case of islet cell carcinoma.

Pancreaticoduodenectomy can be performed through a midline incision from xiphoid to umbilicus or through a bilateral subcostal incision. The initial portion of the procedure is an assessment of resectability. The liver and visceral and parietal peritoneal surfaces are thoroughly assessed. The gastrohepatic omentum is opened, and the celiac axis area is examined for enlarged lymph nodes. The base of the transverse mesocolon to the right of the middle colic vessels is examined for tumor involvement.

The ascending and hepatic flexure of the colon are mobilized off the duodenum and head of the pancreas and reflected medially. A Kocher maneuver is performed by dissecting behind the head of the pancreas. The superior mesenteric vein is identified early in the case and dissected up toward the inferior border of the neck of the pancreas. The gastroepiploic vein and artery are ligated to prevent any traction injury. The relation of the tumor to the superior mesenteric vein and artery cannot be accurately assessed by palpation at this point and is not completely determined until later in the operation when the neck of the pancreas is divided and the surgeon is committed to resection. Mesenteric vascular involvement is best determined by a high quality preoperative CT scan.

It is important to assess for an aberrant right hepatic artery, which is present in 20% of patients. The aberrant artery arises from the superior

mesenteric artery posterior to the pancreas and ascends parallel and adjacent to the superior mesenteric and portal veins. The presence of an aberrant right hepatic artery should be apparent on the preoperative CT scan and can be identified intraoperatively by palpation on the back side of the hepatoduodenal ligament, where a prominent pulse will be felt posterior and to the right of the portal vein.

The porta hepatis is examined. Enlarged or firm lymph nodes that can be swept down toward the head of the pancreas with the specimen do not preclude resection. If the assessment phase reveals no contraindications to the Whipple procedure (Table 33-19), the resection phase commences.

Table 33-19 Findings at Exploration
Findings contraindicating resection
Liver metastases (any size)
Celiac lymph node involvement
Peritoneal implants
Hepatic hilar lymph node involvement
Findings not contraindicating resection
Invasion at duodenum or distal stomach
Involved peripancreatic lymph nodes
Involved lymph nodes along the porta hepatis that can be swept down with the specimen

If the pylorus is to be preserved, the stomach and proximal duodenum are mobilized off the pancreas, preserving the gastroepiploic vessels down to the pylorus. The proximal hepatic artery is identified usually by removing a lymph node that commonly lies just anterior to the artery. The hepatic artery is dissected and traced toward the porta hepatis. Small vessels in this area can be ligated with 3-0 or 4-0 silk ligatures to prevent bothersome hemorrhage later in the case that makes subsequent dissection more tedious. The gastroduodenal branch of the hepatic artery is identified. A test clamping is performed to assure that a strong pulse remains in the proper hepatic artery before division of the gastroduodenal artery. Once the gastroduodenal artery is divided, the hepatic artery is retracted medially and the common bile duct is retracted laterally to reveal the glistening anterior surface of the portal vein behind them. Dissection is performed only on the anterior surface of the vein. If there is no tumor involvement, the neck of the pancreas will separate from the vein easily. A large, blunt-tipped clamp is a safe instrument to use for this dissection. The tunnel under the neck of the pancreas can then be completed mostly under direct vision from inferior and superior.

The gallbladder is then mobilized from the liver, the cystic duct and artery are ligated, and the gallbladder is removed. The common hepatic duct is circumferentially dissected. Either the duodenum is divided 2 cm distal to the pylorus (PPPD) or the antrum is divided. The jejunum is divided beyond the ligament of Treitz, and the mesentery is ligated until the jejunum can be delivered posterior to the superior mesenteric vessels from left to right.

The common hepatic duct is then divided just above the entrance of the cystic duct, and the duct is dissected down to the superior margin of the duodenum. Inferior traction on the distal bile duct opens the plane to make visible the anterior portion of the portal vein. The pancreatic neck is divided anterior to the portal vein (Fig. 33-73). The pancreatic head and uncinate process then are dissected off of the right lateral aspect of the superior mesenteric vein, ligating the fragile branches draining the head and uncinate process into the portal vein (Fig. 33-74). The uncinate process is then dissected off of the posterior and lateral aspect of the superior mesenteric artery. This can be the most tedious portion of the operation, but thoroughly clearing all tissue from the mesenteric vessels helps avoid incomplete resection. The wound is irrigated and meticulous hemostasis is assured at this point because the view of the portal vein area and retroperitoneum is more difficult after the reconstruction phase is completed.

The reconstruction involves anastomoses of the pancreas first, then the bile duct, and, finally, the duodenum or stomach. There are various techniques for the pancreatic anastomoses, and all have equivalent outcomes. After the pancreatic anastomosis is completed, the choledochojejunostomy is performed about 10 cm down the jejunal limb from the pancreatic anastomosis. This is usually performed in an end-to-side fashion with one layer of interrupted sutures. The duodenojejunostomy or gastrojejunostomy is performed another 10 to 15 cm downstream from the biliary anastomosis, using a two-layer technique.

VARIATIONS AND CONTROVERSIES

The preservation of the pylorus has several theoretical advantages, including prevention of reflux of pancreaticobiliary secretions into the stomach, decreased incidence of marginal ulceration, normal gastric acid secretion and hormone release, and improved gastric function. Patients with pylorus-preserving resections have appeared to regain weight better than historic controls in some studies. Return of gastric emptying in the immediate postoperative period may take longer after the pylorus-preserving operation, and it is controversial whether there is any significant improvement in long-term quality of life with pyloric preservation.^{314,315}

Techniques for the pancreaticojejunostomy include end-to-side or end-to-end and duct-to-mucosa sutures or invagination (Fig. 33-75). Pancreaticogastrostomy has also been investigated.

Techniques for pancreaticojejunostomy. **A to D.** Duct-to-mucosa, end-to-side. **E.** Intraoperative photographs of end-to-side pancreaticojejunostomy. **F to J.** End-to-end invagination. **K to O.** End-to-side invagination.

Some surgeons use stents, glue to seal the anastomosis, or octreotide to decrease pancreatic secretions. No matter what combination of these techniques is used, the pancreatic leakage rate is always about 10%. Therefore, the choice of techniques depends more on the surgeon's personal experience.

Traditionally, most surgeons place drains around the pancreatic and biliary anastomoses because disruption of the pancreaticojejunostomy cannot be avoided in one out of 10 patients. This complication can lead to the development of an upper abdominal abscess or can present as an external pancreatic fistula. Usually, a pure pancreatic leak is controlled by the drains and will eventually seal spontaneously. Combined pancreatic and biliary leaks are cause for concern because bile will activate the pancreatic enzymes. In its most virulent form, disruption leads to necrotizing

retroperitoneal infection, which can erode major arteries and veins of the upper abdomen, including the exposed portal vein and its branches or the stump of the gastroduodenal artery. Impending catastrophe is often preceded by a small herald bleed from the drain site. Depending on the clinical situation, such an event is an indication to perform an angiogram or return the patient to the operating room to widely drain the pancreaticojejunostomy and to repair the involved blood vessel. Open packing may be necessary to control diffuse necrosis and infection. Some studies have questioned the practice of routine drain placement after pancreaticoduodenectomy. These studies indicated that most pancreatic leaks can be managed with percutaneous drainage.³¹⁶

Many patients with pancreatic cancer are malnourished preoperatively and suffer from gastroparesis in the immediate postoperative period. Routine placement of a feeding jejunostomy tube and gastrostomy tube has become less common, and most surgeons use these tubes selectively. Gastrostomy tubes may decrease the length of stay in patients who might be predicted to have severe gastroparesis. Jejunostomy tubes are certainly not benign and can result in leaks and intestinal obstruction. However, parenteral nutrition is also associated with serious complications such as line sepsis, loss of gut mucosal integrity, and hepatic dysfunction.

Because of the high incidence of direct retroperitoneal invasion and regional lymph node metastasis at the time of surgery, it has been argued that the scope of resection for pancreatic cancer should be enlarged to include a radical regional lymphadenectomy and resection of areas of potential retroperitoneal invasion. The "radical pancreaticoduodenectomy" includes extension of the pancreatic resection to the middle body of the pancreas, segmental resection of the portal vein, if necessary, resection of retroperitoneal tissue along the right perinephric area, and lymphadenectomy to the region of the celiac plexus. In the hands of experienced surgeons, these techniques are associated with greater blood loss but no increase in mortality; however, improved survival has not been demonstrated.³¹⁷ Total pancreatectomy has also been considered in the past. Although pancreatic leaks are eliminated, major morbidity from brittle diabetes and exocrine insufficiency outweigh any theoretical benefit.

Pancreatic cancer can recur locally after pancreaticoduodenectomy. Intraoperative radiotherapy (IORT) delivers a full therapeutic dose of radiation to the operative bed at the time of resection. Radiation to surrounding normal areas is minimized, but the radiation is delivered all in one setting, usually about 15 minutes, rather than in fractionated doses over time. IORT is best performed in a shielded, dedicated, operating room suite rather than by transporting the patient in the middle of an already long and complicated operation. IORT may improve local control and palliate symptoms after pancreaticoduodenectomy. However, IORT has not been shown to be superior to standard external beam radiation therapy, and further randomized trials are needed to determine how this modality should be utilized.³¹⁸

COMPLICATIONS OF PANCREATICODUODENECTOMY

The operative mortality rate for pancreaticoduodenectomy has decreased to <5% in "high volume" centers (where individual surgeons perform more than fifteen cases per year), suggesting that patients in rural areas would benefit from referral to large urban centers.^{319,320} The most common causes of death are sepsis, hemorrhage, and cardiovascular events. Postoperative complications are unfortunately still very common, and include delayed gastric emptying, pancreatic fistula, and hemorrhage.

Delayed gastric emptying is common after pancreaticoduodenectomy and is treated conservatively as long as complete gastric outlet obstruction is ruled out by a contrast study. IV erythromycin may help in the acute phase, but the problem usually improves with time.

Considerable attention has been focused on the prevention of pancreatic leak after pancreas resection. Modifications of the anastomotic technique (end-to-side or end-to-end, duct-to-mucosa or invaginated), the use of jejunum or the stomach for drainage, the use of pancreatic duct stents, the use of octreotide, and various sealants have all been evaluated. Octreotide, a synthetic analogue of somatostatin with a longer half-life, has been evaluated as a pharmacologic therapy to reduce pancreatic secretion and the rate of pancreatic fistula after pancreatic resection. European studies advocate the routine use of octreotide while North American trials conclude that octreotide is useless. European studies have demonstrated a significant reduction in the rate of postoperative pancreatic fistula with prophylactic preoperative octreotide injection.^{321–323} However, recent randomized prospective studies in the United States showed that octreotide did not prevent postoperative pancreatic fistula when used following pancreatic resection.^{206,324–330} However, a subgroup analysis done by Suc and colleagues³²⁹ suggested that there may be a benefit to using octreotide in a high-risk group of patients undergoing pancreaticoduodenectomy who have a pancreatic duct measuring <3 mm. Some studies suggest a higher rate of complications^{324,326} in patients who receive octreotide even though the difference was not statistically significant, while others report a significantly lower rate of complications with the use of octreotide.^{322,323} Finally, the optimal dose, route (IV drip vs. subcutaneous injection), and timing (preoperative, intraoperative, or postoperative) of octreotide use is unclear.

Many technical modifications to the classic pancreaticoduodenectomy have been described. However, >70 technical variations to the pancreaticoenteric anastomosis have not clearly demonstrated an objective method to consistently decrease the rate of fistula, which varies from 0

to 40% depending on the definition of fistula.^{324,325,330–338} Yeo compared the incidence of pancreatic fistula in patients who had a pancreaticoduodenectomy with reconstruction via a pancreaticogastrostomy or pancreaticojejunostomy.³³⁸ There was no significant difference between the two techniques in the incidence of pancreatic fistula. A recent meta-analysis summarized the results of 16 trials comparing pancreaticogastrostomy to pancreaticojejunostomy. All of the observational clinical studies reported superiority of pancreaticogastrostomy over pancreaticojejunostomy, most likely influenced by publication bias. In contrast, all randomized prospective trials failed to show advantage of a particular technique, suggesting both techniques provide equally good results.³³⁹

Other options to consider when performing the pancreatic anastomosis are the duct-to-mucosa vs. the invagination techniques. Many surgeons choose the technique at the time of operation, depending on the size of the pancreatic duct and the texture of pancreas.³⁴⁰ The duct-to-mucosa anastomosis results in a low pancreatic fistula rate³⁴¹ in patients with a large pancreatic duct and a fibrotic pancreas. However, the end-to-end invagination technique may be more secure in patients with a small duct and soft pancreas.

Even though there has been little convincing evidence for the use of a pancreatic duct stent, proponents suggest that a stent may discourage a pancreatic leak and aid in technical precision.^{342,343} Both internal stenting as well as external stenting have been shown to reduce the incidence of pancreatic fistula in some clinical studies.³⁴¹

Some studies^{336,344} suggest that an isolated Roux-en-Y pancreaticoenteric anastomosis may be associated with a lower rate of postoperative pancreatic leak. The logic behind this technical modification is that the use of separate Roux-en-Y limbs for biliary and pancreatic secretions may protect the pancreatic anastomosis from activated pancreatic enzymes.

Avoiding the pancreatic anastomosis altogether by ductal ligation or occlusion has also been evaluated as a potential technique to reduce the rate of postoperative pancreatic fistula.³⁴⁵ Ductal occlusion with neoprene or prolamine, which are nonresorbable glues, has been abandoned due to pancreatic atrophy and loss of exocrine function.³⁴⁶ Another study by Tran and associates³⁴⁷ comparing duct occlusion and pancreaticojejunostomy showed that duct occlusion significantly increases the risk of endocrine insufficiency without a decrease in the postoperative complication rate. To avoid long-term loss of function, absorbable glues, such as fibrin glue, have been evaluated to limit the action of pancreatic enzymes until the anastomosis is healed. Fibrin glue has been used for both duct occlusion and has also been applied to the surface of the pancreatic stump and anastomotic site without clear improvement in pancreatic fistula rate. The effect of BioGlue applied to the anastomotic surface after the Whipple procedure and pancreatic stump after distal pancreatectomy was recently evaluated in a retrospective cohort study. There were no statistically significant differences in the incidence or severity grades of postoperative pancreatic fistulas.³⁴⁸

If not combined with a biliary leak, pancreatic fistula, although serious, can usually be managed conservatively. In about 95% of cases, reoperation is not indicated and prolonged drainage, using drains placed in the original operation or percutaneously after resection, results in spontaneous closure of the fistula.³⁴⁹

Hemorrhage can occur either intraoperatively or postoperatively. Intraoperative hemorrhage typically occurs during the dissection of the portal vein. A major laceration of the portal vein can occur at a point in the operation at which the portal vein is not yet exposed. Temporary control of hemorrhage is generally possible in this situation by compressing the portal vein and superior mesenteric vein against the tumor with the surgeon's left hand behind the head of the pancreas. An experienced assistant is needed to divide the neck of the pancreas to the left of the portal vein and achieve proximal and distal control. Sometimes, the vein can be sutured closed with minimal narrowing. Other times, a segmental resection and interposition graft (internal jugular vein) may be needed.

Postoperative hemorrhage can occur from inadequate ligature of any one of numerous blood vessels during the procedure. Hemorrhage can also occur due to digestion of retroperitoneal blood vessels due to a combined biliary-pancreatic leak. Uncommonly, a stress ulcer, or later, a marginal ulcer, can result in GI hemorrhage. Typically, a vagotomy is not performed when pancreaticoduodenectomy is performed for pancreatic cancer, but patients are placed on proton pump inhibitors.

OUTCOME AND VALUE OF PANCREATICOUDUODENECTOMY FOR CANCER

Survival figures indicate that few, if any, patients are cured indefinitely of pancreatic cancer with pancreaticoduodenectomy. The tumor tends to recur locally with retroperitoneal and regional lymphatic disease. In addition, most patients also develop hematogenous metastases, usually in the liver. Malignant ascites, peritoneal implants, and malignant pleural effusions are all common. Median survival after pancreaticoduodenectomy is about 22 months. Even long-term (5-year) survivors often eventually die due to pancreatic cancer recurrence. Although pancreaticoduodenectomy may be performed with the hope of the rare cure in mind, the operation more importantly provides better palliation than any other treatment, and

is the only modality that offers any meaningful improvement in survival. If the procedure is performed without major complications, many months of palliation are usually achieved. It is the surgeon's duty to make sure patients and their families have a realistic understanding of the true goals of pancreaticoduodenectomy in the setting of pancreatic cancer.

ADJUVANT CHEMOTHERAPY AND RADIATION

Small studies in the 1980s suggested that adjuvant chemotherapy with 5-FU combined with radiation improves survival by about 9 months after pancreatic resection for pancreatic adenocarcinoma.³⁵⁰ Subsequent, noncontrolled studies have reinforced that concept; however, the data have been criticized due to the low number of patients and low dose of radiation therapy that was given. In addition, gemcitabine has recently replaced 5-FU as standard therapy in pancreatic cancer but is thought to be too toxic when given with radiotherapy at current doses. However, a recent large European multicenter trial concluded that there was no value to chemoradiotherapy, although the study suggested the possibility that chemotherapy alone might have survival benefit.³⁵¹ In contrast to that study, remarkable results in adjuvant therapy have been reported by the Virginia Mason Clinic with combination 5-FU, cisplatin, interferon- α and external beam radiation. Although the toxicity is high (42% hospitalized for GI toxicity), the promising results prompted larger confirmatory studies. Unfortunately, one such study was stopped due to toxicity. Nevertheless, pending further study, it is typical in the United States for patients with acceptable functional status to receive adjuvant chemotherapy and radiotherapy after surgery.

NEOADJUVANT TREATMENT

There are several potential advantages to the use of chemoradiation before an attempt at surgical resection. For example, it avoids the risk that adjuvant treatment is delayed by complications of surgery. Neoadjuvant treatment also may decrease the tumor burden at operation, increasing the rate of resectability and killing some tumor cells before they can be spread intraoperatively. Another potential advantage is that it allows patients with occult metastatic disease to avoid the morbidity of pancreatic resection. As many as 20% of patients treated with neoadjuvant chemoradiation develop metastatic disease detected by restaging CT and do not go on to surgery. Preoperative chemoradiation has been shown not to increase the perioperative morbidity or mortality of pancreaticoduodenectomy. It may even decrease the incidence of pancreatic fistula. However, level I data to support neoadjuvant over standard adjuvant chemoradiation in pancreatic cancer is lacking. Prospective randomized trials investigating this concept are ongoing but are difficult to complete due to the high number of patients who fail to complete or receive a full course of either therapy. Studies so far indicate that local or regional recurrence is decreased with this technique, but so far there is no generally accepted survival advantage compared to traditional postoperative therapy.³⁵²

POSTOPERATIVE SURVEILLANCE

Recurrence after successful resection usually manifests as hepatic metastases. After adjuvant chemoradiation with 5-FU and external beam radiation, gemcitabine is usually administered on a weekly basis for 6 months. During this time period, patients are monitored with frequent physical examinations and laboratory tests, including CA19-9. CT scans are typically ordered after a course of chemotherapy is completed or when a rising CA19-9 or new symptoms suggest recurrence. Surgical therapy for recurrent disease is usually reserved for patients who remain reasonable operative candidates who develop symptomatic gastric outlet or bowel obstruction.

FUTURE THERAPY

With recent developments in molecular biology techniques and the mapping of the entire human genome, new therapies for pancreatic cancer are becoming available. Several strategies are possible, including immunotherapeutic gene therapy, replacement of tumor suppressor gene function, inactivation of oncogenes, and suicide gene therapy.³⁵³ With immunotherapeutic gene therapy, the goal is to assist the immune system in recognizing the cancer cells. Cancer cells have been forced to express tumor-specific antigens and cytokines that activate the immune system and that may have antitumor effects. Because pancreatic cancer is a disease with multiple genetic aberrations, inactivated tumor suppressor genes have been replaced, and mutated oncogenes have been inactivated with gene therapy. In suicide gene therapy, a transgene is introduced that converts an inactive nontoxic drug into an active cytotoxic agent. The herpes simplex virus-thymidine kinase system has been the most extensively studied.³⁵³ Various delivery systems, including viral vectors, liposomes, and protein-conjugated DNA, exist. With each of these strategies and delivery systems, tumor cell-specific delivery would be extremely desirable but awaits the discovery of effective tumor-specific promoters. Clinical trials for pancreatic cancer are ongoing and offer hope for more meaningful treatment.

AMPULLARY AND PERIAMPULLARY CANCER

Ampullary cancers need to be distinguished from periampullary cancers. The ampulla is the junction of the biliary and pancreatic ducts within the

duodenum. Periapillary cancer includes tumors arising from the distal bile duct, duodenal mucosa, or pancreas just adjacent to the ampulla, and the ampulla can be overgrown by cancers that arise from these adjacent areas, making it impossible to determine the true site of origin. Clinically, the term *periampullary cancer* is, therefore, a nonspecific term used to refer to a variety of tumors arising at the intersection of these four sites. The term *ampullary cancer* is more specific and is reserved for tumors that arise at the ampulla. Based on their location, ampullary cancers are usually detected relatively early due to the appearance of jaundice and have a more favorable prognosis. The ampulla of Vater is lined by an epithelial layer that transitions from pancreatic and biliary ductal epithelium to duodenal mucosal epithelium. Ampullary adenocarcinomas can therefore have an intestinal and/or pancreaticobiliary histologic morphology, with the former having a better prognosis. Patients with ampullary cancer have a 10-year survival of about 35%, which is a much better prognosis than patients with pancreatic adenocarcinoma. The difference in survival is not entirely explained by an earlier presentation and lower incidence of lymph node metastases. There are probably biologic, particularly molecular, differences between ampullary and pancreatic adenocarcinoma of the pancreas. Intestinal type ampullary cancers have a lower incidence of EGFr and mutant p53 overexpression, and fewer activating K-*ras* mutations. These tumors are more likely to have genetic changes similar to colon cancer such as microsatellite instability and adenomatous polyposis coli mutations.

MANAGEMENT OF PERIAMPULLARY ADENOMAS

Benign tumors such as ampullary adenomas can also originate at the ampulla. The accuracy of endoscopic biopsy in distinguishing ampullary cancer from benign adenoma is poor with false negative rates from 25 to 56% even if sphincterotomy precedes the biopsy. However, benign villous adenomas of the ampullary region can be excised locally. This technique is applicable only for small tumors (approximately 2 cm or less) with no evidence of malignancy upon biopsy. EUS may help to accurately determine if there is invasion into the duodenal wall. In the absence of invasion, adenomas may be amenable to an endoscopic or transduodenal excision. A longitudinal duodenotomy is made and the tumor is excised with a 2- to 3-mm margin of normal duodenal mucosa. In some centers, small periampullary adenomas can also be removed endoscopically. A preoperative diagnosis of cancer is a contraindication to transduodenal excision, and pancreaticoduodenectomy should be performed. Likewise, if final pathologic examination of a locally excised tumor reveals invasive cancer, the patient should be returned to the operating room for a pancreaticoduodenectomy. An important subset of patients are those with FAP, who develop periampullary or duodenal adenomas. These lesions have a high incidence of harboring carcinoma, and frequently recur unless the mucosa at risk is resected. A standard (not pylorus-sparing) Whipple is the procedure of choice in FAP patients with periampullary lesions.

CYSTIC NEOPLASMS OF THE PANCREAS

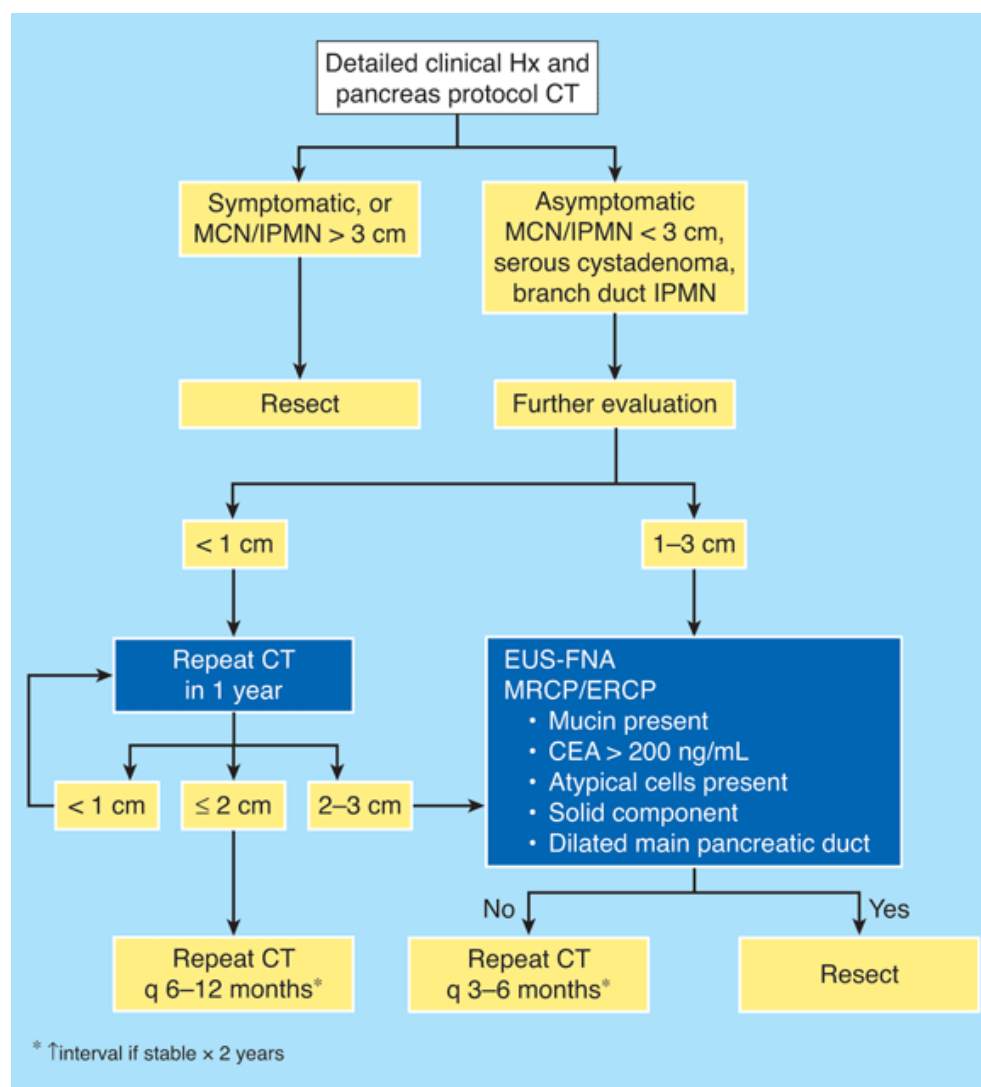

A cystic neoplasm needs to be considered when a patient presents with a fluid-containing pancreatic lesion (Fig. 33-76). Cystic neoplasms of the pancreas may be more frequent than previously recognized and are being identified with increasing frequency as the use of abdominal CT scanning has increased. Most of these lesions are benign or slow growing, and the prognosis is significantly better than with pancreatic adenocarcinoma. However, some of these neoplasms slowly undergo malignant transformation and thus represent an opportunity for surgical cure, which is exceedingly uncommon in the setting of pancreatic adenocarcinoma. The dilemma for the surgeon is an accurate assessment of the risk-benefit ratio of resection vs. observation of these lesions in individual patients. Radiologic features including the size of the lesion and its growth rate, the density of the lesion, characteristics of the wall such as nodules, septations, or calcifications, and the relationship between the lesion and the pancreatic duct can help categorize these lesions. Although a thorough history and radiographic findings often suggest a particular diagnosis, EUS-guided FNA and analysis of cyst fluid or ERCP provide useful additional information to guide clinical decision making. Cysts that contain thick fluid with mucin, elevated carcinoembryonic antigen (CEA), or atypical cells must be treated as potentially malignant (Fig. 33-77).

Algorithm for management of pancreatic cystic neoplasms. CEA = carcinoembryonic antigen; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; FNA = fine-needle aspiration; Hx = history; IPMN = intraductal papillary mucinous neoplasm of the pancreas; MCN = mucinous cystic neoplasm; MRCP = magnetic resonance cholangiopancreatography.

PSEUDOCYSTS

The most common cystic lesion of the pancreas is the pseudocyst, which, of course, has no epithelial lining and is a nonneoplastic complication of pancreatitis or pancreatic duct injury. As discussed in "Complications of Chronic Pancreatitis," the diagnosis is usually straightforward from the clinical history. Although not usually necessary, analysis of pseudocyst fluid would reveal a high amylase content. The danger comes in mistaking a cystic pancreatic neoplasm for a pseudocyst and incorrectly draining a cystic neoplasm into the GI tract rather than resecting the neoplasm. For this reason, biopsy of the pseudocyst wall is a common step in the management of pancreatic pseudocysts.

CYSTADENOMA

Serous cystadenomas are essentially considered benign tumors without malignant potential. Serous cystadenocarcinoma has been reported very rarely (<1%). Therefore, malignant potential should not be used as an argument for surgical resection, and the majority of these lesions can be safely observed in the absence of symptoms due to mass effect or rapid growth. The average rate of growth is about 0.45 cm/y. About 50% of cystadenomas are asymptomatic and detected as an incidental finding. Most symptomatic patients have mild upper abdominal pain, epigastric fullness, or moderate weight loss. Occasionally, cystadenomas can grow to a size capable of producing jaundice or GI obstruction due to mass effect (Fig. 33-78). For symptomatic patients with serous cystadenoma, surgical resection is indicated. For lesions in the tail, splenectomy is not necessary, given the benign nature of the tumor. In appropriate candidates, a laparoscopic approach to distal pancreatectomy can be considered.^{354,355} These cysts are frequently found in older women in which pancreatic resection for a benign neoplasm should be avoided in the

absence of significant symptoms. All regions of the pancreas are affected, with half in the head/uncinate process, and half in the neck, body, or tail of the pancreas. They have a spongy appearance, and multiple small cysts (microcystic) are more common than larger cysts (macroscopic or oligocystic). These lesions contain thin serous fluid that does not stain positive for mucin and is low in CEA (<200 ng/mL). Typical imaging characteristics include a well-circumscribed cystic mass, small septations, fluid close to water density, and sometimes, a central scar with calcification. If a conservative management is adopted, it is important to be sure of the diagnosis. EUS-FNA should yield nonviscous fluid with low CEA and amylase levels, and if cells are obtained, which is rare, they are cuboidal and have a clear cytoplasm.

MUCINOUS CYSTADENOMA AND CYSTADENOCARCINOMA

Mucinous cystic neoplasms (MCNs) encompass a spectrum ranging from benign but potentially malignant to carcinoma with a very aggressive behavior (Table 33-20). There is often heterogeneity within the lesions with benign and malignant-appearing regions, making it impossible to exclude malignancy with biopsy. MCNs are commonly seen in perimenopausal women, and about two-thirds are located in the body or tail of the pancreas. Like cystadenomas, most MCNs are now incidental findings identified during imaging performed for other reasons. When symptoms are present, they are usually nonspecific and include upper abdominal discomfort or pain, early satiety, and weight loss. On imaging studies, the cysts have thick walls and do not communicate with the main pancreatic duct (see Fig. 33-76). There may be nodules or calcifications within the wall of the cyst. The cysts are lined by tall columnar epithelium that fills the cyst with viscous mucin. The submucosal layer consists of a highly cellular stroma of spindle cells with elongated nuclei similar to the "ovarian stroma," which is a key pathologic feature distinguishing these lesions. Elevated CEA levels in the fluid (>200 ng/mL) may suggest malignant transformation. Solid areas may contain atypical cells or invasive cancer, and extensive sampling of the specimen is necessary to accurately predict prognosis. Resection is the treatment of choice for most mucin-producing cystic tumors. Malignancy cannot be ruled out without removal and extensive sampling of the tumor. Current thinking is that all of these tumors will eventually evolve into cancer if left untreated. Malignant transformation is more common with larger tumors, and older patients, and there appears to be a stepwise accumulation of mutations (K-ras, p53). Because most MCNs are located in the body and tail of the pancreas, distal pancreatectomy is the most common treatment. For small lesions, it may be appropriate to preserve the spleen but splenectomy ensures removal of the lymph node basin that can potentially be involved. It is very important not to rupture the cyst during resection and the tumor should be removed intact, not morselized. Therefore, a laparoscopic approach may not be appropriate for larger lesions. Completely resected MCNs without atypia are usually cured especially if small (<3 cm). Even patients with moderate dysplasia or carcinoma in situ are usually cured by complete resection. In the presence of invasive carcinoma, mucinous cystadenocarcinoma, the prognosis is dismal, similar to typical ductal adenocarcinoma of the pancreas.

Table 33-20 World Health Organization Classification of Primary Tumors of the Exocrine Pancreas
A. Benign
1. Serous cystadenoma (16%)
2. Mucinous cystadenoma (45%)
3. Intraductal papillary-mucinous adenoma (32%)
4. Mature cystic teratoma
B. Borderline
1. Mucinous cystic tumor with moderate dysplasia
2. Intraductal papillary mucinous tumor with moderate dysplasia
3. Solid pseudopapillary tumor
C. Malignant
1. Ductal adenocarcinoma
2. Serous/mucinous cystadenocarcinoma (29%)
3. Intraductal mucinous papillary tumor

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM

Intraductal papillary mucinous neoplasms (IPMNs) usually occur within the head of the pancreas and arise within the pancreatic ducts. The ductal epithelium forms a papillary projection into the duct, and mucin production causes intraluminal cystic dilation of the pancreatic ducts. Imaging studies demonstrate diffuse dilation of the pancreatic duct, and the pancreatic parenchyma is often atrophic due to chronic duct obstruction. However, classic features of chronic pancreatitis, such as calcification and a beaded appearance of the duct, are not present. At ERCP, mucin can be seen extruding from the ampulla of Vater, a so-called *fish-eye lesion*, that is virtually diagnostic of IPMN (Fig. 33-79). Initial reports suggested a male predominance, but more recent series indicate an equal distribution. Patients are usually in their seventh to eighth decade of life and present with abdominal pain or recurrent pancreatitis, thought to be caused by obstruction of the pancreatic duct by thick mucin. Some patients (5 to 10%) have steatorrhea, diabetes, and weight loss secondary to pancreatic insufficiency. Some IPMNs primarily involve the main pancreatic duct, while others involve the branch ducts (Figs. 33-80 and 33-81). Branch-duct type IPMNs are often found in the uncinate process, are sometimes asymptomatic, and are less frequently associated with malignant transformation. The surgical management of IPMNs is complicated by the fact that

the lesion itself is small and preoperative imaging studies show a dilated pancreatic duct but not necessarily the mass. Mucus can dilate the duct proximal and distal to the lesion. Furthermore, these lesions can spread microscopically along the duct, and there can be skip areas of normal duct between the diseased portions.

Operative specimen of pancreas with multifocal intraductal papillary mucinous neoplasms (*black arrow*) and a focus of invasive adenocarcinoma (*white arrow*).

(From Asiyanbola B, Andersen DK: IPMN. Editorial Update. AccessSurgery, McGraw-Hill, 2008, with permission.)

Therefore, thorough preoperative imaging including EUS, MRCP, or ERCP, and sometimes pancreatic ductoscopy, which can also be repeated intraoperatively, is useful (see Fig. 33-79). The surgeon needs to be prepared to extend the resection, if necessary, based on intraoperative findings and frozen section of the margin. Extending the resection to the point of total pancreatectomy is controversial due to the morbidity of this operation. Like MCNs, the IPMNs require careful histologic examination of the entire specimen for an invasive component, which is present in about 35 to 40% of cases.

Survival of patients with IPMN, even when malignant and invasive, can be quite good. As with MCN, patients with borderline tumors or carcinoma in situ are usually cured. In IPMN associated with invasive carcinoma, the 5- and 10-year survival is 60% and 50%, which is much better than typical pancreatic adenocarcinoma.³⁵⁶

For this reason, if recurrence occurs in the remaining pancreas, further resection is warranted because several series have shown that some of these cases are salvageable. Patients with IPMN are also at risk for other malignancies and should undergo colonoscopy and close surveillance.

SOLID-PSEUDOPAPILLARY TUMOR

Solid-pseudopapillary tumors are rare and typically occur in young women. Previous names for this entity include, *solid and cystic*, *solid and papillary*, *cystic and papillary*, and *papillary-cystic tumor*. They are typically well circumscribed on CT (Fig. 33-82). The cysts are not true epithelial-lined cysts but rather represent a necrotic/degenerative process. Histology may be similar to neuroendocrine tumors, but they do not stain positive for neuroendocrine markers such as chromogranin. Most are cured by resection but liver and peritoneal metastasis has been reported.

Fig. 33-82.

Abdominal computed tomographic scan of a 25-year-old woman demonstrating a well-circumscribed cystic lesion with septation in body/tail of pancreas. At surgery, the tumor was adherent to the splenic artery. Pathologic diagnosis was solid-pseudopapillary carcinoma.

OTHER CYSTIC NEOPLASMS

Rarely, typical ductal adenocarcinoma of the pancreas may undergo cystic degeneration due to central necrosis. Occasionally, this will create difficulty in the proper preoperative diagnosis and should be kept in mind when deciding to conservatively follow a cystic pancreatic neoplasm. It is more common, 5 to 10%, for neuroendocrine tumors of the pancreas to contain cysts. These cysts are filled with serosanguineous fluid rather than necrotic debris. Lymphoepithelial cysts of the pancreas usually occur in men in their fifth to sixth decade. These benign lesions may be unilocular or multilocular and vary widely in size. The contents of the cyst are also variable and may be thin serous fluid or cheesy/caseous material if there is increased keratin formation. A substantial number of patients with von Hippel-Lindau syndrome develop pancreatic cysts that resemble serous cystadenomas. There may be multiple lesions scattered throughout the pancreas. Patients with polycystic kidney and hepatic disease may also develop benign pancreatic cysts (cystadenomas). With all of these rare cystic neoplasms, careful clinical history, high-quality pancreatic imaging, and sampling of the cyst fluid for analysis will guide proper treatment.

PANCREATIC LYMPHOMA

Lymphoma can affect the pancreas. Primary involvement of the pancreas with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases. If the diagnosis cannot be confirmed preoperatively, laparoscopic exploration and biopsy are indicated.³⁵⁷ There is no role for resection in the management of pancreatic lymphoma. Endoscopic stenting to relieve jaundice followed by chemotherapy is the standard treatment, and long-term remission is often achieved.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 34. Spleen >

KEY POINTS

1. The human spleen plays a key immunologic role in defense against a number of organisms, particularly encapsulated bacteria.
2. The spleen can cause significant morbidity and/or hematologic disturbance if it becomes hyperfunctioning (hypersplenism) or hypertrophied (splenomegaly).
3. There is a broad spectrum of nontraumatic diseases for which elective splenectomy can be curative or palliative. They can be broadly categorized as red blood cell disorders and hemoglobinopathies, white blood cell disorders, platelet disorders, bone marrow disorders, infections and abscesses, cysts and tumors, storage diseases and infiltrative disorders, and miscellaneous conditions.
4. Partial splenectomy may be a suitable alternative to total splenectomy for certain conditions of hypersplenism or splenomegaly, particularly in children in whom preservation of splenic immunologic function is especially important.
5. Preoperative splenic artery embolization for elective splenectomy has benefits and disadvantages. It may be most suitable in cases of enlarged spleen. Conclusive evidence is lacking.
6. Overwhelming postsplenectomy infection (OPSI) is an uncommon but potentially grave disease. Children and those undergoing splenectomy for hematologic malignancy are at elevated risk.
7. Vaccination of the splenectomized patient remains the most effective prevention strategy against OPSI. Preoperative vaccination before elective splenectomy is most prudent.
8. Antibiotic prophylactic strategies against OPSI vary widely. Data regarding their use are lacking.
9. Laparoscopic splenectomy provides equal hematologic outcomes with decreased morbidity compared with the open operation. The laparoscopic approach has emerged as the standard for elective, nontraumatic splenectomy.
10. Inadvertent intraoperative splenic injury is a scenario for which every abdominal surgeon should be prepared. Availability of a predetermined algorithm, with emphasis on the patient's condition, facilitates intraoperative decision making.

HISTORICAL BACKGROUND

The spleen has had a remarkable number of attributes and functions ascribed to it throughout history. In 350 B.C. Aristotle described how the "hot character" of the spleen aided in digestion. Writings dating back to the first century variously describe the spleen as the seat of laughter and also as the source of black bile giving rise to melancholy. Thus the term *spleen* came to be associated with the derivative meaning of "ill temper." Historically, credence was given to the idea of the spleen as a locus of conflicting emotions. In the midseventeenth century Blackmore characterized the spleen as the organ to which "Hypochondrial and Hysterical Affections" could be attributed. Throughout the centuries the spleen also has been considered

an impediment to fleetness of foot for both man and beast. Until modern times, however, removal of the spleen usually resulted in the death of the patient.

Anecdotal reports of splenic surgery began to emerge in the sixteenth century. By the end of the eighteenth century, the vast majority of splenectomies performed were partial, with the majority of patients requiring surgical attention for left upper quadrant stab wounds resulting in partial or total splenic prolapse. By 1877 only 50 splenectomies had ever been performed, with a mortality rate of >70%. Yet by 1900, large series of splenectomies were reported with an operative mortality rate that had already dropped to <40%, and a 1920 report¹ of the Mayo Clinic experience with splenectomy noted an 11% mortality rate. Somewhat less dramatic progress has since occurred, with the largest series of laparoscopic splenectomies reporting \leq 1% overall mortality.^{2,3}

EMBRYOLOGY AND ANATOMY

Consisting of an encapsulated mass of vascular and lymphoid tissue, the spleen is the largest reticuloendothelial organ in the body. Arising from the primitive mesoderm as an outgrowth of the left side of the dorsal mesogastrium, by the fifth week of gestation the spleen is evident in an embryo 8 mm long. The organ continues its differentiation and migration to the left upper quadrant, where it comes to rest with its smooth, diaphragmatic surface facing posterosuperiorly.³

The most common anomaly of splenic embryology is the accessory spleen. Present in up to 20% of the population, one or more accessory spleens may also occur in up to 30% of patients with hematologic disease. Over 80% of accessory spleens are found in the region of the splenic hilum and vascular pedicle. Other locations for accessory spleens in descending order of frequency are the gastrocolic ligament, the pancreas tail, the greater omentum, the stomach's greater curve, the splenocolic ligament, the small and large bowel mesentery, the left broad ligament in women, and the left spermatic cord in men (Fig. 34-1).^{4,5}

The abdominal surface of the diaphragm separates the spleen from the lower left lung and pleura and the ninth to eleventh ribs. The visceral surface faces the abdominal cavity and contains gastric, colic, renal, and pancreatic impressions. Spleen size and weight vary with age, with both diminishing in the elderly and in those with underlying pathologic conditions. The average adult spleen is 7 to 11 cm in length and weighs 150 g (range 70 to 250 g). Splenomegaly is described variably within the surgical literature as *moderate*, *massive*, and *hyper*, which reflects a lack of consensus. Most would agree, however, that *splenomegaly* applies to organs weighing ≥ 500 g and/or averaging ≥ 15 cm in length.

Massive splenomegaly similarly lacks a consensus definition but has been described variably as spleens >1 kg in mass or >22 cm in length (Fig. 34-2).⁶ Spleens palpable below the left costal margin are thought to be at least double normal size, with an estimated weight of ≥ 750 g.⁶

Splenomegaly, shown in a three-dimensional reconstruction of computed tomographic scans.
(Courtesy of Ivan George, University of Maryland School of Medicine.)

The spleen's superior border separates the diaphragmatic surface from the gastric impression of the visceral surface and often contains one or two notches, which are particularly pronounced when the spleen is greatly enlarged.

Of particular clinical relevance, the spleen is suspended in position by several ligaments and peritoneal folds to the colon (splenocolic ligament), the stomach (gastrosplenic ligament), the diaphragm (phrenosplenic ligament), and the kidney, adrenal gland, and tail of the pancreas (splenorenal ligament) (Fig. 34-3). The gastrosplenic ligament contains the short gastric vessels; the remaining ligaments are avascular, with rare exceptions, such as in patients with portal hypertension. The relationship of the pancreas to the spleen also has important clinical implications. In cadaveric anatomic series, the tail of the pancreas has been demonstrated to lie within 1 cm of the splenic hilum 75% of the time and in 30% of patients actually to abut the spleen.²

Fig. 34-3.

The spleen derives most of its blood from the splenic artery, the longest and most tortuous of the three main branches of the celiac artery. The splenic artery can be characterized by the pattern of its terminal branches. The *distributed type* of splenic artery is the most common (70%) and is distinguished by a short trunk with many long branches entering over three fourths of the spleen's medial surface. The less common *magistral type* of splenic artery (30%) has a long main trunk dividing near the hilum into short terminal branches, and these enter over 25 to 30% of the spleen's medial surface. The spleen also receives some of its blood supply from the short gastric vessels that branch from the left gastroepiploic artery running within the gastrosplenic ligament. The splenic vein joins the superior mesenteric vein to form the portal vein and accommodates the major venous drainage of the spleen.

When a normal, freshly excised spleen is sectioned, the cut surface is finely granular and predominantly dark red with whitish nodules distributed liberally across its expanse. This gross observation reflects the spleen's microstructure. The splenic parenchyma is composed of two main elements: the red pulp, constituting approximately 75% of total splenic volume, and the white pulp (Fig. 34-4). At the interface between the red and white pulp is the narrow marginal zone.

Fig. 34-4.

The red pulp is comprised of large numbers of venous sinuses, which ultimately drain into tributaries of the splenic vein. The sinuses are surrounded and separated by the reticulum, a fibrocellular network of collagen fibers and fibroblasts. Within this network or mesh lie splenic macrophages. These intersinusoidal regions appear as *splenic cords*. The venous sinuses are lined by long, narrow endothelial cells that are variably in close apposition to one another or are separated by intercellular gaps in a configuration unique to the spleen. The red pulp serves as a dynamic filtration system, enabling macrophages to remove microorganisms, cellular debris, antigen-antibody complexes, and senescent erythrocytes from the circulation.

Around the terminal millimeters of splenic arterioles, a *periarticular lymphatic sheath* replaces the native adventitia of the vessel. The sheath is comprised of T lymphocytes and intermittent aggregations of B lymphocytes or lymphoid follicles. When antigenically stimulated, the follicles, serving as centers of lymphocyte proliferation, develop germinal centers, which regress as the stimulus or infection subsides. This white pulp consists of nodules that normally are ≤ 1 mm in size but can increase to several centimeters when nodules coalesce, as occurs in certain lymphoproliferative disorders. At the junction between the white and red pulp is the marginal zone, where lymphocytes are more loosely aggregated. Blood is delivered from this zone to the red pulp, where lymphocytes and locally produced immunoglobulins ultimately enter the systemic circulation.

PHYSIOLOGY AND PATHOPHYSIOLOGY

The spleen is contained by a 1- to 2-mm thick capsule. In humans, the capsule is rich in collagen and contains some elastin fibers. Many mammals have splenic capsules and trabeculae with abundant smooth muscle cells, which upon autonomic stimulation contract to expel large volumes of stored blood into the general circulation. Such spleens are descriptively characterized as *storage spleens*. The human splenic capsule and trabeculae, by contrast, contain few or no smooth muscle cells, and their function is largely related to immunologic protection. Thus the term *defense spleen* characterizes the human

organ.⁷ Historically the four splenic functions have been accurately noted as (a) filtration, (b) host defense, (c) storage, and (d) cytopoiesis. For the adult human, the most important, dominant functions are filtration and host defense.

Total splenic inflow of blood is approximately 250 to 300 mL/min. Blood flows through successively tapering arteries to arterioles, traverses the white pulp, crosses the marginal zone, and enters the red pulp. From that entry the flow rate through the spleen may vary greatly. Animal studies measuring the transit times of isotopically labeled blood through the spleen have revealed three distinct velocities of flow. Humans have long been recognized to have both a fast or closed circulation—with blood passing directly from arterioles into venous sinuses—and a slower or open circulation. Most of the spleen's filtration function occurs via the slower circulation. During open circulation, blood percolates through the reticular space and splenic cords, thus gaining access through gaps or slits in the endothelial cell lining to the sinuses. Flowing into and out of the venous sinuses through these gaps, the blood is exposed to extensive contact with splenic macrophages. In addition, because the passage of plasma through these spaces does not slow in a similar manner, a temporary and unique adhesive contact between blood cells and components of the splenic cord may occur. That there is a selective slowing of blood cell flow vs. plasma flow is further evidenced by the fact that within the spleen the erythrocyte concentration (hematocrit) is twice that of the general circulation. During this contact with splenic macrophages, it is likely that the removal of both cellular debris and senescent blood cells occurs.

The process by which the spleen removes erythrocyte inclusions, such as Heinz bodies (intracellular altered hemoglobin) without cell lysis while red blood cells travel through the spleen is not well understood. The spleen acts as the major site for clearance from the blood of damaged or aged red blood cells and in addition has a part in the removal of abnormal white blood cells and platelets. A minimum of 2 days of the erythrocyte's 120-day life cycle is spent sequestered in the spleen. Daily, approximately 20 mL of aged red blood cells are removed. Evidence suggests that, as erythrocytes age, previously undetected antigens on their surfaces may attach to autoantibodies in the circulation; then macrophages may bind to the antibodies and initiate phagocytosis. It is probable that the erythrocyte is damaged over time by multiple passages through the spleen as well as delayed transit through the congested and relatively hypoxic and acidotic environment of the splenic cords.

The spleen plays a significant although not indispensable role in host defense, contributing to both humoral and cell-mediated immunity. Antigens, described earlier, are filtered in the white pulp and presented to immunocompetent centers within the lymphoid follicles. This gives rise to the elaboration of immunoglobulins (predominantly immunoglobulin M). After an antigen challenge, such an acute immunoglobulin M response results in the release of opsonic antibodies from the white pulp of the spleen. Antigen clearance is then facilitated by the splenic and hepatic reticuloendothelial systems.

The spleen also produces opsonins, tuftsin, and properdin. Circulating monocytes are converted within the red pulp into fixed macrophages that account for the spleen's remarkable phagocytic activity.

The spleen also appears to be a major source of the protein properdin, important in the initiation of the alternate pathway of complement activation. The splenic reticuloendothelial system is better able to clear bacteria that are poorly or inadequately opsonized from the circulation than is the hepatic reticuloendothelial system.⁸ Encapsulated bacteria generally fit such a profile, hence the risk posed by pneumococcus and *Haemophilus influenzae* to an asplenic patient. There appears to be sufficient physiologic capacity within the complement cascade to withstand the loss of tuftsin and properdin production without an increase in patient vulnerability after splenectomy.⁹

In patients with chronic hemolytic disorders, splenic tissue may become permanently hypertrophied. The reticular spaces of

the red pulp become distended with macrophages engorged with the products of erythrocyte breakdown, and splenomegaly can result. It is important to distinguish between *splenomegaly* and *hypersplenism*, two similar but distinct terms that it is critical to understand when discussing splenic pathology. *Splenomegaly* refers simply to abnormal enlargement of the spleen. There is not a single universally accepted standard, but most would agree that an ex vivo mass of >1 kg or a pole-to-pole length of >15 cm generally qualifies as splenomegaly. Hypersplenism often is found in association with splenomegaly but is not synonymous with it. Hypersplenism is defined as the presence of one or more cytopenias in the context of a normally functioning bone marrow.

Disorders causing hypersplenism can be categorized as either (a) those in which increased destruction of abnormal blood cells occurs in an intrinsically normal spleen (e.g., hemolytic anemias) or (b) primary disorders of the spleen resulting in increased sequestration and destruction of normal blood cells (e.g., infiltrative disorders).

The life cycles of cellular elements vary widely in human blood. A neutrophil in circulation has a normal half-life of approximately 6 hours. The spleen's role in the normal clearance of neutrophils is not well established. It is clear that hypersplenism may result in neutropenia through sequestration of normal white blood cells or the removal of abnormal ones. Platelets, on the other hand, generally survive in the circulation for 10 days. Under normal circumstances a third of the total platelet pool is sequestered in the spleen. Thrombocytopenia may result from excessive sequestration of platelets as well as accelerated platelet destruction in the spleen. Splenomegaly may result in sequestration of up to 80% of the platelet pool. The spleen may also contribute to the immunologic alteration of platelets, which leads to thrombocytopenia in the absence of splenomegaly (e.g., idiopathic thrombocytopenic purpura, or ITP).

The immunologic functions of the spleen are consistent with those of other lymphoid organs. It is a site of blood-borne antigen presentation and the initiation of T- and B-lymphocyte activities involved in humoral and cellular immune responses. Alteration of splenic immune function often gives rise to antibody production, which results in blood cell destruction.

Although the spleen contributes to the process of erythrocyte maturation, in adult humans there is little evidence of normal hematopoietic function. The spleen does have a minor role in hematopoiesis in the fourth month in the human fetus, and reactivation can occur in childhood if the bone marrow fails to meet the hematologic needs. Splenic hematopoiesis giving rise to abnormal red blood cells is seen in adults with myeloproliferative disorders. In addition, in response to some anemias, elements of the red pulp may revert to hematopoiesis.

IMAGING FOR EVALUATION OF SIZE AND PATHOLOGY

Imaging of the spleen is performed most frequently to assess its size before elective splenectomy. Other indications for splenic imaging include trauma, investigations of left upper quadrant pain, characterization of splenic lesions such as tumors, cysts, and abscesses, and guidance for percutaneous procedures.^{10,11}

Ultrasound

Ultrasound is the least invasive mode of splenic imaging. It is rapid, easy to perform, and does not expose the patient to ionizing radiation. It is often the first imaging modality applied to the spleen during evaluation and resuscitation of the trauma patient, although questions of sensitivity and specificity remain.¹² In the elective setting, such as for routine diagnostic purposes or for preoperative planning, the sensitivity of ultrasound for detecting textural lesions of the spleen can be quite good in experienced hands. Percutaneous ultrasound-guided procedures for splenic disease (e.g., cyst aspiration, biopsy), historically avoided due to the risk of hemorrhage and other complications, are becoming more common as the safety of these procedures is being increasingly demonstrated.^{10,11}

Computed Tomography

Computed tomography (CT) affords a high degree of resolution and detail of the splenic parenchyma. Modern-day CT is more automated and thus less operator dependent than ultrasound, which makes it the preferred imaging modality for many practitioners. CT has become an invaluable tool in the evaluation and management of the blunt trauma patient, and standardized scoring systems for splenic trauma based on CT images now aid in management decisions.¹³ In the nontrauma setting, CT is extremely useful for assessment of splenomegaly, identification of solid and cystic lesions, and guidance of percutaneous procedures. The use of iodinated contrast material adds diagnostic clarity to CT imaging of the spleen, although at the cost of the small but real risks of renal impairment or allergic reaction.

Plain Radiography

Rarely is plain radiography used for primary splenic imaging. Plain films can indirectly provide an outline of the spleen in the left upper quadrant or suggest splenomegaly by revealing displacement of adjacent air-filled structures (e.g., the stomach or splenic flexure of the colon). Plain films may also demonstrate splenic calcifications. Splenic calcifications often are found in association with splenomegaly but are otherwise a nonspecific finding. Splenic calcifications can indicate a number of benign, neoplastic, or infectious processes, including phlebolith, splenic artery aneurysm, sickle cell changes, tumors (e.g., hemangioma, hemangiosarcoma, lymphoma), echinococcosis, or tuberculosis.¹⁴

Magnetic Resonance Imaging

Although magnetic resonance imaging offers excellent detail and versatility in abdominal imaging, it is more expensive than CT scanning or ultrasound and offers no obvious advantage for primary imaging of the spleen. Magnetic resonance imaging can be a valuable adjunct to the more commonly used imaging techniques when splenic disease is suspected but not definitively diagnosed.^{14,15}

Angiography

Angiography of the spleen most commonly refers to invasive arterial imaging, and when it is combined with therapeutic splenic arterial embolization (SAE), there are multiple applications for this procedure: localization and treatment of hemorrhage in select trauma patients¹⁶; delivery of a variety of therapies in patients with cirrhosis or portal and sinistral hypertension, and in transplant patients¹⁷; and adjunct (or, more controversially, as an alternative) to splenectomy for treatment of hematologic disorders such as ITP or hypersplenism.^{18,19} Preoperative or intraoperative SAE for elective splenectomy is also a common, although not universal, practice. Few prospective data have been published in the last 5 years on preoperative SAE. Preoperative SAE is purported not only to facilitate operation but also possibly to allow a laparoscopic approach in patients whose spleens had previously been considered too large for, or otherwise not amenable to, laparoscopic resection. Limited success in using partial SAE as an alternative to therapeutic splenectomy in chronic ITP has been previously reported.^{18,19} Its detractors argue that the need for increased analgesics and occasional extended hospital stay preoperatively, the possibility of pancreatitis, and the well-described risks of invasive arteriography negate any presumed benefits of preoperative SAE.

Nuclear Imaging

Radioscintigraphy with technetium Tc 99m sulfur colloid demonstrates splenic location and size. It may be especially helpful in locating accessory spleens after unsuccessful splenectomy for ITP and has recently proven useful in diagnosing splenosis.^{20,21}

Unfortunately, no conclusive outcome benefit has been shown for preoperative technetium scanning before splenectomy.²²

Splenic Index

The splenic index (SI) is a useful concept, initially proposed by Cools and colleagues,²³ expressing the volume of the spleen in milliliters. The SI is obtained by multiplying the spleen's length, width, and height as determined by a reliable imaging modality and using these values in a specific standard ellipsoid volume and linear regression formula.²⁴ Normal values for SI range from 120 mL to 480 mL, and the normal ex vivo weight of the spleen is approximately 150 g.²³

INDICATIONS FOR SPLENECTOMY

Splenectomy is therapeutic for a large host of conditions, which can be divided into the following broad categories: splenic rupture (trauma), red blood cell disorders and hemoglobinopathies, white blood cell disorders, platelet disorders, bone marrow disorders (myeloproliferative disorders), cysts and tumors, infections and abscesses, storage diseases and infiltrative disorders, and a number of miscellaneous disorders and lesions (Table 34-1).

Table 34-1 Indications for and Expected Response to Splenectomy in Various Diseases and Conditions		
Disease/Condition	Indications for Splenectomy	Response to Splenectomy
Hereditary spherocytosis	Hemolytic anemia, recurrent transfusions, intractable leg ulcers	Improves or eliminates anemia
Hereditary elliptocytosis	Limited role for splenectomy	—
Pyruvate kinase deficiency	Only in severe cases, recurrent transfusions	Decreased transfusion requirement, palliative only
Glucose-6-phosphate dehydrogenase deficiency	None	—
Warm-antibody autoimmune hemolytic anemia	Failure of medical (steroid) therapy	60–80% response rate, recurrences common
Sickle cell disease	History of acute sequestration crisis, splenic symptoms or infarction (consider concomitant cholecystectomy)	Palliative, variable response
Thalassemia	Excessive transfusion requirements, symptomatic splenomegaly or infarction	Diminished transfusion requirements, relief of symptoms
Acute myeloid leukemia (AML)	Intolerable symptomatic splenomegaly	Relief of abdominal pain and early satiety
Chronic myeloid leukemia	Symptomatic splenomegaly	Relief of abdominal pain and early satiety
Chronic myelomonocytic leukemia	Symptomatic splenomegaly	Relief of abdominal pain and early satiety
Essential thrombocythemia	Only for advanced disease (i.e., transformation to myeloid metaplasia or AML) with severe symptomatic splenomegaly	Relief of abdominal pain and early satiety
Polycythemia vera	Only for advanced disease (i.e., transformation to myeloid metaplasia or AML) with severe symptomatic splenomegaly	Relief of abdominal pain and early satiety

Myelofibrosis (agnogenic myeloid metaplasia)	Severe symptomatic splenomegaly	76% clinical response at 1 y, high risk of hemorrhagic, thrombotic, and infectious complications (26%)
Chronic lymphocytic leukemia	Cytopenias and anemia	75% response rate
Hairy cell leukemia	Cytopenias and symptomatic splenomegaly	40–70% response rate
Hodgkin's disease	Surgical staging in select cases	—
Non-Hodgkin's lymphoma	Cytopenias, symptomatic splenomegaly	Improved complete blood count values, relief of symptoms
Idiopathic thrombocytopenic purpura	Failure of medical therapy, recurrent disease	75–85% rate of long-term response
Thrombotic thrombocytopenic purpura	Excessive plasma exchange requirement	Typically curative
Abscesses of the spleen	Therapy of choice	Curative
Symptomatic parasitic cysts	Therapy of choice	Curative; exercise caution not to spill cyst contents
Symptomatic nonparasitic cysts	Partial splenectomy for small cysts; unroofing for large cysts	Curative
Gaucher's disease	Hypersplenism	Improves cytopenias; does not correct underlying disease
Niemann-Pick disease	Symptomatic splenomegaly	Improves symptoms; does not correct underlying disease
Amyloidosis	Symptomatic splenomegaly	Improves symptoms; does not correct underlying disease
Sarcoidosis	Hypersplenism or symptomatic splenomegaly	Improves symptoms and cytopenias; does not correct underlying disease
Felty's syndrome	Neutropenia	80% durable response rate
Splenic artery aneurysm	Splenectomy best for distal lesions near splenic hilum	Curative
Portal hypertension	Portal or sinistral hypertension due to splenic vein thrombosis	Palliative

Overall, the most common indication for splenectomy is trauma to the spleen, whether external trauma (blunt or penetrating) or iatrogenic injury (e.g., during operative procedures for other reasons). Inadvertent intraoperative injury to the spleen in the nontrauma patient is discussed in a later section. Management of splenic injury in the trauma patient is beyond the scope of this chapter. Regarding elective splenectomy, the most common indication in the past had been staging for Hodgkin's disease. More recent data suggest that ITP is now the most frequent indication for elective splenectomy.^{2,25}

Red Blood Cell Disorders

CONGENITAL

Hereditary Spherocytosis

Hereditary spherocytosis (HS) results from an inherited dysfunction or deficiency in one of the erythrocyte membrane

proteins (*spectrin*, *ankyrin*, *band 3 protein*, or *protein 4.2*). The resulting destabilization of the membrane lipid bilayer allows a pathologic release of membrane lipids. The red blood cell assumes a more spherical, less deformable shape, and the spherocytic erythrocytes are sequestered and destroyed in the spleen. Hemolytic anemia ensues; in fact, HS is the most common hemolytic anemia for which splenectomy is indicated.²⁶ HS is inherited primarily in an autosomal dominant fashion; the estimated prevalence in Western populations is 1 in 5000.

Patients with typical HS forms may have mild jaundice. Splenomegaly usually is present on physical examination. Laboratory examination reveals varying degrees of anemia: patients with mild forms of the disease may have no anemia; patients with severe forms may have hemoglobin levels as low as 4 to 6 g/dL. The mean corpuscular volume is typically low to normal or slightly decreased. For screening, a combined elevated mean corpuscular hemoglobin concentration and an elevated erythrocyte distribution width are an excellent predictor. Other laboratory indicators of HS include those providing evidence of rapid red blood cell destruction, including elevated reticulocyte count, elevated lactate dehydrogenase level, and increased level of unconjugated bilirubin. Spherocytes are readily apparent on peripheral blood film.

Dramatic clinical improvement—even despite persistent hemolysis—often occurs after splenectomy in patients with severe disease. Because children can be affected with HS, the timing of splenectomy is important and is aimed at reducing the quite small possibility of overwhelming postsplenectomy sepsis. Delaying such an operation until the patient is between the ages of 4 and 6—unless the anemia and hemolysis accelerate—is recommended by most.²⁶

Gallstones are more likely to develop in patients with HS, and over half of patients between the ages of 10 and 30 with HS have cholelithiasis.²⁷ For children with cholelithiasis prophylactic cholecystectomy is recommended at the time of splenectomy.²⁸

Hereditary elliptocytosis (HE) merits brief discussion to distinguish it from HS. Both HS and HE are conditions of the red blood cell membrane that result from genetic defects in skeletal membrane proteins. With the HE defect, the red blood cell elongates as it circulates, so that far fewer red blood cells are sequestered or destroyed when transiting the splenic parenchyma. Unless >50% of red blood cells are affected (a scenario that could permit development of a clinical syndrome like HS) HE may be considered harmless.

Red Blood Cell Enzyme Deficiencies

Red blood cell enzyme deficiencies associated with hemolytic anemia may be classified into two groups: deficiencies of enzymes involved in glycolytic pathways, such as pyruvate kinase (PK) deficiency, and deficiencies of enzymes needed to maintain a high ratio of reduced to oxidized glutathione in the red blood cell, protecting it from oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Pyruvate Kinase Deficiency

The most common red blood cell enzyme deficiency to cause congenital chronic hemolytic anemia is PK deficiency.²⁹ Its pathophysiology is unclear. PK deficiency affects people worldwide, with a slight preponderance among those of northern European or Chinese descent. Clinical manifestations of the disease vary widely, from transfusion-dependent severe anemia in early childhood to well-compensated mild anemia in adolescents or adults. Diagnosis is made either by a screening test or by detection of specific mutations at the complementary DNA or genomic level. Splenomegaly is common, and in severe cases splenectomy can alleviate transfusion requirements.⁵ As with other disorders that cause hemolytic anemia in children, splenectomy should be delayed if possible to at least 4 years of age to reduce the risk of postsplenectomy infection.

Glucose-6-Phosphate Dehydrogenase Deficiency

The most common red blood cell enzyme deficiency overall is G6PD deficiency. It is far more prevalent than PK deficiency with >400 million people affected worldwide, although most experience only moderate health risks and no longevity reduction.³⁰ Clinical manifestations—chronic hemolytic anemia, acute intermittent hemolytic episodes, or no hemolysis—depend on the variant of G6PD deficiency. The mainstay of therapy is avoidance of drugs known to precipitate hemolysis in patients with G6PD deficiency. Transfusions are given in cases of symptomatic anemia. Conventional wisdom is that splenectomy is not indicated in this disease,⁵ and certainly the overwhelming majority of patients with G6PD deficiency will neither require nor benefit from splenectomy. However, one report described a small collection of cases of six symptomatic G6PD deficiency patients who had severe hemolytic anemia and required transfusion, all of whom were identified to share a common mutation at exon 10.³⁰ All underwent splenectomy. A complete response occurred in four patients (transfusion requirement eliminated) and a partial response in one (transfusion requirement reduced); no follow-up data were provided for the remaining patient. This study indicates that for a carefully select group of patients with severe hemolytic anemia attributable to G6PD deficiency, splenectomy may be of benefit, although more data must be collected before such a recommendation can be made.

ACQUIRED

Warm-Antibody Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemias (AIHAs) are characterized by the destruction of red blood cells, whose erythrocyte life span is diminished by autoantibodies leveled against antigens. AIHA is classified as either primary or secondary, depending on whether an underlying cause, such as a disease or toxin, is identified. AIHA is also divided into "warm" and "cold" categories, based on the temperature at which the autoantibodies exert their effect. In cold-agglutinin disease severe symptoms are uncommon and splenectomy is almost never indicated; therefore, this entity is not discussed further in this section. However, warm-antibody AIHA has clinical consequences with which the surgeon should be familiar.

Warm-antibody AIHA, although occurring primarily in midlife, can affect individuals at all ages. The disorder is more common among women, and fully half of warm-antibody AIHA cases are idiopathic. Clinical presentation may be acute or gradual. Findings include mild jaundice and symptoms and signs of anemia. One third to one half of patients present with splenomegaly. Sometimes in such cases the spleen is palpable on physical examination. The diagnosis relies on demonstrating hemolysis as indicated by anemia, reticulocytosis, and/or products of red blood cell destruction, including bilirubin, in the blood, urine, and stool. A positive result on direct Coombs' test confirms the AIHA diagnosis by distinguishing autoimmune from other forms of hemolytic anemia.

Treatment of AIHA depends on the severity of the disease and whether it is primary or secondary. Severe symptomatic anemia demands prompt attention, often requiring red blood cell transfusion. The mainstay treatment for both primary and secondary forms of symptomatic, unstable AIHA is corticosteroids. Therapy should continue until a response is noted by a rise in hematocrit and fall in reticulocyte count, which generally occurs within 3 weeks.

Clinical response to splenectomy for AIHA varies, and the evidence from a number of small case series is conflicting. For example, one 2004 series reported a favorable response to splenectomy in patients with AIHA secondary to chronic lymphocytic leukemia,³¹ whereas more recent series found no benefit from splenectomy in patients with AIHA secondary to systemic lupus erythematosus or inflammatory bowel disease.³²

Favorable responses to splenectomy have been reported in patients with warm-antibody AIHA. Transient responses are more common, however, and many patients eventually experience hemolysis again despite splenectomy.^{31,32} The decision

regarding splenectomy in the case of AIHA should be individualized based on careful consideration of the clinical history and frank discussion with the patient.

Hemoglobinopathies

Sickle cell disease is an inherited chronic hemolytic anemia that results from the mutant sickle cell hemoglobin (HbS) within the red blood cell and is inherited in an autosomal codominant fashion. Persons who inherit an HbS gene from one parent (heterozygous) are carriers; those who inherit an HbS gene from both parents (homozygous) have sickle cell anemia.

In sickle cell disease the underlying abnormality is the mutation of adenine to thymine in the sixth codon of the β -globin gene, which results in the substitution of valine for glutamic acid as the sixth amino acid of the β -globin chain. Mutant β chains included in the hemoglobin tetramer create HbS. Deoxygenated HbS is insoluble and becomes polymerized and sickled. The subsequent lack of deformability of the red blood cell, in addition to other processes, results in microvascular congestion, which may lead to thrombosis, ischemia, and tissue necrosis. The disorder is characterized by painful intermittent episodes.

Sequestration occurs in the spleen, with splenomegaly resulting early in the disease course. In most patients subsequent infarction of the spleen and autosplenectomy occur at some later time.³³ The most frequent indications for splenectomy in sickle cell disease are recurrent acute sequestration crises, hypersplenism, and splenic abscess.³⁴ The occurrence of one major acute sequestration crisis, characterized by rapid painful enlargement of the spleen and circulatory collapse, generally is considered sufficient grounds for splenectomy. Preoperative preparation should include special attention to adequate hydration and avoidance of hypothermia.

Splenectomy does not affect the sickling process, and therapy for sickle cell anemia remains largely palliative. Transfusions are indicated for anemia, for moderately severe episodes of acute chest syndrome (i.e., a new infiltrate on chest radiograph associated with new symptoms, such as fever, cough, sputum production, or hypoxia),³⁵ and preoperatively before splenectomy. Patients experiencing stroke or a severe crisis may require hydration and an exchange transfusion, which may be performed manually or with automated apheresis equipment. Hydroxyurea is an oral chemotherapeutic agent that upregulates fetal hemoglobin, which interferes with polymerization of HbS and thus reduces the sickling process.

Thalassemia

Thalassemia is the term for a group of inherited disorders of hemoglobin synthesis prevalent among people of Mediterranean extraction and classified according to the hemoglobin chain (α , β , or γ) affected. As a group the thalassemias are the most common genetic diseases known to arise from a single gene defect.³⁶ Most forms of this disorder are inherited in Mendelian recessive fashion from asymptomatic carrier parents. In the so-called thalassemia belt that extends the shores of the Mediterranean as well as through the Arabian Peninsula, Turkey, Iran, India, and southeastern Asia the incidence of thalassemia is between 2.5 and 15%.³⁷ However, thalassemias have been found in people of all ethnic origins.³⁸

In all forms of thalassemia the primary defect is absent or reduced production of hemoglobin chains. From this abnormality two significant consequences arise: (1) reduced functioning of hemoglobin tetramers, yielding hypochromia and microcytosis; and (2) unbalanced biosynthesis of individual α and β subunits, which results in insoluble red blood cells that cannot release oxygen normally and may precipitate with cell aging. Both underproduction of hemoglobin and excess production of unpaired hemoglobin subunits contribute to thalassemia-associated morbidity and mortality.

A diagnosis of thalassemia major (homozygous form) is made by demonstrating hypochromic microcytic anemia associated

with randomly distorted red blood cells and nucleated erythrocytes (target cells) on peripheral blood smear.⁵ Elevated reticulocyte count and white blood cell count are among the associated findings. Because α chains are needed to form both fetal hemoglobin and adult hemoglobin, α -thalassemia becomes symptomatic in utero or at birth. By contrast, β -thalassemia becomes symptomatic at 4 to 6 months, because β chains are involved only in adult hemoglobin synthesis.

The clinical spectrum of the thalassemias is wide. Heterozygous carriers of the disease are usually asymptomatic. Homozygous individuals, on the other hand, typically present before 2 years of age with pallor, growth retardation, jaundice, and abdominal swelling due to liver and spleen enlargement. Among other characteristics of thalassemia major are intractable leg ulcers, head enlargement, frequent infections, and the need for periodic blood transfusions. Untreated individuals usually die in late infancy or early childhood from severe anemia.⁵

Treatment for thalassemia involves red blood cell transfusions to maintain a hemoglobin level of >9 mg/dL, along with intensive parenteral chelation therapy with deferoxamine. Splenectomy is indicated for patients with excessive transfusion requirements (>200 mL/kg per year), discomfort due to splenomegaly, or painful splenic infarction.^{5,39} Careful assessment of the risk:benefit ratio is essential. Thalassemia patients are at high risk for pulmonary hypertension after splenectomy; the precise etiology of this sequela is under investigation.⁴⁰ The increase in infectious complications is likely to be due to a coexisting immune deficiency, in large part brought about by iron overload, which may be associated both with the thalassemia itself and with transfusions. The disproportionately high rate of overwhelming postsplenectomy infection in thalassemia patients has led some investigators to consider partial splenectomy in children; some success in reducing mortality has been reported.⁴¹ However, splenectomy should be delayed until after the age of 4 years unless it is absolutely necessary.

White Blood Cell Disorders

The role of splenectomy in patients with white blood cell disorders varies. As for the myelogenous diseases mentioned previously, splenectomy for white blood cell disorders can be effective therapy for symptomatic splenomegaly and hypersplenism, improving some clinical parameters but generally not altering the course of the underlying disease. Historically, splenectomy has played a role during surgical staging for Hodgkin's disease, although this practice has become less common with the advent of advanced imaging technologies and less extensive biopsy strategies.⁴² Careful consideration of the intended benefits of splenectomy must be weighed against the significant perioperative and postsplenectomy risks in this often complex patient population.⁴³

CHRONIC LYMPHOCYTIC LEUKEMIA

The main characteristic of chronic lymphocytic leukemia (CLL) is a progressive accumulation of long-lived but nonfunctional lymphocytes. Symptoms of CLL are nonspecific and include weakness, fatigue, fever without illness, night sweats, and frequent bacterial and viral infections. The most frequent finding is lymphadenopathy. When the spleen is enlarged, it may be massive or barely palpable below the costal margin. Splenectomy is indicated to improve cytopenias and was shown to be 75% effective in a combined group of patients who had either CLL or nonmalignant Hodgkin's disease.⁴⁴ Splenectomy may facilitate chemotherapy in patients whose cell counts were prohibitively low before spleen removal. Palliative splenectomy also is indicated for symptomatic splenomegaly.

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) is an uncommon blood disorder, representing only 2% of all adult leukemias. HCL is characterized

by splenomegaly, pancytopenia, and large numbers of abnormal lymphocytes in the bone marrow. These lymphocytes contain irregular hair-like cytoplasmic projections identifiable on the peripheral smear. Many HCL patients have few symptoms and require no specific therapy. Splenectomy does not correct the underlying disorder but does return cell counts to normal in 40 to 70% of patients and alleviates symptoms of splenomegaly.^{45,46}

HODGKIN'S DISEASE

Hodgkin's disease (HD) is a disorder of the lymphoid system characterized by the presence of Reed-Sternberg cells (which actually form the minority of the Hodgkin's tumor). More than 90% of patients with HD present with lymphadenopathy above the diaphragm. Lymph nodes can become particularly bulky in the mediastinum, which may result in shortness of breath, cough, or obstructive pneumonia. Lymphadenopathy below the diaphragm is rare on presentation but can arise with disease progression. The spleen is often an occult site of spread, but massive splenomegaly is not common. In addition, large spleens do not necessarily signify involvement.

Four major histologic types exist: lymphocyte predominance type, nodular sclerosis type, mixed cellularity type, and lymphocyte depletion type. The histologic type, along with location of disease and symptomatology, influence survival for patients with HD. Stage I disease is limited to one anatomic region; stage II disease is defined by the presence of two or more contiguous or noncontiguous regions on the same side of the diaphragm; stage III disease involves disease on both sides of the diaphragm, but limited to lymph nodes, spleen, and Waldeyer's ring (the ring of lymphoid tissue formed by the lingual, palatine, and nasopharyngeal tonsils); stage IV disease includes involvement of the bone marrow, lung, liver, skin, GI tract, or any organ or tissue other than the lymph nodes or Waldeyer's ring.⁴⁷

Staging laparotomy for HD is less commonly performed in the current era of minimally invasive surgery and advanced imaging techniques. More liberal use of chemotherapy for patients with HD has significantly reduced the indications for surgical staging. Current indications for surgical staging include clinical stage I or II disease of the nodular sclerosing type and no symptoms referable to HD.⁵ The surgical staging procedure for HD includes a biopsy of the liver, splenectomy, and the removal of representative nodes in the retroperitoneum, mesentery, and hepatoduodenal ligament. An iliac marrow biopsy generally is included. Unlike in non-Hodgkin's lymphoma, studies have concluded that surgical staging has altered clinical staging in as many as 42% of cases (26 to 37% upgraded, 7 to 15% downgraded).⁵ Staging information affects treatment, because patients with early-stage disease who have no splenic involvement may be candidates for radiotherapy alone. Those with splenic involvement generally require chemotherapy or multimodality therapy.

NON-HODGKIN'S LYMPHOMA

Non-Hodgkin's lymphoma (NHL) encompasses all malignancies derived from the lymphoid system except classic HD. A proliferation of any one of the three predominant lymph cell types—natural killer cells, T cells, or B cells—may be included in the category of NHL. Because of the wide net cast by NHL, the clinical presentations of the disorders under its umbrella vary. The subentities of NHL may be clinically classified into nodal or extranodal, as well as indolent, aggressive, and very aggressive groups. Patients with indolent lymphomas may present with mild or no symptoms and seek medical attention for a swollen lymph node, whereas the aggressive and very aggressive lymphomas create easily noticeable symptoms, such as pain, swelling due to obstruction of vessels, fever, and night sweats. Surgical staging is no longer indicated for NHL, because the combination of history and physical examination, chest radiograph and abdominal/pelvic CT scan, biopsy of involved lymph nodes (including laparoscopically directed nodal and liver biopsies), and bone marrow biopsy is sufficient.⁵ Splenomegaly exists in some, but not all, forms of NHL, and splenectomy is indicated for management of symptoms related to an enlarged spleen as well as for improvement of cytopenias.

Platelet Disorders

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP), also called *immune thrombocytopenic purpura*, is an autoimmune disorder characterized by a low platelet count and mucocutaneous and petechial bleeding. The low platelet count stems from premature removal of platelets opsonized by antiplatelet immunoglobulin G autoantibodies produced in the spleen. This clearance occurs through the interaction of platelet autoantibodies with Fc receptors expressed on tissue macrophages, predominantly in the spleen and liver. The estimated incidence of ITP is 100 persons per million annually, about one half of whom are children.⁴⁸ Adult-onset and childhood-onset ITP are strikingly different in their clinical course and management.

Patients with ITP typically present with petechiae or ecchymoses, although some experience major bleeding from the outset. Bleeding may occur from mucosal surfaces in the form of gingival bleeding, epistaxis, menorrhagia, hematuria, or even melena. The severity of bleeding frequently corresponds to the deficiency in platelets: Patients with counts $>50,000/\text{mm}^3$ usually present with incidental findings; those with counts between 30,000 and 50,000/ mm^3 often have easy bruising; those with platelet counts between 10,000 and 30,000/ mm^3 may develop spontaneous petechiae or ecchymoses; and those with counts $<10,000/\text{mm}^3$ are at risk for internal bleeding.⁴⁸ The incidence of major intracranial hemorrhage is approximately 1%, and it usually occurs early in the disease course. The duration of the bleeding helps to distinguish acute from chronic forms of ITP. Children often present at a young age (peak age of approximately 5 years) with sudden onset of petechiae or purpura several days to weeks after an infectious illness. In contrast, adults experience a more chronic form of disease with an insidious onset. Splenomegaly is uncommon with ITP in both adults and children, and its occurrence should prompt a search for a separate cause of thrombocytopenia. Up to 10% of children, however, have a palpable spleen tip.⁴⁸

Diagnosis of ITP is based on exclusion of other possibilities in the presence of a low platelet count and mucocutaneous bleeding. Other diseases resulting in secondary forms of immune thrombocytopenic purpura, such as systemic lupus erythematosus, antiphospholipid syndrome, lymphoproliferative disorders, HIV infection, and hepatitis C should be identified and treated when present. In addition, any history of use of a drug known to cause thrombocytopenia, such as certain antimicrobials, anti-inflammatories, antihypertensives, and antidepressants, should be sought. In addition to low platelet count, another laboratory finding characteristic of ITP is the presence of large, immature platelets (megathrombocytes) on peripheral blood smear.

The usual first line of therapy is oral prednisone at a dosage of 1.0 to 1.5 mg/kg per day.⁴⁸ No consensus exists as to the optimal duration of steroid therapy, but most responses occur within the first 3 weeks. Response rates range from 50 to 75%, but relapses are common. IV immunoglobulin, given at 1.0 g/kg per day for 2 to 3 days, is indicated for internal bleeding when platelet counts remain $<5000/\text{mm}^3$ or when extensive purpura exists.⁴⁸ IV immunoglobulin is thought to impair clearance of immunoglobulin G-coated platelets by competing for binding to tissue macrophage receptors.⁴⁹ An immediate response is common but a sustained remission is not.⁵⁰ Splenectomy is indicated for failure of medical therapy, for prolonged use of steroids with undesirable effects, or for most cases of first relapse.⁵ Prolonged use of steroids can be defined in various ways, but a persistent need for more than 10 to 20 mg/d for 3 to 6 months to maintain a platelet count of $>30,000/\text{mm}^3$ generally prompts referral for splenectomy.⁴⁸ Splenectomy provides a permanent response without subsequent need for steroids in 75 to 85% of patients (see "Splenectomy Outcomes" later). Responses usually occur within the first postoperative week. For patients with extremely low platelet counts ($<10,000/\text{mm}^3$) platelets should be available for surgery but should not be given preoperatively. Once the splenic pedicle is ligated, platelets are given to those who continue to bleed.

In children with ITP, the course is self limited, with durable and complete remission in >70% of patients regardless of therapy. Because of the good prognosis without treatment, the decision to intervene is controversial and is based largely on the fear of intracranial hemorrhage discussed earlier. Therefore children with typical ITP—and certainly those without hemorrhage—are managed principally by observation, with short-term therapy in select cases. Urgent splenectomy, in conjunction with aggressive medical therapy, may play a role in the rare circumstance of severe, life-threatening bleeding in both children and adults.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a serious disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, and neurologic complications. Abnormal platelet clumping occurs in arterioles and capillaries, reducing the lumen of these vessels and predisposing the patient to microvascular thrombotic episodes. The reduced lumen size also causes shearing stresses on erythrocytes, which leads to deformed red blood cells subject to hemolysis. Hemolysis may be due in part to sequestration and destruction of erythrocytes in the spleen. Research has demonstrated that the underlying abnormality is likely related to the persistence of unusually large multimers of von Willebrand factor associated with platelet clumping in the patient's blood.⁵¹

TTP occurs in approximately 3.7 individuals per million,⁵² but this rare disorder's dramatic clinical sequelae and favorable response to early therapy demand an understanding of its clinical presentation to ensure an early diagnosis. Clinical features of the disorder include petechiae, fever, neurologic symptoms, renal failure, and, infrequently, cardiac symptoms such as heart failure or arrhythmias. Petechial hemorrhages in the lower extremities are the most common presenting sign. Along with fever, patients may experience flu-like symptoms, malaise, or fatigue. Neurologic changes range from generalized headaches to altered mental status, seizures, and even coma. Generally, however, the mere presence of petechiae and thrombocytopenia are sufficient to lead to the diagnosis of TTP and consideration of treatment.

The diagnosis is confirmed by the peripheral blood smear, which shows schistocytes, nucleated red blood cells, and basophilic stippling. Although other conditions such as tight aortic stenosis or prosthetic valves may lead to the presence of schistocytes, these conditions generally are not accompanied by thrombocytopenia. TTP may be distinguished from autoimmune causes of thrombocytopenia, such as Evans syndrome (ITP and autoimmune hemolytic anemia) or systemic lupus erythematosus, by a negative result on Coombs' test.⁵¹

Plasma exchange is the first-line therapy for TTP. This treatment consists of the daily removal of a single volume of the patient's plasma and its replacement with fresh-frozen plasma until the thrombocytopenia, anemia, and associated symptoms are corrected. Therapy is then tapered over 1 to 2 weeks.⁵¹ Splenectomy plays a key role for patients who experience relapse or who require multiple plasma exchanges to control symptoms, and generally is well tolerated without significant morbidity.⁵³

Bone Marrow Disorders (Myeloproliferative Disorders)

The myeloproliferative disorders are characterized by an abnormal growth of cell lines in the bone marrow. They include chronic myeloid leukemia, acute myeloid leukemia, chronic myelomonocytic leukemia, essential thrombocythemia, polycythemia vera, and myelofibrosis, also known as *agnogenic myeloid metaplasia* [see "Myelofibrosis (Agnogenic Myeloid Metaplasia)" later in this chapter]. The common underlying problem leading to splenectomy in these disorders is symptomatic splenomegaly. Symptoms due to splenomegaly consist of early satiety, poor gastric emptying, heaviness or pain in the left upper quadrant, and even diarrhea. Hypersplenism, when it occurs in these conditions, usually is associated with

splenomegaly. Splenectomy performed in the setting of the myeloproliferative disorders is generally for treatment of the pain, early satiety, and other symptoms of splenomegaly.

Splenomegaly can sometimes be treated nonsurgically by chemotherapeutic agents (busulfan, hydroxyurea, interferon- α) to achieve mild to moderate size reductions and some relief of symptoms, but discontinuation of treatment may result in rapid splenic regrowth. Radiation has been used since 1903 to treat symptomatic splenomegaly, but today it is principally used in situations in which splenectomy is not an option.

CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia (CML) is a disorder of the primitive pluripotent stem cell in the bone marrow that results in a significant increase in erythroid, megakaryotic, and pluripotent progenitors in the peripheral blood smear. The genetic hallmark is a transposition between the *bcr* gene on chromosome 9 and the *abl* gene on chromosome 22. CML accounts for 7 to 15% of all leukemias, with an incidence of 1.5 in 100,000 in the United States.⁵⁴ It is often asymptomatic, but CML can cause fatigue, anorexia, sweating, and left upper quadrant pain and early satiety secondary to splenomegaly. Enlargement of the spleen is found in roughly one half of patients with CML. Splenectomy is indicated to ease pain and early satiety.⁵⁵

ACUTE MYELOID LEUKEMIA

Like CML, acute myeloid leukemia (AML) involves the abnormal growth of stem cells in the bone marrow. Unlike CML, AML has a presentation that is more rapid and dramatic. The proliferation and accumulation of hematopoietic stem cells in the bone marrow and blood inhibit the growth and maturation of normal red blood cells, white blood cells, and platelets. Death usually results within weeks to months if AML goes untreated. The incidence of AML is approximately 9200 new cases each year in the United States, and it accounts for 1.2% of all cancer deaths.⁵⁶ Patients with other myeloproliferative disorders, such as polycythemia vera, primary thrombocytosis, or myeloid metaplasia, are at increased risk for leukemic transformation to AML. Presenting signs and symptoms of AML include a viral-like illness with fever, malaise, and frequently bone pain due to the expansion of the medullary space. Splenectomy is indicated in AML only in the uncommon circumstance that left upper quadrant pain and early satiety become unbearable. The benefit must be weighed against the heightened risk of postsplenectomy infection in AML patients immunocompromised due to neutropenia and chemotherapy.

CHRONIC MYELOMONOCYTIC LEUKEMIA

Like CML and AML, chronic myelomonocytic leukemia (CMML) is characterized by a proliferation of hematopoietic elements in the bone marrow and blood. CMML differs from CML in that it is associated with monocytosis in the peripheral smear ($>1 \times 10^3$ monocytes/mm³) and in the bone marrow. Splenomegaly occurs in one half of these patients, and splenectomy can result in symptomatic relief.

ESSENTIAL THROMBOCYTHEMIA

Essential thrombocythemia (ET) represents abnormal growth of the megakaryocyte cell line, resulting in increased levels of platelets in the bloodstream. The diagnosis is made after the exclusion of other chronic myeloid disorders such as CML, polycythemia vera, and myelofibrosis that may also present with thrombocytosis.⁵⁷ Clinical manifestations of ET include vasomotor symptoms, thrombohemorrhagic events, recurrent fetal loss, and the transformation to myelofibrosis with myeloid metaplasia or AML. Hydroxyurea is used to reduce thrombotic events in ET but does not alter transformation to myelofibrosis or leukemia. Splenomegaly occurs in one third to one half of patients with ET. Splenectomy is not felt to be helpful in the early stages of ET and is best reserved for the later stages of disease, when myeloid metaplasia has developed.⁵⁷ Even in

these circumstances, candidates should be chosen selectively, because significant bleeding has been reported to complicate splenectomy in these patients.

POLYCYTHEMIA VERA

Polycythemia vera (PV) is a clonal, chronic, progressive myeloproliferative disorder characterized by an increase in red blood cell mass, frequently accompanied by leukocytosis, thrombocytosis, and splenomegaly. Patients with PV typically enjoy longer survival than those affected by hematologic malignancies but remain at risk for transformation to myelofibrosis or AML. The disease is rare, with an annual incidence of 5 to 17 cases per million population.⁵⁸ Physical findings include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. Treatment should be tailored to the risk status of the patient and ranges from phlebotomy and aspirin administration to the use of chemotherapeutic agents. As in ET, splenectomy is not helpful in the early stages of disease and is best reserved for patients with late-stage disease in whom myeloid metaplasia has developed and splenomegaly-related symptoms are severe.⁵⁵

MYELOFIBROSIS (AGNOGENIC MYELOID METAPLASIA)

The term *myelofibrosis* may be used to describe either the generic condition of fibrosis of the bone marrow (which may be associated with a number of benign and malignant disorders) or a specific, chronic, malignant hematologic disease associated with splenomegaly, the presence of red blood cell and white blood cell progenitors in the bloodstream, marrow fibrosis, and extramedullary hematopoiesis, otherwise known as *agnogenic myeloid metaplasia (AMM)*. AMM also can be referred to as *myelosclerosis*, *idiopathic myeloid metaplasia*, and *osteosclerosis*. In this chapter the term *myelofibrosis* is synonymous with AMM.

In AMM fibrosis of the bone marrow is believed to be a response to a clonal proliferation of hematopoietic stem cells. Marrow failure is common. The true incidence of AMM is unknown due to the scarcity of epidemiologic data, but one study estimated its U.S. incidence at 1.46 per 100,000 population.⁵⁹ Excessive radiation exposure may play a role in the development of AMM, because persons within close proximity of the atomic bomb blasts in Japan, as well as those with a history of exposure to the contrast agent thorium dioxide (Thorotrast), have been shown to exhibit a higher incidence of AMM.

The diagnosis is made by a careful examination of the peripheral blood smear and bone marrow. Nucleated red blood cells and immature myeloid elements in the blood are present in 96% of cases and strongly suggest the diagnosis. Teardrop poikilocytosis is another frequent finding. Care must be taken, however, to exclude a history of a primary neoplasm (such as lymphoma or adenocarcinoma of the stomach, lung, prostate, or breast) or tuberculosis, because patients with these conditions may develop secondary myelofibrosis.

Treatment depends on symptoms: Asymptomatic patients are closely followed, whereas symptomatic patients undergo therapeutic intervention targeted to their symptoms.⁶⁰ Splenomegaly-related symptoms are best treated with splenectomy. Although some chemotherapeutic agents (busulfan, hydroxyurea, interferon- α) and low-dose radiation can reduce splenic size, their discontinuation usually results in rapid splenic regrowth.

A thorough preoperative work-up must precede splenectomy in patients with AMM. The candidate must possess acceptable cardiac, pulmonary, hepatic, and renal reserve for the operation. The coagulation system should be examined; testing should include measurement of coagulation factors V and VIII and fibrin split products, platelet count, and bleeding time. Low platelet counts may require administration of adrenal steroids and/or platelet transfusion at the time of surgery. Splenectomy provides durable, effective palliation for nearly all patients with AMM, although postoperative complications are more common in patients with AMM than in those with other hematologic indications.⁵ The Mayo Clinic recently published its 30-year

experience with 314 myelofibrosis patients who underwent splenectomy: nearly half of the operations (49%) were performed to alleviate the mechanical symptoms of splenomegaly; the remainder were undertaken to manage anemia, thrombocytopenia, or portal hypertension. Response to splenectomy was 76% overall at 1 year; overall complication rate was 28%, including 21 perioperative deaths.⁶¹ Thrombosis, hemorrhage, and infection complications were common, with preoperative thrombocytopenia an independent predictor of mortality risk. These data underscore the severity of this malignancy and emphasize need for careful patient selection when considering splenectomy in AMM.

Infections and Abscesses

Primary infections of the spleen are infrequently reported. However, the potential effects of certain systemic infections on the spleen merit close attention, mostly because of the potential risk of spontaneous splenic rupture. Infectious mononucleosis due to either Epstein-Barr virus or cytomegalovirus infection imparts a small but often-discussed risk of spontaneous splenic rupture in both adults and children. The true incidence may be underreported, however. Recent case reports abound in the literature regarding spontaneous splenic rupture due to a variety of infectious causes (malaria, *Listeria* infection, fungal infections, dengue, and Q fever, to name a few) as well as a variety of neoplastic and other noninfectious causes (lymphoma, angiosarcoma, amyloidosis, pregnancy). The presumed pathophysiologic mechanism is infiltration of the splenic parenchyma with inflammatory cells, which distorts the architecture and fibrous support system of the spleen and thins the splenic capsule.⁶² In this setting, splenic rupture can occur spontaneously or after a seemingly minor external trauma or even a Valsalva maneuver.⁶³

Abscesses of the spleen are uncommon, with an incidence of 0.14 to 0.7% based on autopsy findings.⁶⁴ They occur more frequently in tropical locations, where they are associated with thrombosed splenic vessels and infarction in patients with sickle cell anemia. Five distinct mechanisms of splenic abscess formation have been described: (a) hematogenous infection; (b) contiguous infection; (c) hemoglobinopathy; (d) immunosuppression, including HIV infection and chemotherapy; and (e) trauma. Presentation frequently is delayed, with most patients enduring symptoms for 16 to 22 days before diagnosis. Clinical manifestations include fever, left upper quadrant pain, leukocytosis, and splenomegaly in about one third of patients. The diagnosis is confirmed by ultrasound or CT scan, which has a 95% sensitivity and specificity. Upon discovery of a splenic abscess, broad-spectrum antibiotics should be started, with adjustment to more specific therapy based on culture results and continuation of treatment for 14 days. Splenectomy is the operation of choice, but percutaneous and open drainage are options for patients who cannot tolerate splenectomy.⁵ Percutaneous drainage is successful for patients with unilocular disease.

Cysts and Tumors

Splenic cysts can be categorized according to a number of criteria; one clinically relevant scheme is to characterize splenic cysts as either parasitic or nonparasitic.

Parasitic infection is the most common cause of splenic cysts worldwide, and the majority are due to *Echinococcus* species. Such cysts are more commonly found in areas where the pathogen is endemic. Symptoms, when present, generally are related to the presence of a mass lesion in the left upper quadrant or a lesion that impinges on the stomach. Ultrasound can establish the presence of a cystic lesion and occasionally incidentally detect asymptomatic lesions as well. Serologic testing for echinococcal antibodies can confirm or exclude the cystic lesion as parasitic, an important piece of information when planning operative therapy. Symptomatic parasitic cysts are best treated with splenectomy. Avoidance of spillage of parasitic cyst contents into the peritoneal cavity to avoid the possibility of anaphylactic shock is an important principle in surgical

management.

Cysts resulting from trauma are termed *pseudocysts* due to their lack of cellular lining. Less common examples of nonparasitic cysts are dermoid, epidermoid, and epithelial cysts.⁶⁵ The treatment of nonparasitic cysts depends on whether or not they produce symptoms. Asymptomatic nonparasitic cysts may be observed with close follow-up by ultrasound to exclude significant expansion. Patients should be advised of the risk of cyst rupture with even minor abdominal trauma if they elect nonoperative management for large cysts. Small symptomatic nonparasitic cysts may be excised with splenic preservation, and large symptomatic nonparasitic cysts may be unroofed. Both of these operations may be performed laparoscopically.⁶⁶

The most common primary tumor of the spleen is sarcoma. Autopsy studies reveal an approximately 0.6% rate of tumor metastasis to the spleen; most of these metastases are carcinomas.⁶⁷ Lung cancer is the tumor that most commonly spreads to the spleen.

Storage Diseases and Infiltrative Disorders

GAUCHER'S DISEASE

Gaucher's disease is an inherited lipid storage disorder characterized by the deposition of glucocerebroside in cells of the macrophage-monocyte system. The underlying abnormality is a deficiency in the activity of a lysosomal hydrolase. Abnormal glycolipid storage results in organomegaly, particularly hepatomegaly and splenomegaly.⁶⁸ Patients with Gaucher's disease frequently experience symptoms related to splenomegaly, including early satiety and abdominal discomfort, and to hypersplenism, including thrombocytopenia, normocytic anemia, and mild leukopenia. These latter findings occur as a result of excessive sequestration of formed blood elements in the spleen. Other symptoms in patients with Gaucher's disease include bone pain, pathologic fractures, and jaundice. Splenectomy alleviates hematologic abnormalities in patients with hypersplenism but it does not correct the underlying disease process. Partial splenectomy has been shown to be effective in children to correct both hematologic problems and symptoms due to splenomegaly without incurring the risk of overwhelming postsplenectomy sepsis.

NIEMANN-PICK DISEASE

Niemann-Pick disease is an inherited disorder of abnormal lysosomal storage of sphingomyelin and cholesterol in cells of the macrophage-monocyte system. Four types of the disease (A, B, C, and D) exist, with unique clinical presentations. Types A and B result from a deficiency in lysosomal hydrolase and are the forms most likely to demonstrate splenomegaly with its concomitant symptoms.

AMYLOIDOSIS

Amyloidosis is a disorder of abnormal extracellular protein deposition. There are multiple forms of amyloidosis, each with its own individual clinical presentation, and the severity of disease may range from asymptomatic to multiorgan failure. Patients with primary amyloidosis, associated with plasma cell dyscrasia, have splenic involvement in approximately 5% of cases. Secondary amyloidosis, associated with chronic inflammatory conditions, also may present with an enlarged spleen. Symptoms of splenomegaly are relieved by splenectomy.

SARCOIDOSIS

Sarcoidosis is an inflammatory disease of young adults characterized by noncaseating granulomas in affected tissues. Signs and symptoms of the disease range in severity and typically are nonspecific, such as fatigue and malaise. Any organ system

may be involved. The most commonly involved organ is the lung, followed by the spleen. Splenomegaly occurs in approximately 25% of patients. Massive splenomegaly (>1 kg) is rare.⁶⁹ Other affected tissues include the lymph nodes, eyes, joints, liver, spleen, and heart. When splenomegaly occurs and causes symptoms related to size or hypersplenism, splenectomy effectively relieves symptoms and corrects hematologic abnormalities such as anemia and thrombocytopenia. Spontaneous splenic rupture has been reported in sarcoidosis.⁷⁰

Miscellaneous Disorders and Lesions

SPLENIC ARTERY ANEURYSM

Although splenic artery aneurysm is rare, it is the most common visceral artery aneurysm. Women are four times more likely to be affected than men. The aneurysm usually arises in the middle to distal portion of the splenic artery. In one series, mortality was significantly higher in patients with underlying portal hypertension (>50%) than in those without it (17%).⁷¹ Indications for treatment include presence of symptoms, pregnancy, intention to become pregnant, and presence of pseudoaneurysms associated with inflammatory processes. Aneurysm resection or ligation alone is acceptable for amenable lesions in the midsplenic artery, but distal lesions in close proximity to the splenic hilum should be treated with concomitant splenectomy. An excellent prognosis follows elective treatment. Splenic artery embolization has been used to treat splenic artery aneurysm, but painful splenic infarction and abscess may follow.

PORTAL HYPERTENSION

Portal hypertension can result from numerous causes but is usually due to cirrhosis. Splenomegaly and splenic congestion often accompany portal hypertension, which leads to sequestration and destruction of circulating cells in the spleen. Splenectomy is not indicated for hypersplenism per se in patients with portal hypertension, however, because no correlation exists between the degree of pancytopenia and long-term survival in these patients.⁵ In rare circumstances in which splenectomy is required to reduce bleeding from esophageal varices exacerbated by thrombocytopenia, a concomitant splenorenal shunt procedure should be performed to decompress the portal system.⁵

Portal hypertension secondary to splenic vein thrombosis is potentially curable with splenectomy. Patients with bleeding from isolated gastric varices who have normal liver function test results, especially those with a history of pancreatic disease, should be examined for splenic vein thrombosis and treated with splenectomy if findings are positive.

FELTY'S SYNDROME

The triad of rheumatoid arthritis, splenomegaly, and neutropenia is called *Felty's syndrome*. It exists in approximately 3% of all patients with rheumatoid arthritis, two thirds of whom are women. Immune complexes coat the surface of white blood cells, which leads to their sequestration and clearance in the spleen with subsequent neutropenia. This neutropenia (<2000 neutrophils/mm³) increases the risk for recurrent infections and often drives the decision for splenectomy. The size of the spleen is variable, from nonpalpable in 5 to 10% of patients to massively enlarged in others. In Felty's syndrome the spleen is four times heavier than normal. Corticosteroids, hematopoietic growth factors, methotrexate, and splenectomy have all been used to treat the neutropenia of Felty's syndrome. Responses to splenectomy have been excellent, with >80% of patients showing a durable increase in white blood cell count. More than one half of patients who had infections before surgery did not have any infections after splenectomy.⁷² Besides symptomatic neutropenia, other indications for splenectomy include transfusion-dependent anemia and profound thrombocytopenia.

PREOPERATIVE CONSIDERATIONS

Vaccination

Splenectomy imparts a small (<1 to 5%) but definite lifetime risk of fulminant, potentially life-threatening infection (see "Overwhelming Postsplenectomy Infection" for further discussion on the risk of infection). Therefore, when elective splenectomy is planned, vaccinations against encapsulated bacteria should be given at least 2 weeks before surgery to protect against such infection. The most common bacteria to cause serious infections in asplenic hosts are *Streptococcus pneumoniae*, *H. influenzae* type B, and meningococcus. Vaccinations against these bacteria are available and should be given.

If the spleen is removed emergently (e.g., for trauma), vaccinations should be given as soon as possible after surgery, with at least 1 to 2 days allowed for recovery. After splenectomy, annual influenza immunization is advisable. Splenectomized patients should be well educated regarding the potential consequences of overwhelming postsplenectomy infection and should be encouraged to maintain documentation of their own immunization status.⁷³

Splenic Artery Embolization

The presumed advantages and disadvantages of SAE as a preoperative adjunct to elective splenectomy were discussed previously in the section "Imaging for Evaluation of Size and Pathology: Angiography." To reiterate, the purported advantages of preoperative SAE include reduced operative blood loss from a devascularized spleen¹⁹ and reduced spleen size, which allows easier dissection and removal. Its detractors argue that equivalent splenectomy-related blood loss,⁷⁴ the need for more analgesics and occasionally an extended hospital stay preoperatively, the possibility of pancreatitis, and the well-described risks of invasive arteriography cancel out any presumed benefits of preoperative embolization.⁷⁵ No consensus exists at this time concerning the role of preoperative SAE with regard to elective splenectomy. It is the authors' practice to preoperatively embolize spleens measuring ≥ 20 cm in length; this has allowed even spleens >30 cm to be resected laparoscopically with an excellent conversion rate.

Deep Vein Thrombosis Prophylaxis

Deep vein thrombosis (DVT) after splenectomy is not infrequent, especially in cases involving splenomegaly and myeloproliferative disorders.⁷⁶ The risk of portal vein thrombosis (PVT) may reach 40% for patients presenting with both splenomegaly and myeloproliferative disorders. Postsplenectomy PVT typically presents with anorexia, abdominal pain, leukocytosis, and thrombocytosis. Effective PVT treatment is possible by maintaining a high index of suspicion, achieving early diagnosis with contrast-enhanced CT, and starting anticoagulation immediately. DVT prophylaxis, including use of sequential compression devices and SC administration of heparin (5000 U), should be initiated for patients undergoing splenectomy.⁷⁷ In the prevention of venous thromboembolism after splenectomy, no clear advantage has been confirmed for the use of low molecular weight heparin (LMWH) rather than low-dose unfractionated heparin.⁷⁸ Each patient's risk factors for DVT should be evaluated, and when elevated risk exists (obesity, history of prior venous thromboembolism, known hypercoagulable state, older age), a more aggressive antithrombotic regimen, including LMWH, may be pursued.

SPLENECTOMY TECHNIQUES

Patient Preparation

All patients undergoing elective splenectomy should be vaccinated at least 1 week preoperatively with polyvalent pneumococcal, meningococcal, and *Haemophilus* vaccines. Assessment of the potential need for transfusion of blood products and optimization of preoperative coagulation status are necessary. It is the authors' practice to order blood typing and

antibody screening tests for normosplenic patients undergoing elective splenectomy. Anemic patients should be transfused before surgery to a hemoglobin level of 10 g/dL. In more complex cases, including patients with splenomegaly, at least 2 to 4 units of cross-matched blood should be available at the time of surgery. Thrombocytopenia may be transiently corrected with platelet transfusions. Thrombocytopenic patients preferably should not undergo transfusion before the day of surgery and ideally not before the intraoperative ligation of the splenic artery.

Patients who have been maintained on corticosteroid therapy preoperatively should receive parenteral corticosteroid therapy perioperatively. Bowel preparation is not routinely performed for patients undergoing elective splenectomy. All splenectomy patients do receive DVT prophylaxis, as discussed previously. After endotracheal intubation, a nasogastric (NG) tube is inserted for stomach decompression.

Open Splenectomy

Although laparoscopic surgery increasingly has achieved acceptance as the standard approach for normosplenic patients requiring splenectomy, open splenectomy (OS) is still widely practiced. Traumatic rupture of the spleen continues as the most common indication for OS. Several other clinical scenarios favor an OS approach, including massive splenomegaly, ascites, portal hypertension, multiple prior operations, extensive splenic irradiation, and possible splenic abscess.

During OS, the patient is placed in the supine position with the surgeon situated at the patient's right. A left subcostal incision paralleling the left costal margin and lying two fingerbreadths below it is preferred for most elective splenectomies. A midline incision is optimal for exposure when the spleen is ruptured or massively enlarged or when abdominal access is needed for a staging laparotomy for Hodgkin's disease. A thoracoabdominal incision, although rarely used, may be necessary for access to a challenging or significantly enlarged spleen.

The spleen is mobilized by dividing ligamentous attachments, usually beginning with the splenocolic ligament (Fig. 34-5). In patients with significant splenomegaly, once lesser sac access has been achieved through either the gastrosplenic or gastrohepatic attachments, ligating the splenic artery in continuity along the superior border of the pancreas may be preferable. This maneuver may serve several purposes: allowing safer manipulation of the spleen and dissection of the splenic hilum, facilitating some shrinkage of the spleen, and providing an autotransfusion of erythrocytes and platelets. Further medial mobilization of the spleen is achieved by incising its lateral peritoneal attachments, most notably the splenophrenic ligament. Then follows individual ligation and sequential division of the short gastric vessels, steps that if carefully executed reduce the risk of these vessels' retracting and bleeding. Splenic hilar dissection then takes place. Whenever possible, care should be taken to dissect and individually ligate the splenic artery and vein (in that order) before dividing them. As noted in the discussion of splenic anatomy, the tail of the pancreas lies within 1 cm of the splenic hilum in 75% of patients; therefore, during hilar dissection great care must be taken to avoid injuring the pancreas.

Splenocolic ligament is divided at the beginning of open splenectomy.

Once the spleen is excised, hemostasis is secured by irrigating, suctioning, and scrupulously inspecting the bed of dissection. The splenic bed is not routinely drained. A thorough search for accessory spleens must be undertaken when a hematologic disorder has occasioned splenectomy. At the completion of surgery, the nasogastric tube is removed.

Laparoscopic Splenectomy

Laparoscopic splenectomy (LS) has steadily supplanted OS as the approach of choice for most elective splenectomies. The benefits of LS for patients with normal-sized spleens were described first in case reports and then in large series. An ever-increasing amount of research confirms the value of LS, in appropriately experienced hands, for a growing number of patient groups: patients with splenomegaly, those with multiple prior abdominal operations, morbidly obese patients, those who need concomitant procedures, and even pregnant patients.⁶

Since the introduction of the lateral approach,⁷⁷ most LS procedures are now performed with the patient in the right lateral decubitus position (Fig. 34-6). A midway "double-access" technique in which the patient is in a 45-degree right lateral decubitus position has also been advocated. This positioning permits concomitant surgery, such as laparoscopic cholecystectomy, more easily than does the lateral approach. The double-access technique requires the placement of five or six trocars. The lateral approach routinely involves the use of three or four trocars positioned as shown in Fig. 34-6. Use of an angled (30- or 45-degree) laparoscope (2 mm, 5 mm, or 10 mm) greatly facilitates the procedure. Exposure of the vital anatomy in a manner that allows for a more intuitive sequence of dissection, paralleling that of OS, may be considered an additional advantage of the lateral approach.

Patient positioning and trocar placement for laparoscopic splenectomy.

Placement of trocars in the left upper quadrant should be performed under laparoscopic visualization, particularly if any degree of splenomegaly exists, because the latter can significantly reduce the available operating space. As with OS, the splenocolic ligament and the lateral peritoneal attachments are divided with resultant medial mobilization of the spleen. The short gastric vessels may be divided by any number of methods, including individual application of clips, endovascular stapling, or, most commonly, use of hemostatic energy sources as in ultrasonic dissection, diathermy, or radiofrequency ablation. With the lower pole of the spleen gently retracted, the splenic hilum is accessible to further applications of clips or an endovascular stapling device. The splenic artery and vein are divided separately when possible (Fig. 34-7). Good long-term outcomes, however, are increasingly being achieved with mass hilar stapling (Fig. 34-8). Using the lateral approach with the spleen thus elevated, the surgeon can easily visualize the tail of the pancreas and avoid injury when placing the endovascular stapler.

Splenic hilum can be divided laparoscopically en masse.

Once excised, the spleen is placed in a durable ripstop nylon sack (Fig. 34-9), the neck of which is drawn through one of the 10-mm trocar sites. Morcellation of the spleen takes place within the sack and allows piecemeal extraction; a blunt instrument should be used to disrupt and remove the spleen to avoid the risk of sack rupture, spillage of contents, and subsequent splenosis (Fig. 34-10).

Hand-assisted LS has been suggested as a safer, more expeditiously performed procedure, especially in patients with splenomegaly. In this technique, which under direct laparoscopic visualization allows identification, retraction, and dissection of appropriate tissues by palpation, the surgeon's left hand is completely introduced into the peritoneal cavity (left-handed surgeons would insert their right hands). Hemostasis is achieved by the use of clips, staples, and energy sources similar to those described earlier. The excised specimen is delivered via the hand access port. In cases in which normal-sized spleens are removed, the advantages of the hand-assisted approach may be lessened due to the size of the incision necessary to

admit the surgeon's hand.

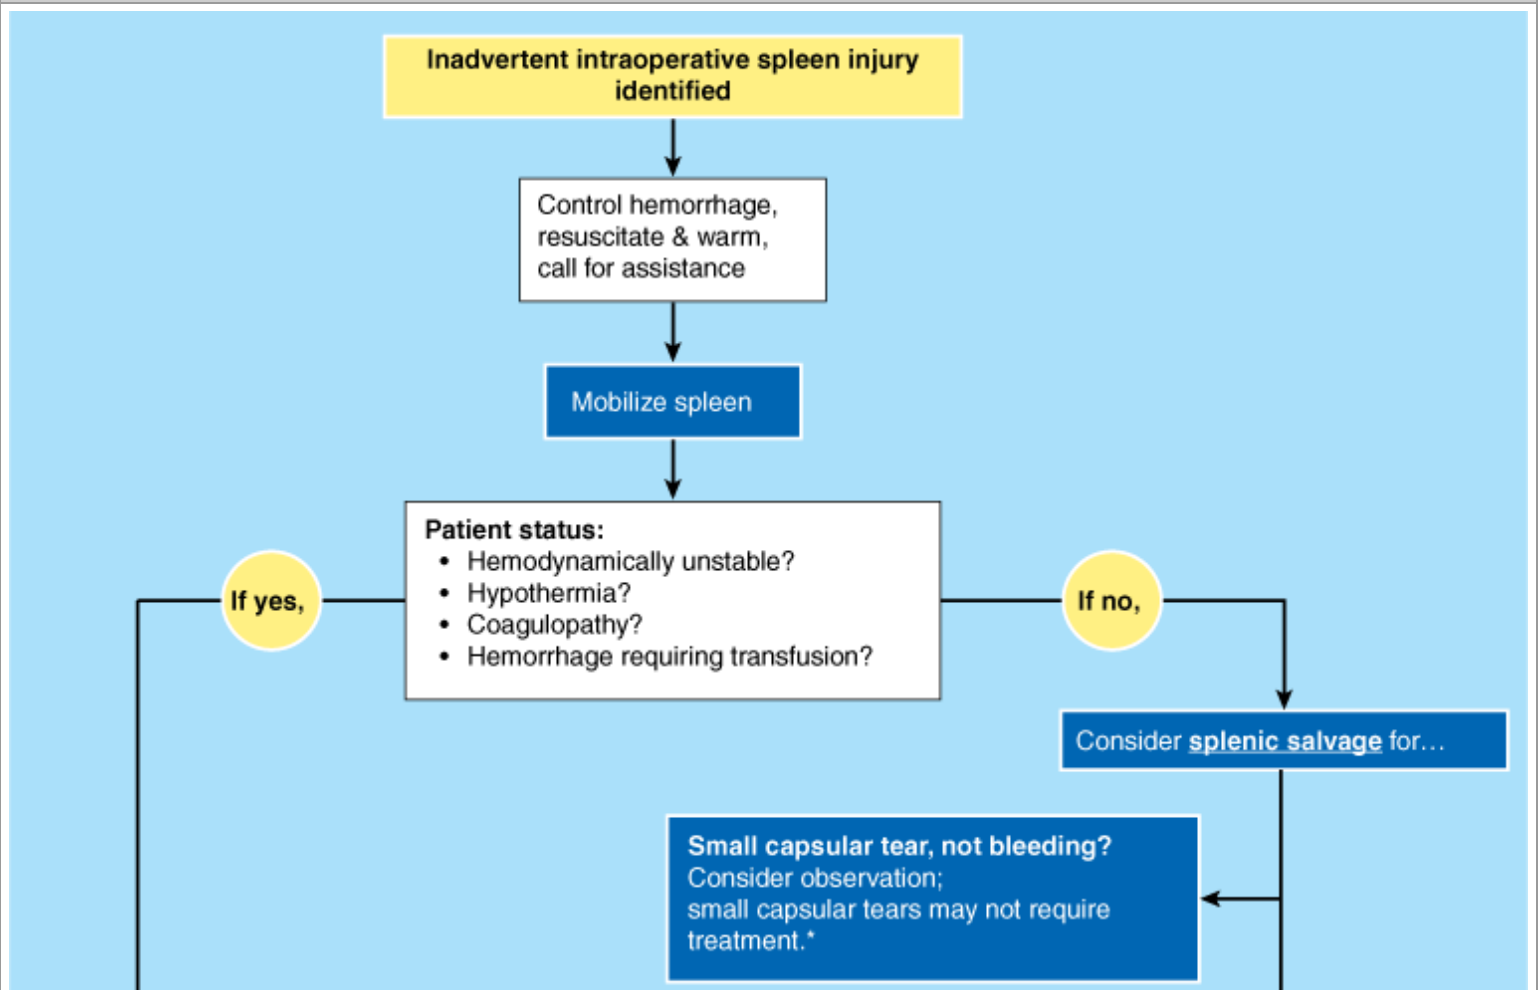

Partial Splenectomy

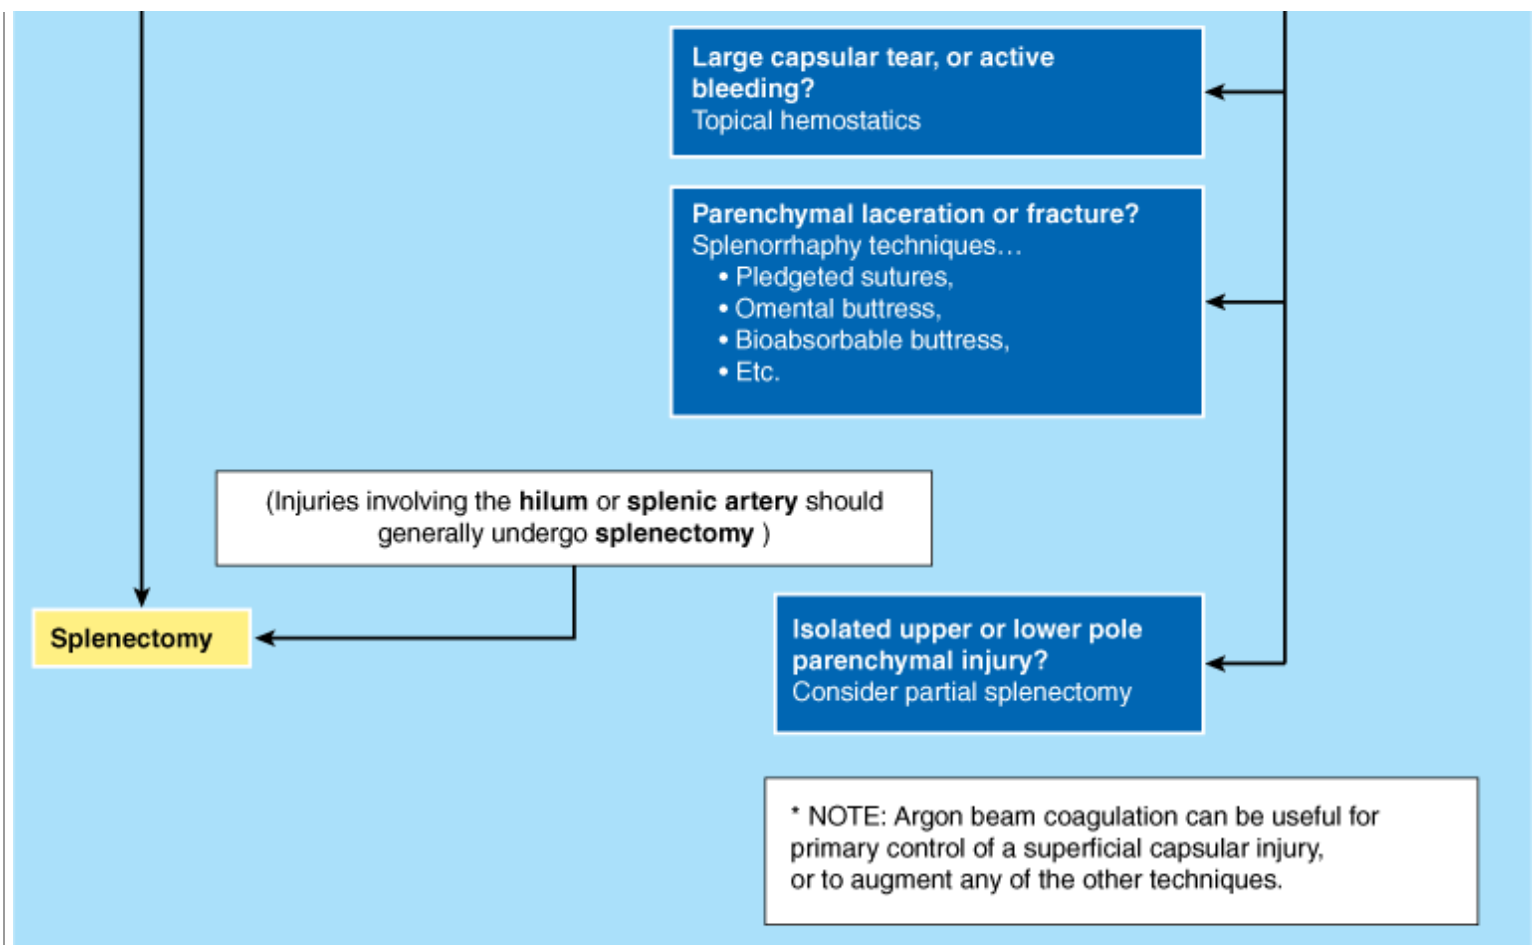

The past few decades have witnessed ever-widening endorsement for and practice of partial splenectomy. This technique, initially reported in the early eighteenth century, is particularly indicated to minimize the risk of postsplenectomy sepsis in children. Certain lipid storage disorders leading to splenomegaly (e.g., Gaucher's disease) and some forms of traumatic splenic injury (blunt and penetrating) are amenable to treatment with partial splenectomy. Both the laparoscopic and open approaches for partial splenectomy have been well described. The spleen must be adequately mobilized, and the splenic hilar vessels attached to the targeted segment ligated and divided. The devascularized segment of spleen is transected along an obvious line of demarcation. Bleeding from the cut surface of the spleen usually is limited and can be controlled by various methods, including cauterization, argon coagulation, or application of direct hemostatic agents such as cellulose gauze and fibrin glue.

Inadvertent Intraoperative Splenic Injury (Fig. 34-11)

Inadvertent intraoperative injury to the spleen is a noted occurrence in the surgical literature, familiar to and dreaded by the abdominal surgeon. The true incidence is unknown. It is likely underreported, although far from uncommon. The gravity of such injury is not to be underestimated. In addition to the risk of death, significant short-term morbidity is associated with injury to the spleen, including increased blood loss, need for transfusion, and prolonged hospital stay.⁸⁰

Treatment algorithm for inadvertent intraoperative spleen injury.

Intraoperative injury to the spleen has been linked with numerous operations commonly performed by abdominal surgeons, such as gastric fundoplication, colectomy, paraesophageal hernia repair, nephrectomy, and abdominal and pelvic vascular surgery.^{81–83} There are also reports of splenic injuries after endoscopic procedures, such as colonoscopy.^{84–87}

Improper traction on the spleen against its peritoneal attachments is the most common mechanism of intraoperative injury. Capsular tears are the most common type of injury, but parenchymal lacerations and subcapsular hematomas also occur. The lower pole is more commonly injured, owing to its orientation as well as the greater concentration of peritoneal attachments found here.⁸⁸

The time-honored surgical tenets of liberal exposure and visualization are particularly germane to the avoidance of splenic injury. Incisions and approaches must be tailored to both patient circumstances and surgeon experience. There is some evidence to support the assertion that use of the laparoscopic approach may reduce the incidence of splenic injury for certain operations.⁸⁹ An unexpected flow or pooling of blood from the left upper quadrant should raise suspicion of possible splenic injury. As with all hemorrhage, prompt temporary control of bleeding is required. Direct compression of the spleen itself, packing of the left upper quadrant, compression of the vessels at the splenic hilum or pressure on the splenic artery at the superior pancreatic margin, or supraceliac compression of the aorta can slow or stop hemorrhage and allow more deliberate consideration of management options.

As the patient's condition is stabilized, the spleen is mobilized from its peritoneal attachments and the nature of the injury

assessed. Overall, the patient's condition is the primary determinant of whether splenic salvage can be attempted. Hemodynamic instability, hemorrhage requiring transfusion, hypothermia, and coagulopathy are all situations more suited to prompt splenectomy and hemostasis. The type of injury plays a role as well; it has been suggested that hilar injury is best managed by splenectomy.⁸⁰ Barring these unfavorable circumstances, however, and recalling that the majority of intraoperative splenic injuries are capsular tears, it is reasonable to expect that splenic preservation can be achieved in many appropriately selected situations. Presented with one of these situations, the surgeon has at his or her disposal a number of useful and well-described splenorrhaphy techniques: application of topical hemostatics,⁸⁰ suture plication of disrupted parenchyma with or without omental buttress,^{80,90} and the use of bioabsorbable mesh sheets sutured as buttressing "jackets," which compress the organ while simultaneously promoting clot formation at the level of the splenic capsule.^{80,91}

SPLENECTOMY OUTCOMES

Changes in blood composition resulting from splenectomy include the appearance of Howell-Jolly bodies and siderocytes. After splenectomy leukocytosis and increased platelet counts are common as well. Although platelet counts most often rise within 2 days, they may not peak for several weeks in patients with preoperative thrombocytopenia (see "Hematologic Outcomes" later). Similarly, within 1 day after splenectomy the white blood cell count typically rises, and such elevation may continue for several months.

Complications

Complications of splenectomy may be classified as pulmonary, hemorrhagic, infectious, pancreatic, and thromboembolic. Left lower lobe atelectasis is the most common complication after OS; pleural effusion and pneumonia also can occur. Hemorrhage can occur intraoperatively or postoperatively, presenting as subphrenic hematoma. Transfusions have become less common since the advent of LS, although the indication for operation influences the likelihood of transfusion as well. Subphrenic abscess and wound infection are among the perioperative infectious complications. The placement of a drain in the left upper quadrant may be associated with postoperative subphrenic abscess and is not routinely recommended. Pancreatitis, pseudocyst, and pancreatic fistula are among the pancreatic complications that may result from intraoperative trauma to the pancreas during dissection of the splenic hilum. Thromboembolic phenomena are well described in patients undergoing splenectomy; therefore DVT prophylaxis is routinely recommended. In patients with hemolytic anemia or myeloproliferative disorders and splenomegaly, thrombotic risk is heightened, particularly the risk of portal vein thrombosis.⁷⁶ Patients undergoing splenectomy for malignancy or myeloproliferative disorders should be strongly considered for perioperative pharmacoprophylaxis, either LMWH or unfractionated heparin.

Hematologic Outcomes

The results of splenectomy may be appraised according to the level of hematologic response (e.g., rise in platelet and hemoglobin levels) in those disorders in which the spleen contributes to the hematologic problem. Hematologic responses may be divided into initial and long-term responses. For thrombocytopenia, an initial response typically is defined as a rise in platelet count within several days of splenectomy. Reported series demonstrate the effectiveness of LS in providing a long-term platelet response in approximately 80% of individuals with ITP (Table 34-2). These results are consistent with the long-term success rate associated with OS.^{105,108}

NA = not available.

For chronic hemolytic anemias, a rise in hemoglobin levels to >10 g/dL without the need for transfusion signifies a successful response to splenectomy. By this criterion, splenectomy has been reported to be successful for the vast majority of patients with chronic hemolytic anemia. For hemolytic anemia due to spherocytosis, the success rate is usually higher, ranging from 90 to 100%.¹⁰⁹

Splenectomy results also may be examined in terms of surgical and postsurgical characteristics, including operative time, recovery time, and morbidity and mortality rates, all of which tend to vary according to hematologic indication (Tables 34-3 and 34-4).

Results of few prospective, randomized trials comparing LS and OS have been published. In one prospective study investigators randomly assigned 28 thalassemia patients to undergo OS or LS.¹⁰⁰ There were no mortalities and no differences in complication rates in the two groups. Some differences were noted in operative times, transfusion requirements, and length of stay, but no hematologic outcome data have yet been published. Previously reported retrospective comparisons between LS and OS indicate that the laparoscopic approach typically results in longer operative times, shorter hospital stays, lower morbidity rates, similar blood loss, and similar mortality rates compared with OS.^{79,105} A meta-analysis of 51 series encompassing >2900 patients generally supports these observations, although there was a suggestion that hemorrhagic complications may be higher with the laparoscopic approach.¹¹¹ Questions of the cost effectiveness of LS persist, although analysis of this issue is hindered by a lack of universally accepted metrics as well as a paucity of recent objective data. Proponents of LS argue that the generally higher operating room charges are offset by the reduced hospital stay and

presumably shorter time of lost productivity. For those institutions with experienced personnel and technical capability, the laparoscopic approach has emerged as the standard for elective, nontraumatic splenectomy.

Overwhelming Postsplenectomy Infection

Asplenic patients bear an increased susceptibility to infection for the remainder of their lives. Although the overwhelming majority of splenectomized patients experience no ill consequence from the absence of the spleen, the potentially catastrophic consequences of overwhelming postsplenectomy infection (OPSI) demand lifelong vigilance and intimate knowledge of the appropriate precautions and preventative measures. All involved—patient, family members, and physicians—need to play an active role.

CLINICAL FEATURES

Sepsis in splenectomized patients is a medical emergency. Therefore, any clinical suggestion of infection, including seemingly isolated fevers, must be viewed with a high index of suspicion and treated empirically as thorough investigation proceeds. OPSI may begin with a relatively mild-appearing prodrome with nonspecific symptoms. In addition to fever, nonspecific symptoms such as malaise, myalgias, headache, vomiting, diarrhea, abdominal pain, and others should be viewed with alarm in the asplenic patient. Absent the spleen, the infectious process signaled by such symptoms can progress rapidly to fulminant bacteremic septic shock, with hypotension, anuria, and disseminated intravascular coagulation. The need for a high index of suspicion, prompt action, and aggressive education of the patient, family, and medical provider cannot be overstated.

The true incidence of OPSI is not precisely known, because defining criteria vary among published series. Overall lifetime risk remains low, ranging from <1 to 5%.^{73,112–114} Among those who develop OPSI, some characteristics can be identified that impart greater risk. Reason for splenectomy is the single most influential determinant of OPSI risk. Case series demonstrate that those who undergo splenectomy for hematologic disease (malignancy, myelodysplasia, or hemoglobinopathy) are far more susceptible to OPSI than patients who undergo splenectomy for trauma or iatrogenic reasons.⁷³ Age is also an important consideration, with children <5 years of age and adults >50 years being at elevated risk.¹¹⁴ Finally, time interval from spleen removal must be considered. A large number of OPSI cases occur many years to decades later.¹¹² This observation underscores both the threat of this lethal disease and the need for lifelong vigilance.

MICROBIOLOGY AND PATHOGENESIS

Life-threatening infection in the asplenic patient is attributable to three factors: loss of splenic macrophages, diminished tuftsin production, and loss of the spleen's reticuloendothelial screening function. In the normal host, these three factors work in concert to eliminate opsonized bacteria from the bloodstream. This system is particularly suited to the removal of encapsulated bacteria, whose polysaccharide coating is a natural defense against opsonization (*S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis* are classic examples). Infections with protozoa that invade the red blood cell, such as *Babesia microti* (transmitted by tick bites), *Ehrlichia*, and *Plasmodium*, occur more frequently in splenectomized individuals than in normal hosts.⁷³ Other potential infectious bacterial sources include group A streptococci, *Capnocytophaga canimorsus* (transmitted by dog bites), group B streptococci, *Enterococcus* species, *Bacteroides* species, *Salmonella* species, and *Bartonella* species.¹¹⁵ In the absence of the spleen, elimination of these pathogens from the bloodstream falls solely to the liver, a process that has been demonstrated to be less effective.⁸

ROLE OF VACCINATION

Mortality rates for OPSI in the prevaccination era are testimony to the importance of the vaccines available today. The use of

currently available vaccines against pneumococcus and other encapsulated organisms has led to a drop in the overall incidence of OPSI to <1%.¹¹² The mechanism by which vaccination protects asplenic patients is not entirely understood. Serum antibody titers do not necessarily correspond to clinical immunity.¹¹⁶ Moreover, antibody levels after pneumococcus vaccination decline steadily within 5 to 10 years. Revaccination is reasonably recommended for these patients, although the efficacy of this measure is not proven.¹¹² Timing of vaccination generally is accepted as a minimum of 2 weeks before planned elective splenectomy and within 7 to 10 days after unplanned or emergent splenectomy, although data supporting this practice are lacking.

Despite the current marked reduction in OPSI-related mortality, an alarming number of "vaccine failures" have been noted. OPSI developed in 41% of patients in one trauma series, despite the fact that these patients received the appropriate vaccines after splenectomy.¹¹² Nonetheless, vaccination of asplenic patients against encapsulated organisms has value when applied to the population as a whole. The most common causal organism, accounting for as many as 50 to 90% of all OPSI cases, remains pneumococcus. Meningococcus, *H. influenzae* type B, and group A streptococci follow in order of frequency.¹¹⁵

ANTIBIOTICS AND THE ASPLENIC PATIENT

Antibiotic therapy for the asplenic patient can be considered in three contexts: deliberate therapy for established or presumed infections, prophylaxis in anticipation of invasive procedures (e.g., dental procedures), and general prophylaxis. For the latter two indications, unfortunately, evidence supporting efficacy is scant, and guidelines for antibiotic prophylaxis are not uniform. Optimal duration of chemoprophylaxis in children is unclear. Daily doses of antibiotics until 5 years of age or at least 5 years after splenectomy are commonly recommended,¹¹⁷ although some advocate continuation into at least young adulthood.¹¹⁵ Concerns regarding compliance and bacterial resistance have been raised, which have led some authors to suggest that lifelong daily antibiotic prophylaxis be recommended only for those patients whose antibody titers fail to respond appropriately to vaccination or, alternately, that asplenic patients be advised to carry at all times a reserve supply of antibiotic to be self-administered at the earliest sign of infection.¹¹⁸ Confounding the issue further, OPSI has been noted to occur even in appropriately vaccinated patients taking daily antibiotic prophylaxis at the time of infection.¹¹⁸ Considering OPSI's grave consequences as well as its relatively low incidence, controlled trials resulting in meaningful data on this issue seem unlikely to be performed.

Several risk management strategies are commonly recommended to asplenic patients: wearing a medical bracelet, carrying a laminated medical alert card, possessing a medical letter with specific empiric therapy instructions (including drug names and dosages), and keeping a 5-day supply of stand-by antibiotics, particularly when travel is anticipated.⁷³ A recent review of the literature provides no reason to depart from these precautions.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 35. Abdominal Wall, Omentum, Mesentery, and Retroperitoneum >

KEY POINTS

1. Musculoaponeurotic anatomic features of the abdominal wall layers differ superior to and inferior to the arcuate line on the posterior aspect of the rectus sheath.
2. Defects of the complex process of abdominal wall development in the fetus can occur in several ways resulting in persistent midgut herniation (omphalocele and gastroschisis) or vitelline duct remnant abnormalities (Meckel's diverticulum, or vitelline duct fistula or cyst).
3. The management of rectus sheath hematomas consists of reversal of any anticoagulation or coagulopathy and observation, unless either hemodynamic instability or enlargement necessitates surgical evacuation.
4. Incisional hernias of the anterior abdominal wall may occur in up to 10–20% of prior abdominal operations of all types.
5. Primary suture repair of abdominal wall incisional hernias is associated with an unacceptably high incidence of hernia recurrence, and has prompted the wide use of prosthetic mesh materials for hernia repair.
6. Laparoscopic incisional hernia repair offers important advantages over open repairs including reduced pain medication use, earlier return to normal function, and possibly superior protection from hernia recurrence.
7. Sclerosing mesenteritis is a poorly understood mesenteric process characterized by variable degrees of inflammation and fibrosis within mesenteric tissues of the small and large bowel, which frequently requires surgical biopsy to rule out neoplasm and to establish the correct diagnosis.
8. Retroperitoneal fibrosis is a primary or secondary fibroproliferative process in the retroperitoneum characterized by distortion of retroperitoneal structures, including the ureters and inferior vena cava.
9. Treatment of retroperitoneal fibrosis may include ureterolysis or ureteral stenting, and medical therapies such as corticosteroids or tamoxifen.

ABDOMINAL WALL

General Considerations

The abdominal wall is defined superiorly by the costal margins, inferiorly by the symphysis pubis and pelvic bones, and posteriorly by the vertebral column. It serves to support and protect abdominal and retroperitoneal structures, and its complex muscular functions enable twisting and flexing motions of the trunk. Surgical implications of abdominal wall structure become apparent during the course of managing primary abdominal wall diseases or gaining access to the peritoneal cavity. A surgeon must have a thorough understanding of the arrangement of abdominal wall muscles and aponeuroses.

Surgical Anatomy

The abdominal wall is an anatomically complex, layered structure with segmentally derived blood supply and innervation (Fig. 35-1). It is mesodermal in origin and develops as bilateral migrating sheets that originate in the paravertebral region and envelop the future abdominal area. The leading edges of these structures develop into the rectus abdominis muscles, which eventually meet in the midline of the anterior abdominal wall. The muscle fibers of the rectus abdominis are arranged vertically and are encased within an aponeurotic sheath, the anterior and posterior layers of which are fused in the midline at the *linea alba*. The rectus abdominis has insertions on the symphysis pubis and pubic bones, on the anteroinferior aspects of the fifth and sixth ribs, as well as on the seventh costal cartilages and the xiphoid process. The lateral border of the rectus muscles assumes a convex shape that gives rise to the surface landmark of the *linea semilunaris*. There usually are three tendinous intersections or inscriptions that cross the rectus muscles: one at the level of the xiphoid process, one at the level of the umbilicus, and one halfway between the xiphoid process and the umbilicus (see Fig. 35-1).

Fig. 35-1.

Anterior abdominal wall. The linea alba is the midline aponeurotic demarcation between the bellies of the rectus abdominis muscles. The rectus abdominis muscle and its tendinous intersections on the left are shown deep to the reflected anterior rectus sheath. Segmental cutaneous nerve branches also are shown. m. = muscle.

Lateral to the rectus sheath are three muscular layers with oblique fiber orientations relative to one another (Fig. 35-2). These layers are derived from the laterally migrating mesodermal tissues during the sixth to seventh week of fetal development, before fusion of the developing rectus abdominis muscles in the midline. The external oblique muscle runs inferiorly and medially, arising from the margins of the lowest eight ribs and costal cartilages. The external oblique muscle originates laterally on the latissimus dorsi and serratus anterior muscles, as well as on the iliac crest. Medially it forms a tendinous aponeurosis, which is contiguous with the anterior rectus sheath. The *inguinal ligament* is the inferior-most edge of the external oblique aponeurosis, reflected posteriorly in the area between the anterior superior iliac spine and pubic tubercle. The internal oblique muscle lies immediately deep to the external oblique muscle and arises from the lateral aspect of the inguinal ligament, the iliac crest, and the thoracolumbar fascia. Its fibers course superiorly and medially and form a tendinous aponeurosis that contributes components to both the anterior and posterior rectus sheath. The lower medial and inferior-most fibers of the internal oblique course may fuse with the lower fibers of the transversus abdominis muscle (the *conjoined area*). The inferior-most fibers of the internal oblique muscle are contiguous with the cremasteric muscle in the inguinal canal. These relationships are of critical significance in the management of inguinal hernia. The transversus abdominis muscle is the deepest of the three lateral muscles and, as its name implies, runs transversely from the bilateral lowest six ribs, the lumbosacral fascia, and the iliac crest to the lateral border of the rectus abdominis musculoaponeurotic structures.

The complexities of the anterior and posterior aspects of the rectus sheath are best understood in their relationship to the *arcuate line* (semicircular line of Douglas), which lies roughly at the level of the anterior superior iliac spines (Fig. 35-3). Above the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis and the external lamina of the internal oblique aponeurosis, whereas the posterior rectus sheath is formed by the internal lamina of the internal oblique aponeurosis, the transversus abdominis aponeurosis, and the transversalis fascia. Below the arcuate line, the anterior rectus sheath is formed by the external oblique aponeurosis, the laminae of the internal oblique aponeurosis, and the transversus abdominis aponeurosis. There is no aponeurotic posterior covering of this lower portion of the rectus muscles, although the transversalis fascia remains a contiguous structure on the posterior aspect of the abdominal wall in this area as well.

Cross-sectional anatomy of the abdominal wall above and below the arcuate line of Douglas. The lower right abdominal wall segment shows clearly the absence of an aponeurotic covering of the posterior aspect of the rectus abdominis muscle inferior to the arcuate line. Superior to the arcuate line, there are both internal oblique and transversus abdominis aponeurotic contributions to the posterior rectus sheath.

[Reproduced with permission from Moore KL, Dailey AF (eds): *Clinically Oriented Anatomy*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 1999, p 185.]

The majority of the blood supply to the muscles of the anterior abdominal wall is derived from the superior and inferior epigastric arteries (Fig. 35-4). The superior epigastric artery arises from the internal thoracic artery, whereas the inferior epigastric artery arises from the external iliac artery. A collateral network of branches of the subcostal and lumbar arteries also contributes to the abdominal wall blood supply. The lymphatic drainage of the abdominal wall is predominantly to the major nodal basins in the superficial inguinal and axillary areas.

The superior and inferior epigastric arteries form an anastomosing network of vessels in and around the rectus sheath, with collateralization to subcostal and lumbar vessels situated more laterally on the abdominal wall. Lymphatic drainage is via axially or inguinal nodal basins.

[Reproduced with permission from Moore KL, Dailey AF (eds): *Clinically Oriented Anatomy*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 1999, p 86.]

Innervation of the anterior abdominal wall is segmentally related to specific spinal levels. The motor nerves to the rectus muscles, the internal oblique muscles, and the transversus abdominis muscles run from the anterior rami of spinal nerves at the T6 to T12 levels. The overlying skin is innervated by afferent branches of the T4 to L1 nerve roots, with the nerve roots of T10 subserving sensation of the skin around the umbilicus (Fig. 35-5).

Physiology

The rectus muscles, the external oblique muscles, and the internal oblique muscles work as a unit to flex the trunk anteriorly or laterally. Rotation of the trunk is achieved by the contraction of the external oblique muscle and the contralateral internal oblique muscle. For example, rotation of the trunk to the right is produced by contraction of the left external oblique muscle and the right internal oblique muscle. In addition, all four muscle groups (i.e., rectus muscles, external oblique muscles, internal oblique muscles, and transversus abdominis muscles) are involved in raising intra-abdominal pressure. If the diaphragm is relaxed when the abdominal musculature is contracted, the pressure exerted by the abdominal muscles results in expiration of air from the lungs or a cough if this contraction is forceful. Thus, these abdominal muscles are the primary muscles of expiration. If the diaphragm is contracted when the abdominal musculature is contracted (*Valsalva maneuver*) the increased abdominal pressure aids in processes such as micturition, defecation, and childbirth.

Abdominal Anatomy and Surgical Incisions

The abdominal wall can be viewed as a barrier to successful exposure of pathology in the deeper tissues. Surgeons must deal with this barrier every day to access sites of disease, and this engenders practical questions of where and how to make incisions. Structural characteristics of the abdominal wall are encountered with every abdominal incision used to gain entry to the peritoneal cavity or extraperitoneal tissues. Incisions for open surgery generally are located in proximity to the principal

operative targets. Laparoscopic port site incisions might be remote from the site of interest and are carefully planned based on the anticipated instrument approach angles and necessary working distances both to the operative site and between ports. Orientation of the line of any incision may be determined based on expected quality of exposure; closure considerations, including cosmesis; avoidance of previous incision sites; and simple surgeon preference. In general, the incision for open peritoneal access can be longitudinal (in or off the midline), transverse (lateral to or crossing the midline), or oblique (directed either upward or downward toward the flank) (Fig. 35-6). Modifications of these general classes of incisions are numerous and can consist of various extensions that are intended to optimize exposure in specific clinical situations. In some infrequent situations, combinations of incision types may be used. For the majority of nonlaparoscopic procedures on the GI tract, midline incisions are used because of the flexibility offered by this approach in establishing adequate exposure. The incision in the fused midline aponeurotic tissue (linea alba) is simple and requires no division of skeletal muscle. Paramedian incisions are made longitudinally 3 cm off the midline, through the rectus abdominis sheath structures, and have largely been abandoned in favor of midline or nonlongitudinal access methods. Incisions lateral to the midline made with transverse or oblique orientations may divide the successive muscular layers or bluntly split them in the direction of their fibers. The latter muscle-splitting approach (exemplified by the classic McBurney incision for appendectomy) may be less destructive to tissue and thus allow healing with less scarring and tissue distortion but generally offers more limited exposure than other methods. Subcostal incisions on the right (Kocher incision for cholecystectomy) or left (for splenectomy) are archetypal muscle-dividing incisions that generally result in transection of some or all of the rectus abdominis muscle fibers and investing aponeuroses. These incisions generally are closed in two layers. The more superficial one incorporates the anterior aponeurotic sheath of the rectus muscle medially, transitioning to external oblique muscle and aponeurosis more laterally. The posterior, deeper layer consists of internal oblique and transversus abdominis muscle. The anatomic considerations are the same for closure of transverse muscle-dividing incisions, either lateral to or crossing the midline. The Pfannenstiel incision, used commonly for pelvic procedures, is distinguished by transverse skin and anterior rectus sheath incisions, followed by rectus muscle retraction and longitudinal incision of the peritoneum. Irrespective of the incision type, suture apposition of abdominal wall tissues during closure ideally is accomplished without great tension and with great precision. The surgeon must appreciate all necessary anatomic distinctions to minimize the opportunity for defective healing.

Various anterior abdominal wall incisions for exposure of peritoneal structures. *A*, Midline incision; *B*, paramedian incision; *C*, right subcostal incision and "saber slash" extension to costal margin (*dashed line*); *D*, bilateral subcostal (also bucket handle, chevron, gable) incision, and "Mercedes Benz" extension (*dashed line*); *E*, Rocky-Davis incision and Weir extension (*dashed line*); *F*, McBurney incision; *G*, transverse incision and extension across midline (*dashed line*); and *H*, Pfannenstiel incision.

Abdominal incisions are injuries inflicted under controlled circumstances that can lead to short- and long-term complications and patient disability. The question of how large an incision must be to allow safe operative maneuvers at the surgical site of interest has no simple answer. In general, it is prudent to make incisions no larger than is necessary to safely accomplish the operative goals. Efforts to deal with this issue have engendered surgical solutions intended both to reduce patient disability and to improve the overall ergonomics associated with smaller access sites. Laparoscopic surgery, and now natural orifice transluminal endoscopic surgery (NOTES), have owed their development largely to the belief that avoidance of surgical injury to the abdominal wall is of significant benefit to the patient. For open surgery, a variety of devices are available to retract the abdominal wall and facilitate peritoneal exposure without subjecting the patient to excessively large incisions or surgical personnel to exhausting retraction tasks (Fig. 35-7). Examples include the Bookwalter, Omni-Tract, and Thompson retractors.

Bookwalter retractor in use for exposure of peritoneal structures during abdominal surgery. Devices of this type are valuable exposure aids that reduce the physical demands on personnel in the operating room and allow more complete focus on the surgical site of interest.

Congenital Abnormalities

The abdominal wall layers begin to form in the first weeks after conception. Prominent in the early embryonic abdominal wall is a large central defect through which pass the vitelline (omphalomesenteric) duct and allantois. The vitelline duct connects the embryonic and fetal midgut to the yolk sac. During the sixth week of development, the abdominal contents grow too large for the abdominal wall to completely contain and the embryonic midgut herniates into the umbilical cord. Although outside the confines of the developing abdomen, it undergoes a 270-degree counterclockwise rotation and, at the end of the twelfth week, returns to the abdominal cavity. Defects in abdominal wall closure may lead to omphalocele or gastroschisis. In omphalocele, viscera protrude through an open umbilical ring and are covered by a sac derived from the amnion. In gastroschisis, the viscera protrude through a defect lateral to the umbilicus and no sac is present.

During the third trimester, the vitelline duct regresses. Persistence of a vitelline duct remnant on the ileal border results in *Meckel's diverticulum*. Complete failure of the vitelline duct to regress results in a *vitelline duct fistula*, which is associated with drainage of small intestine contents from the umbilicus. If both the intestinal and umbilical ends of the vitelline duct regress into fibrous cords, a central *vitelline duct (omphalomesenteric) cyst* may occur. Persistent vitelline duct remnants between the GI tract and the anterior abdominal wall may be associated with small intestine volvulus in neonates. When diagnosed, vitelline duct fistulas and cysts should be excised along with any accompanying fibrous cord.

The urachus is a fibromuscular, tubular extension of the allantois that develops with the descent of the bladder to its pelvic position. Persistence of urachal remnants can result in cysts as well as fistulas to the urinary bladder with drainage of urine from the umbilicus. These are treated by urachal excision and closure of any bladder defect that may be present.

Acquired Abnormalities

RECTUS ABDOMINIS DIASTASIS

Rectus abdominis diastasis (or diastasis recti) is a clinically evident separation of the rectus abdominis muscle pillars. This results in a characteristic bulging of the abdominal wall in the epigastrium that is sometimes mistaken for a ventral hernia despite the fact that the midline aponeurosis is intact and no hernia defect is present. Diastasis may be congenital, as a result of a more lateral insertion of the rectus muscles to the ribs and costochondral junctions, but is more typically an acquired condition, occurring with advancing age, in obesity, or after pregnancy. In the postpartum setting, rectus diastasis tends to occur in women who are of advanced maternal age, who have a multiple or twin pregnancy, or who deliver a high-birth-weight infant. Diastasis is usually easily identified on physical examination (Fig. 35-8). Computed tomographic (CT) scanning provides an accurate means of measuring the distance between the rectus pillars and can differentiate rectus diastasis from a true ventral hernia if clarification is required. Surgical correction of rectus diastasis by plication of the broad midline aponeurosis has been described for cosmetic indications and for alleviation of impaired abdominal wall muscular function. However, these approaches introduce the risk of an actual ventral hernia and are of questionable value in addressing pathology.

Fig. 35-8.

Diastasis recti visible in the midepigastrium with Valsalva maneuver. The edges of the rectus abdominis muscle, rigid with voluntary contraction, are palpable along the entire length of the bulging area. This should not be mistaken for a ventral hernia.

RECTUS SHEATH HEMATOMA

The terminal branches of the superior and inferior epigastric arteries course deep to the posterior aspect of the left and right rectus abdominis muscles and enter the posterior rectus sheath. Hemorrhage from any of the network of collateralizing vessels within the rectus sheath and muscles can result in a rectus sheath hematoma. Although a history of major or minor blunt trauma may be elicited, less obvious events also have been reported to cause this condition, such as sudden

contraction of the rectus muscles with coughing, sneezing, or any vigorous physical activity. Spontaneous rectus sheath hematomas have been described in the elderly and in those receiving anticoagulation therapy. Patients frequently describe the sudden onset of unilateral abdominal pain that may be confused with lateralized peritoneal disorders such as appendicitis. Below the arcuate line, a hematoma may cross the midline and cause bilateral lower quadrant pain.

History and physical examination alone may be diagnostic. Pain typically increases with contraction of the rectus muscles and a tender mass may be palpated. The ability to appreciate an intra-abdominal mass is ordinarily degraded with contraction of the rectus muscles. *Fothergill's sign* is a palpable abdominal mass that remains unchanged with contraction of the rectus muscles and is classically associated with rectus hematoma. Hemoglobin level and hematocrit should be measured and coagulation studies should be performed. Abdominal ultrasonography may show a solid or cystic mass within the abdominal wall depending on the chronicity of the bleeding. CT is the most definitive study to establish the correct diagnosis and to exclude other disorders (Fig. 35-9). Magnetic resonance imaging (MRI) also has been used for this purpose.

Fig. 35-9.

Computed tomographic scan showing a medium-sized right rectus sheath hematoma. The hematoma occurred in an elderly patient without a clear history of trauma who was receiving anticoagulation therapy. Because of its size and the patient's slender body habitus, this hematoma was palpable and could be followed clinically.

Specific treatment depends on the severity of the hemorrhage (Fig. 35-10). Small, unilateral, and stable hematomas may be observed without patient hospitalization. Bilateral or large hematomas will likely require hospitalization and possibly resuscitation. The need for transfusion or coagulation factor replacement is determined by the clinical circumstances. Reversal of warfarin (Coumadin) anticoagulation in the acute setting is frequently, but not always, necessary. Emergent operative intervention or angiographic embolization is required infrequently but may be necessary if hematoma enlargement, free bleeding, or clinical deterioration occur. Surgical therapy is used in the rare situations of failed angiographic treatment or

hemodynamic instability that precludes any other options. The operative goals are evacuation of the hematoma and ligation of any bleeding vessel identified. Mortality from this condition is rare but has been reported in elderly patients requiring surgical treatment.

Fig. 35-10.

Management algorithm for rectus sheath hematoma. Most patients present with a mass and/or pain and are managed without intervention. The potential for a rare catastrophic bleeding event must be recognized, however. Surgical evacuation is reserved for those circumstances in which clinical evidence of ongoing bleeding makes any other management option untenable. CBC = complete blood count; CT = computed tomography; OR = operating room.

ABDOMINAL WALL HERNIAS

Hernias of the anterior abdominal wall, or *ventral* hernias, represent defects in the parietal abdominal wall fascia and muscle through which intra-abdominal or preperitoneal contents can protrude. Ventral hernias may be congenital or acquired. Acquired hernias may develop through slow architectural deterioration of the muscular aponeuroses or they may develop from failed healing of an anterior abdominal wall incision (*incisional hernia*). The most common finding is a mass or bulge on the anterior abdominal wall, which may increase in size with a Valsalva maneuver. Ventral hernias may be asymptomatic or cause a considerable degree of discomfort, and generally enlarge over time. Physical examination reveals a bulge on the anterior abdominal wall that may reduce spontaneously, with recumbency, or with manual pressure. A hernia that cannot be reduced is described as *incarcerated* and requires emergent surgical correction. Incarceration of an intestinal segment may be accompanied by nausea, vomiting, and significant pain. Should the blood supply to the incarcerated bowel be compromised, the hernia is described as *strangulated*, and the localized ischemia may lead to infarction and perforation.

Primary ventral hernias (nonincisional) are also termed *true* ventral hernias. These are more properly named according to their anatomic location. *Epigastric* hernias are located in the midline between the xiphoid process and the umbilicus. They are generally small, may be multiple, and at elective repair are usually found to contain omentum or a portion of the falciform ligament. These may be congenital and due to defective midline fusion of developing lateral abdominal wall elements.

Umbilical hernias occur at the umbilical ring and may either be present at birth or develop gradually during the life of the individual. Umbilical hernias are present in approximately 10 percent of all newborns and are more common in premature infants. Most congenital umbilical hernias close spontaneously by age 5 years. If closure does not occur by this time, elective surgical repair usually is advised. Adults with small, asymptomatic umbilical hernias may be followed clinically. Surgical treatment is offered if a hernia is observed to enlarge, if it is associated with symptoms, or if incarceration occurs. Surgical treatment can consist of primary sutured repair or placement of prosthetic mesh for larger defects (>2 cm) using open or laparoscopic methods.

Spigelian hernias can occur anywhere along the length of the Spigelian line or zone—an aponeurotic band of variable width at the lateral border of the rectus abdominis. However, the most frequent location of these rare hernias is at or slightly above the level of the arcuate line. These are not always clinically evident as a bulge and may come to medical attention because of pain or incarceration.

Patients with advanced liver disease, ascites, and umbilical hernia require special consideration. Enlargement of the umbilical ring usually occurs in this clinical situation as a result of increased intra-abdominal pressure from uncontrolled ascites. The first line of therapy is aggressive medical correction of the ascites with diuretics, dietary management, and paracentesis for tense ascites with respiratory compromise. These hernias usually are filled with ascitic fluid, but omentum or bowel may enter the defect after large-volume paracentesis. Uncontrolled ascites may lead to skin breakdown on the protuberant hernia and eventual ascitic leak, which can predispose the patient to bacterial peritonitis. Patients with refractory ascites may be candidates for transjugular intrahepatic portocaval shunting or eventual liver transplantation. Umbilical hernia repair should be deferred until after the ascites is controlled.

INCISIONAL HERNIAS

Approximately 4 million abdominal operations are performed every year and as many as 10 to 20% of these patients have been estimated to develop hernias at the abdominal incision sites. Any such occurrence is termed *incisional hernia* and can be regarded as a wound healing failure. The cause of incisional hernia in any given case can be difficult to determine, but obesity, primary wound healing defects, multiple prior procedures, prior incisional hernias, and technical errors during repair may all be contributory. Hernias can occur at sites of defective healing within the approximated incision or at the suture puncture sites created during the closure, or both. Repair of incisional hernias can be technically challenging, and a myriad of methods have been described. The most important distinctions in describing surgical management of incisional hernias are primary vs. mesh repair and open vs. laparoscopic repair.

Primary repair methods for incisional hernia include both simple suture closure and components separation, and are open procedures. Simple suture approximation of fascial defect edges predictably results in a suture line under tension. Primary repair, even of small hernias (defects <3 cm), is associated with high reported hernia recurrence rates. In a randomized prospective study of open primary and open mesh incisional hernia repairs in 200 patients, investigators from the Netherlands found that after 3 years, recurrence rates were 43% and 24% for the two methods, respectively. Identified risk factors for recurrence were primary suture repair, postoperative wound infection, prostatism, and surgery for abdominal

aortic aneurysm. These investigators concluded that mesh repair was superior to primary repair.

In an effort to decrease the suture line tension associated with primary repair, Ramirez first described the components separation technique. Components separation entails the creation of large subcutaneous flaps lateral to the fascial defect followed by incision of the external oblique muscles and, if necessary, incision of the posterior rectus sheath bilaterally. These fascial releases allow for primary apposition of the fascia under far less tension than in simple primary repair. Components separation hernia repair is associated with a high wound infection risk (20%) and a recurrence rate of 18.2% at 1 year. Components separation is most applicable for the repair of incisional hernias when there are converging needs to (a) avoid the use of prosthetic materials, and (b) achieve a definitive repair. Most commonly this occurs in the setting of a contaminated or potentially contaminated surgical field.

Mesh repair has become the gold standard in the elective management of most incisional hernias. Mesh repairs can be categorized according to the way in which the mesh is placed as well as its relationship to the abdominal wall fascia. Mesh can be placed as an underlay deep to the fascial defect (intraperitoneal or preperitoneal), as an interlay either bridging the gap between the defect edges or within the abdominal wall musculoaponeurotic layers (intraparietal), or as an onlay (superficial to the fascial defect). Laparoscopic repairs use an intraperitoneal underlay technique. Meshes can be characterized by type of material, each of which has a specified density, porosity, and strength. Broadly, these can be prosthetic or biologic. Permanent prosthetic mesh implants are made of materials that do not degrade over time, whereas absorbable meshes are degraded, primarily by hydrolytic enzyme activity. Biologic meshes are prepared from collagen-rich porcine, bovine, or human tissues from which all antigenic cellular materials are removed. These mesh materials can be chemically treated to cross-link collagen molecules, which increases strength and durability at the cost of some impairment in host cellular ingrowth. Over time, biologic mesh–derived collagen can be incorporated into the host tissue, remodeled, and eventually replaced by host collagen. Early in their use, biologic meshes were felt to represent a potentially definitive solution when used to bridge an abdominal wall defect. However, more recent reports show that hernia recurrence rates are excessive in this application. Jin and colleagues found that when human acellular dermis was used to bridge a complicated incisional hernia defect the recurrence rate was 73%, in sharp contrast to a 15% recurrence rate when the same material was used as an onlay or underlay in conjunction with primary closure. Blatnik and associates reported an 80% recurrence rate when human acellular dermis was used to bridge ventral hernia defects, at a cost of \$5100 per patient for the mesh alone. Commonly used meshes for incisional hernia repair are listed in Table 35-1. The principal advantages of prosthetic meshes are ease of use, relatively low cost, and durability. Biologic meshes are useful in the setting of contaminated or potentially contaminated fields but are very expensive and, based on the most recent evidence, do not offer the durability of permanent prosthetic meshes unless combined with a primary repair. Absorbable meshes, composed of the same materials as polysaccharide-derived synthetic absorbable suture, provide relatively inexpensive solutions for temporary abdominal wall support in highly contaminated or infected fields. Use of these meshes leaves patients with recurrent ventral hernias that can be definitively repaired when permitted by improved local wound conditions.

Table 35-1 Meshes Used in Incisional Hernia Repair	
Proprietary Name	Composition
Prosthetic meshes	
Parietex	Polyester/collagen film
Composix	Polypropylene/ePTFE
DualMesh, Dulex, MotifMESH	ePTFE

Prolene, Surgipro, ProLite	Polypropylene
Proceed	Polypropylene/polydioxanone
Sepramesh IP	Polypropylene/hyaluronate gel
C-Qur	Polypropylene/omega-3 fatty acid
TiMESH	Polypropylene/titanium
Proprietary Name	Composition
Biologic meshes	
Surgis Gold	Porcine small intestine submucosa
AlloDerm	Human dermis
SurgiMend	Fetal bovine dermis
CollaMend	Porcine dermis
AlloMax	Human dermis
Proprietary Name	Composition
Absorbable meshes	
Gore Bio-A	Poly(glycolide: trimethylene carbonate)
Vicryl	Polyglactin
Dexon	Polyglycolate

ePTFE = expanded polytetrafluoroethylene.

Open mesh repair of incisional hernias generally requires incision or excision of the previous laparotomy scar, with care taken to avoid injury to the underlying abdominal contents. The peritoneum and hernial sac are then dissected free from the abdominal wall fascia so that at least 3 to 4 cm of fascia is circumferentially exposed. The mesh can then be sutured into place using an underlay, onlay, interlay, or "sandwich-style" (both underlay and onlay) method. The most successful method is to extensively develop a preperitoneal space to accommodate a large sheet of polypropylene or woven polyester mesh.

The mesh, which is isolated from the peritoneal contents, is then secured to the musculoaponeurotic tissues using interrupted nonabsorbable sutures. Tissue ingrowth within the interstices of these mesh types results in dense attachment to whatever tissues the mesh comes into contact with. This effect is desirable when the mesh is located in the preperitoneal position. However, exposure to the underlying bowel ought to be avoided whenever possible. Among the problems attributed to adherence of peritoneal contents to mesh are chronic pain, bowel obstruction, and fistulization to bowel.

Polytetrafluoroethylene (PTFE) does not become incorporated into the surrounding tissues and is not associated with dense adhesions to the intraperitoneal structures. It is therefore commonly used for intraperitoneal applications. Irrespective of technique, the recurrence rate after open incisional hernia repair can be high. In two randomized trials of open mesh repair, one using an underlay technique and one using an onlay technique, the recurrence rates were 20% and 8%, respectively.

Laparoscopic incisional hernia repair was first described by LeBlanc and Booth in 1993. Since that time, many would argue, these procedures have become a new gold standard for abdominal wall reconstruction for ventral hernia. In 2000, data from 407 patients undergoing laparoscopic incisional hernia as part of a multicenter trial revealed a recurrence rate of only 3.4%, after a mean follow-up of >2 years. Of the recurrences noted, the overwhelming majority were felt to be secondary to technical errors committed early in the surgeons' experience that were avoided during the later cases. Recently, investigators at Washington University examined pooled data from 45 different series of laparoscopic and open ventral hernia repair. Use of the laparoscopic technique was associated with statistically fewer wound complications, fewer overall complications, and a

lower recurrence rate than use of the open technique. These benefits of the minimally invasive technique are achieved by eliminating the requisite large abdominal incision at a location where the abdominal wall blood supply has previously been compromised. In addition, with the laparoscopic technique, the entire undersurface of the abdominal wall can be examined, which often reveals multiple secondary defects that might not otherwise be appreciated.

The technique of laparoscopic incisional hernia repair generally involves laterally placed ports for midline defects and contralaterally placed ports for lateral defects. All adhesions to the anterior abdominal wall are divided, with great care taken not to injure the intestine either directly or with thermal or electrical energy. The contents of the hernial sac are completely reduced, but in contrast to open repairs, the sac itself is left in situ. Once the area encompassing all fascial defects is defined, a mesh is fashioned to allow for sufficient overlap (minimum of 3 to 4 cm) under the healthy abdominal wall. After insertion into the abdomen, the mesh is fixed into position with transfascial sutures placed circumferentially around the mesh and spiral tacks placed according to surgeon preference (Fig. 35-11). It has been proposed that transfascial sutures contribute to excessive postoperative pain, and some surgeons have eliminated them from the aforementioned technique, relying solely on spiral tacks for the strength of the repair. LeBlanc reviewed the usefulness of transfascial sutures and cautiously recommended a minimum 5-cm overlap of mesh from defect edge if transfascial sutures are not used.

Intraperitoneal view of polytetrafluoroethylene mesh used for laparoscopic ventral incisional hernia repair. The mesh is in place on the posterior aspect of the abdominal wall without apparent laxity due to the ongoing CO₂ insufflation. Once pneumoperitoneum is released, sufficient laxity is introduced to relieve any pull at the fixation points and to permit good apposition of mesh to the abdominal wall surface.

OMENTUM

Surgical Anatomy

The greater omentum and lesser omentum are fibro-fatty aprons that provide support, coverage, and protection for

peritoneal contents. These structures begin to develop during the fourth week of gestation. The greater omentum develops from the dorsal mesogastrium, which begins as a double-layered structure. The spleen develops in between the two layers, and later in development the two layers fuse, giving rise to the intraperitoneal spleen and the gastrosplenic ligament. The fused layers then hang from the greater curvature of the stomach and drape over the transverse colon, to which their posterior surface becomes fixed. The gastrocolic ligament and the gastrosplenic ligament are those segments of the greater omental apron that connect the named structures. In the adult, the greater omentum lies in between the anterior abdominal wall and the hollow viscera, and usually extends into the pelvis to the level of the symphysis pubis.

The lesser omentum, otherwise known as the *hepatoduodenal* and *hepatogastric ligaments*, develops from the mesoderm of the septum transversum, which connects the embryonic liver to the foregut. The common bile duct, portal vein, and hepatic artery are located in the inferolateral margin of the lesser omentum, which also forms the anterior margin of the foramen of Winslow.

The blood supply to the greater omentum is derived from the right and left gastroepiploic arteries. The venous drainage parallels the arterial supply to a great extent, with the left and right gastroepiploic veins ultimately draining into the portal system.

Physiology

In the early twentieth century, the British surgeon Rutherford Morison noted that the omentum tended to wall off areas of infection and limit the spread of intraperitoneal contamination. He termed the omentum the *abdominal policeman*. Shortly after his description was published, several reports suggested intrinsic hemostatic characteristics of the omentum. In 1996, researchers in the Netherlands demonstrated that the concentration of tissue factor in omentum is over twice the amount per gram of that found in muscle. This facilitates activation of coagulation at sites of inflammation, ischemia, infection, or trauma within the peritoneal cavity. The consequent local production of fibrin contributes to the ability of the omentum to adhere to areas of injury or inflammation.

Omental Infarction

Interruption of the blood supply to the omentum is a rare cause of an acute abdomen that may be secondary to torsion of the omentum around its vascular pedicle, thrombosis or vasculitis of the omental vessels, or omental venous outflow obstruction. Fewer than 100 cases have been reported, and the diagnosis is most likely to be made in male adults. Depending on the location of the infarcted omental tissue, this disease process may mimic appendicitis, cholecystitis, diverticulitis, perforated peptic ulcer, or ruptured ovarian cyst.

Patients typically present with localized right lower quadrant, right upper quadrant, or left lower quadrant pain. Although a mild degree of nausea may be present, patients do not usually have concomitant intestinal symptoms. Physical examination typically reveals a mild tachycardia and a low-grade fever. Abdominal examination may demonstrate a tender, palpable mass associated with guarding and rebound tenderness. The diagnosis is rarely made before abdominal imaging studies are performed. Either abdominal CT or ultrasonography will show a localized, inflammatory mass of fat density. Treatment of omental infarction depends on the certainty with which the diagnosis is made. In patients who are not toxic and whose abdominal imaging results are convincing, supportive care is sufficient. However, many cases are indistinguishable from surgical conditions with immediate surgical implications, such as appendicitis. In these instances, laparoscopic exploration offers the opportunity to establish an accurate diagnosis and determine the most appropriate treatment. Resection of the

infarcted tissue results in rapid resolution of symptoms.

Omental Cysts

Cystic lesions of the omentum and mesentery are related disorders, likely resulting from either peritoneal inclusions or degeneration of lymphatic structures. Omental cysts are far less common than mesenteric cysts. Omental cysts may present as an asymptomatic abdominal mass or may cause abdominal pain with or without appreciable mass or distention. Physical examination may reveal a freely mobile intra-abdominal mass. Both CT and abdominal ultrasound reveal a well-circumscribed, cystic mass lesion arising from the greater omentum. Treatment involves resection of all symptomatic omental cysts. Resection of these benign lesions is readily accomplished using laparoscopic techniques.

Omental Neoplasms

Primary tumors of the omentum are uncommon. Benign tumors of the omentum include lipomas, myxomas, and desmoid tumors. Primary malignant tumors of the omentum are considered mesodermally derived stromal tumors, in which some of the associated immunohistochemical characteristics of GI stromal tumors have been described, including c-kit immunopositivity. Metastatic tumors of the omentum are common, with metastatic ovarian cancer showing the highest preponderance of omental involvement. Malignant tumors of the stomach, small intestine, colon, pancreas, biliary tract, uterus, and kidney may also metastasize to the omentum.

MESENTERY

Surgical Anatomy

The mesentery develops from mesenchyme that attaches the foregut, midgut, and hindgut to the posterior abdominal wall. During embryonic maturation, this mesenchyme forms the dorsal mesentery. In the region of the stomach, the dorsal mesentery becomes the greater omentum, whereas in the region of the jejunum and ileum the dorsal mesentery becomes the mesentery proper. In the region of the colon, the dorsal mesentery is known as the *mesocolon*. During embryonic development, after the 270-degree counterclockwise rotation of the herniated midgut, the reduced mesentery achieves its final fixation state. The segments at the duodenum, ascending colon, and descending colon become fixed to the retroperitoneum, whereas the small intestine mesentery, transverse colon mesentery, and, to a variable extent, the sigmoid colon mesentery remain mobile (Fig. 35-12). Defects in the normal developmental steps of intestinal rotation result in malrotation disorders.

The root of the small intestine mesentery wall normally courses in an oblique direction, from the left upper quadrant at the ligament of Treitz to the right lower quadrant at the ileocecal valve and the fixed cecum. The small and large intestine mesenteries serve as the major pathway for arterial, venous, lymphatic, and neural structures coursing to and from the bowel. Anatomic anomalies of the mesentery related to rotational disorders can lead to paraduodenal or mesocolic hernias (Fig. 35-13), which can present as chronic or acute intestinal obstruction in children or adults.

Sclerosing Mesenteritis

Sclerosing mesenteritis, also referred to as *mesenteric panniculitis* or *mesenteric lipodystrophy*, is a chronic inflammatory and fibrotic process that involves a portion of the intestinal mesentery. There is no gender or race predominance, but the condition is most commonly diagnosed in individuals >50 years of age.

The etiology of this process is unknown, but its cardinal feature is increased tissue density within the mesentery. This can be localized and associated with a discrete non-neoplastic mesenteric mass or more diffuse, sometimes involving large swaths of mesentery without well-defined borders. There may be varying relative degrees of fat tissue degeneration, inflammation, and fibrosis on histologic examination, which gives rise to the various terms used to describe this condition. *Mesenteric lipodystrophy* is used when the inflammatory and fibrotic components are small. *Mesenteric panniculitis* signifies an increased inflammatory component with replacement of degenerative fatty elements. *Sclerosing mesenteritis* signifies a major fibrotic component and is sometimes referred to as *retractile mesenteritis* to describe mesenteric retraction and shortening associated with scarring. It is not clear if these represent stages in a sequential process or variations in disease severity. A discrete mass may be up to 40 cm in diameter, and patients typically present with symptoms of a mass lesion. Abdominal pain is the most frequent presenting symptom, followed by the presence of a nonpainful mass or, more rarely, intestinal obstruction. However, many cases are discovered incidentally when imaging studies (most frequently abdominal CT scanning) are performed for unrelated reasons. This then raises diagnostic questions whose resolution is often pursued using invasive procedures.

CT of the abdomen can verify the presence of a mass lesion or area of the mesentery with a higher density than found in normal mesenteric tissue. This may frequently involve the vascular structures in the mesenteric root (Fig. 35-14). Although CT cannot definitively distinguish sclerosing mesenteritis from a primary or secondary mesenteric tumor, identification of a "fat ring sign" or hypodense zone around the mass area has been suggested as a means of distinguishing sclerosing mesenteritis from lymphoma. The presence of a hyperattenuating stripe also has been suggested as a radiologic finding that

would favor a diagnosis of mesenteritis (Fig. 35-15).

Computed tomographic scan of sclerosing mesenteritis (mesenteric lipodystrophy). This condition cannot easily be distinguished from a neoplasm of the mesentery on radiologic study. In this case, the study showed "fatty mesenteric tumor with involvement of mesenteric vessels," and "mesenteric lipodystrophy" was demonstrated by biopsy findings at exploration. The finding of a hyperattenuating stripe around the lesion, as seen in this image, has been associated with the diagnosis of mesenteritis.

Surgery has been used most frequently to establish a diagnosis and to rule out a neoplastic process. The extent and location of mesenteric involvement defines, and in some cases limits, the options for surgical intervention. In addition to simple biopsy, bowel and mesenteric resection can be considered, particularly in cases in which it is technically feasible based on mass size and the ability to avoid injury to the small intestine blood supply (Fig. 35-16). Often, however, the involvement of the vascular structures at the mesenteric root makes resection unfeasible. In rare cases, an ostomy of some type for fecal diversion in the face of obstruction can be considered. The recent use of positron emission tomography with CT scanning has proven effective in ruling out neoplasia for focal mesenteric masses, which leaves the sclerosing mesenteritis diagnosis as one of exclusion. However, it is not clear that use of this newer modality will eliminate the need to obtain tissue for diagnostic purposes.

Fig. 35-16.

Operative findings at the time of resection of what was believed to be a mesenteric tumor but which proved to be a focus of mesenteric lipodystrophy. In this case, the relatively small site of involvement and the peripheral location in the small intestine mesentery permitted management by resection en bloc with a segment of adjacent small bowel.

In most cases of sclerosing mesenteritis the process appears to be self-limited and may even demonstrate regression if followed with interval imaging studies. Clinical symptoms are very likely to improve without intervention, and therefore aggressive surgical treatments are generally not indicated. In clinically problematic cases that are not amenable to resection because of widespread mesenteric involvement or unfavorable location, medical treatment has been given to alleviate severe symptoms. Among the agents that have been used are corticosteroids, colchicine, tamoxifen, and cyclophosphamide.

Mesenteric Cysts

Cysts of the mesentery are benign lesions with an incidence of <1 in 100,000. Since the first description of such a cyst in 1507, approximately 1000 cases have been described in the literature. The etiology of such cysts remains unknown, but several theories regarding their development have been put forward, including that they are caused by degeneration of the mesenteric lymphatics and that they simply arise as a congenital anomaly.

Mesenteric cysts may be asymptomatic or may cause symptoms of a mass lesion. Symptoms may be acute or chronic. Acute abdominal pain secondary to a mesenteric cyst is generally caused by rupture or torsion of the cyst or by acute hemorrhage into the cyst. Mesenteric cysts may also cause chronic intermittent abdominal pain secondary to compression of adjacent structures or spontaneous torsion followed by detorsion of the cyst. Mesenteric cysts can be the cause of nonspecific symptoms such as anorexia, nausea, vomiting, fatigue, and weight loss.

Physical examination may reveal a mass lesion that is mobile only from the patient's right to left or left to right (Tillaux's sign), in contrast to the findings with omental cysts, which should be freely mobile in all directions. Tillaux was the first to record this physical finding and, in 1850, the first to successfully remove a mesenteric cyst.

CT (Fig. 35-17), abdominal ultrasound, and MRI all have been used to evaluate patients with mesenteric cysts. Each of the aforementioned imaging modalities reveals a cystic structure without a solid component in the central abdomen. These structures are generally unilocular but may on occasion be multiple or multilocular. Irrespective of the imaging method used,

it may be difficult to distinguish these cystic masses from rare solid mesenteric tumors with cystic components, such as a cystic stromal tumor or mesothelioma. Mesenteric cystic lymphangioma may present as numerous, often large cysts in the setting of abdominal pain. These can be difficult to treat and almost invariably recur after excision.

Fig. 35-17.

Computed tomographic scan of a mesenteric cyst. The unilocular appearance without an associated solid component strongly suggests the diagnosis of benign cyst.

When symptomatic, simple mesenteric cysts are surgically excised either openly or laparoscopically when feasible. Cyst unroofing or marsupialization is not recommended, because mesenteric cysts have a high propensity to recur after drainage alone. On rare occasion, adjacent mesentery may be densely adherent to the cyst or mesenteric vessels must be sacrificed to achieve complete excision, in which case segmental bowel resection is performed.

Mesenteric Tumors

Primary tumors of the mesentery are rare. Benign tumors of the mesentery include lipoma, cystic lymphangioma, and desmoid tumors. Primary malignant tumors of the mesentery are similar to those described for the omentum. Liposarcomas, leiomyosarcomas, malignant fibrous histiocytomas, lipoblastomas, and lymphangiosarcomas all have been described. Metastatic small intestine carcinoid in mesenteric lymph nodes may exceed the bulk of primary disease and compromise blood supply to the bowel. Treatment of mesenteric malignancies involves wide resection of the mass. Because of the proximity to the blood supply to the intestine, such resections may be technically unfeasible or involve loss of substantial lengths of bowel.

RETROPERITONEUM

Surgical Anatomy

Although there are ectodermal, mesodermal, and endodermal contributions to the contents of the retroperitoneum, embryonic mesoderm predominates in the developing retroperitoneal space. From the *intermediate* mesoderm arise the organs of the urinary and genital systems. The *lateral plate* mesoderm eventually divides into two layers, the parietal layer

and the visceral layer. These layers eventually become the pleura, pericardium, peritoneum, and retroperitoneum.

The retroperitoneum is defined as the space between the posterior envelopment of the peritoneum and the posterior body wall (Fig. 35-18). The retroperitoneal space is bounded superiorly by the diaphragm, posteriorly by the spinal column and iliopsoas muscles, and inferiorly by the levator ani muscles. Although the retroperitoneum is technically bounded anteriorly by the posterior reflection of the peritoneum, the anterior border of the retroperitoneum is quite convoluted, extending into the spaces in between the mesenteries of the small and large intestine. Because of the rigidity of the superior, posterior, and inferior boundaries, and the compliance of the anterior margin, retroperitoneal tumors tend to expand anteriorly toward the peritoneal cavity. Table 35-2 lists the organs and structures that reside within the retroperitoneum.

Fig. 35-18.

Table 35-2 Retroperitoneal Structures		
Kidneys	Ureters	Bladder
Pancreas	Duodenum (D2 and D3)	Adrenal glands
Ascending colon	Descending colon	Rectum (upper two thirds)
Aorta	Inferior vena cava	Iliac vessels
Seminal vesicles	Vas deferens	Lymphatics (cisterna chyli)
Vagina (uppermost)	Ovaries	Nerves (lumbar sympathetics)

Retroperitoneal Infections

The posterior reflection of the peritoneum limits the spread of most intra-abdominal infections to the peritoneum. Accordingly, the source of retroperitoneal infections is usually an organ contained within or abutting the retroperitoneum. Retrocecal appendicitis, perforated duodenal ulcers, pancreatitis, and diverticulitis may all lead to retroperitoneal infection with or without abscess formation. The substantial space and rather nondiscrete boundaries of the retroperitoneum allow some retroperitoneal abscesses to become quite large before diagnosis.

A patient with a retroperitoneal abscess usually presents with pain, fever, and malaise. The site of the patient's pain may be variable and can include the back, pelvis, or thighs. Clinical findings can include tachypnea and tachycardia. Erythema may be observed around the umbilicus or flank. This is analogous to the ecchymosis seen in these locations after massive retroperitoneal hemorrhage (Cullen's sign and Grey Turner's sign, respectively). A palpable flank or abdominal mass may be present. Laboratory evaluation usually reveals an elevated white blood cell count. The diagnostic imaging modality of choice is CT, which may demonstrate stranding of the retroperitoneal soft tissues and/or a unilocular or multilocular collection (Fig. 35-19).

Computed tomographic scan of a retroperitoneal abscess complicating complex, surgically treated retroperitoneal infection that had resulted from ampullary perforation at the time of endoscopic retrograde cholangiopancreatography. This pattern of infection may be difficult to treat and may result in multiple interventions, such as percutaneous drainage, before resolution.

Management of retroperitoneal infections includes identification and treatment of the underlying condition, IV administration of antibiotics, and drainage of all well-defined collections. Although unilocular abscesses may be drained percutaneously under CT guidance, multilocular collections usually require operative intervention for adequate drainage. Because of the large size of the retroperitoneal space, patients with retroperitoneal abscesses usually do not seek treatment until the abscess is advanced. Consequently, the mortality rate for retroperitoneal abscess, even when the abscess is drained, has been reported to be as high as 25%, or even higher in rare cases of necrotizing fasciitis of the retroperitoneum.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is a class of disorders characterized by hyperproliferation of fibrous tissue in the retroperitoneum. It may be a primary disorder as in idiopathic retroperitoneal fibrosis, also known as *Ormond disease*, or a secondary reaction to an inciting inflammatory process, malignancy, or medication. Idiopathic retroperitoneal fibrosis is a rare disorder, usually affecting 0.5 in 100,000 patients annually. Men are twice as likely to be affected as women, and no predilection for any particular ethnic group is seen. The disease primarily affects individuals in the fourth to the sixth decades of life.

An allergic or autoimmune mechanism has been postulated for this condition. Circulating antibodies to ceroid, a lipoproteinaceous by-product of vascular atheromatous plaque oxidation, are present in >90% of patients with retroperitoneal fibrosis. The relationship of this finding to the occurrence of fibrosis remains uncertain. The early inflammatory reaction involves predominately helper T cells, plasma cells, and macrophages, but these are subsequently replaced by collagen-synthesizing fibroblasts. Microscopically, the infiltrate is indistinguishable from that seen with periadventitial involvement in aortic aneurysmal disease, Riedel's thyroiditis, sclerosing cholangitis, and Peyronie's disease. The fibrotic process begins in the retroperitoneum just below the level of the renal arteries. Fibrosis gradually expands,

encasing the ureters, inferior vena cava, aorta, mesenteric vessels, or sympathetic nerves. Bilateral involvement is noted in 67% of cases.

Retroperitoneal fibrosis may also occur secondary to a variety of inflammatory conditions or as an allergic reaction to a medication. These conditions include abdominal aortic aneurysm, pancreatitis, histoplasmosis, tuberculosis, and actinomycosis. It is also associated with a variety of malignancies, including prostate, pancreatic, and gastric cancers as well as non-Hodgkin's lymphoma, stromal tumors, and carcinoid tumors. Retroperitoneal fibrosis has been described in association with autoimmune disorders, including ankylosing spondylitis, systemic lupus erythematosus, Wegener's granulomatosis, and polyarteritis nodosa. The strongest case for a causal relationship between medication and retroperitoneal fibrosis is made for methysergide, a semisynthetic ergot alkaloid used in the treatment of migraine headaches. Other medications that have been linked to retroperitoneal fibrosis include beta blockers, hydralazine, α -methyldopa, and entacapone, which inhibits catechol-*O*-methyltransferase and is used as an adjunct with levodopa in the treatment of Parkinson's disease. The retroperitoneal fibrosis regresses on discontinuation of these medications.

Presenting symptoms depend on the structure or structures affected by the fibrotic process. Initially, patients complain of the insidious onset of dull, poorly localized abdominal pain. Sudden-onset or severe abdominal pain may signify acute mesenteric ischemia. Other symptoms of retroperitoneal fibrosis include unilateral leg swelling, intermittent claudication, oliguria, hematuria, and dysuria.

As with the patient's symptomatology, findings on physical examination vary with the retroperitoneal structure involved. Consequently, findings may include hypertension, the palpation of an abdominal or flank mass, lower extremity edema (unilateral or bilateral), or diminished lower extremity pulses (unilateral or bilateral). Laboratory evaluation may reveal an elevated blood urea nitrogen and/or creatinine level. As with many autoimmune inflammatory processes, the erythrocyte sedimentation rate almost always is elevated in patients with retroperitoneal fibrosis.

Many imaging modalities have been used with varying sensitivity to diagnose retroperitoneal fibrosis. Abdominal and lower extremity ultrasonography is the least invasive imaging procedure, but results are technician dependent. It may be useful if ilio caval compressive or renal symptoms predominate. Lower extremity ultrasonography may show deep vein thrombosis, whereas abdominal ultrasonography may identify a mass lesion or hydronephrosis. IV pyelography, once the diagnostic procedure of choice, is less commonly used today. If the ureters are involved, the findings of IV pyelography will include ureteral compression, ureteral deviation toward the midline, and hydronephrosis.

Abdominopelvic CT with oral and IV contrast agents is the imaging procedure of choice and generally will allow the extent of the fibrotic process to be determined. If renal function is diminished so that the use of IV contrast agents must be avoided, the ability to characterize retroperitoneal tissue planes will be reduced. In this case, MRI may be used, because the signal intensity of the fibrotic process is discrete from that of muscle or fat. In addition, magnetic resonance angiography generally provides a good assessment of the degree of ilio caval involvement. Once a mass lesion is identified, biopsy of the mass should be performed to rule out a retroperitoneal malignancy. The specimen may be obtained using image-guided techniques or a surgical retroperitoneal biopsy procedure, which may be performed laparoscopically or during open laparotomy.

Once malignancy, drug effects, and infectious causes are ruled out, treatment of the retroperitoneal fibrotic process is instituted. Corticosteroids, with or without surgery, are the mainstay of medical therapy. Surgical treatment consists primarily of ureterolysis or ureteral stenting and is required in patients who present with moderate or massive hydronephrosis. Laparoscopic ureterolysis has been shown to be as efficacious as open surgery in addressing this problem.

Patients with ilio caval thrombosis require anticoagulation, although the required duration of this therapy is unclear. Prednisone is initially administered at a relatively high dose (60 mg every other day for 2 months) and then gradually tapered over the next 2 months. Therapeutic efficacy is assessed on the basis of patient symptoms and interval imaging studies. Cyclosporin, tamoxifen, and azathioprine also have been used to treat patients who respond poorly to corticosteroids.

The overall prognosis in idiopathic retroperitoneal fibrosis is good, with 5-year survival rates of 90 to 100%. Because long-term recurrences have been described, lifelong follow-up is warranted.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 36. Soft Tissue Sarcomas >

KEY POINTS

1. Sarcomas are a heterogeneous group of tumors that can occur throughout the body and encompass more than 50 subtypes with distinct histologic lines of differentiation.
2. These rare tumors account for less than 1% of cancers in adults (estimated 10,000 cases per year in the United States) and represent 7% of cancers in children.
3. Approximately two thirds of soft tissue sarcomas arise in the extremities; the remaining one third are distributed between the retroperitoneum, trunk, abdomen, and head and neck.
4. The treatment algorithm for soft tissue sarcomas depends on tumor stage, site, and histology.
5. Multimodality treatment including surgical resection, radiation therapy and, in selected cases, systemic chemotherapy, has been applied to patients with locally advanced, high-grade, extremity sarcomas.
6. Overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50 to 60%.
7. Of the patients who die of sarcoma, most will succumb to metastatic disease in the lungs, which 80% of the time occurs within 2 to 3 years of the initial diagnosis.
8. Progress in the understanding of soft tissue sarcoma biology is crucial for the development of new therapeutic targets.

OVERVIEW

Incidence

Sarcomas are a heterogeneous group of tumors that arise predominantly from the embryonic mesoderm, but also can originate, as does the peripheral nervous system, from the ectoderm. In 2007, approximately 9220 new cases of soft tissue sarcoma were diagnosed in the United States with 3560 deaths attributable to disease.¹ These rare tumors account for less than 1% of cancers in adults and represent 7% of cancers in children. Several distinct groups of sarcomas are recognized; soft tissue sarcomas, the largest of these groups, are the focus of this chapter. Other groups include bone sarcomas (osteosarcomas and chondrosarcomas), Ewing's sarcomas, and peripheral primitive neuroectodermal tumors.

Soft tissue sarcomas can occur throughout the body and encompass more than 50 histiotypes (Table 36-1) with distinct histologic lines of differentiation. The most common histologic types of soft tissue sarcoma in adults (excluding Kaposi's sarcoma) are malignant fibrous histiocytoma (MFH, 28%), leiomyosarcoma (12%), liposarcoma (15%), synovial sarcoma (10%), and malignant peripheral nerve sheath tumors (6%).² Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood. Most primary soft tissue sarcomas originate in an extremity (50 to 60%); the next most common sites are the trunk, retroperitoneum, and head and neck.

Table 36-1 Relative Frequency of Histologic Subtypes of Soft Tissue Sarcoma²

Histologic Subtypes	<i>n</i>	%
Malignant fibrous histiocyteoma	349	28
Liposarcoma	188	15
Leiomyosarcoma	148	12
Unclassified sarcoma	140	11
Synovial sarcoma	125	10
Malignant peripheral nerve sheath tumor	72	6
Rhabdomyosarcoma	60	5
Fibrosarcoma	38	3
Ewing's sarcoma	25	2
Angiosarcoma	25	2
Osteosarcoma	14	1
Epithelioid sarcoma	14	1
Chondrosarcoma	13	1
Clear-cell sarcoma	12	1
Alveolar soft part sarcoma	7	1
Malignant hemangiopericytoma	5	0.4

Source: Data from Coindre et al.²

During the past 25 years, a multimodality treatment approach has been applied to patients with extremity sarcomas, which had led to modest improvements in both survival and quality of life. However, patients with abdominal sarcomas continue to have high rates of recurrence and poor overall survival. Overall 5-year survival rate for patients with all stages of soft tissue sarcoma is 50 to 60%. Of the patients who die of sarcoma, most will succumb to metastatic disease, which 80% of the time occurs within 2 to 3 years of the initial diagnosis.

Epidemiology

Except for malignant peripheral nerve sheath tumors in patients with neurofibromatosis, sarcomas do not seem to result from the progression or dedifferentiation of benign soft tissue tumors. Despite the variety of histologic subtypes, sarcomas have many common clinical and pathologic features. Overall, the clinical behavior of most soft tissue sarcomas is similar and is determined by anatomic location (depth), grade, and size. The dominant pattern of metastasis is hematogenous, primarily to the lungs. Lymph node metastases are rare (<5%) except for a few histologic subtypes such as epithelioid sarcoma, rhabdomyosarcoma, clear-cell sarcoma, synovial sarcoma, MFH, and angiosarcoma.³

RADIATION EXPOSURE

External radiation therapy is a rare but well-established risk factor for soft tissue sarcoma. An eightfold to 50-fold increase in the incidence of sarcomas has been reported among patients treated for cancer of the breast, cervix, ovary, testes, and lymphatic system.^{4,5} In a review of 160 patients with postirradiation sarcomas, the most common histologic types were osteogenic sarcoma, MFH, angiosarcoma, and lymphangiosarcoma.⁴ In that study, the risk of developing a sarcoma increased with higher radiation doses, and the median latency period was 10 years. Postirradiation sarcomas usually are diagnosed at advanced stages and generally have a poor prognosis.

OCCUPATIONAL CHEMICALS

Exposure to some herbicides such as phenoxyacetic acids and wood preservatives containing chlorophenols has been linked to an increased risk of soft tissue sarcoma.⁶ Several chemical carcinogens, including thorium oxide (Thorotrast), vinyl chloride, and arsenic have been associated with hepatic angiosarcomas.

TRAUMA

Although patients with sarcomas often report a history of trauma, no causal relationship has been established. More often, a minor injury calls attention to a pre-existing tumor that may be accentuated by edema or hematoma.

CHRONIC LYMPHEDEMA

In 1948, Stewart and Treves first described the association between chronic lymphedema after axillary dissection and subsequent lymphangiosarcoma.⁷ Lymphangiosarcoma also has been reported as occurring after filarial infections and in the lower extremities of patients with congenital or heritable lymphedema.

Genetics

Molecular genetics, cytogenetics, and expression profiling have been used to investigate sarcomas, resulting in their classification into two main groups: those with defined diagnostic molecular events and those with variable histologic and genetic changes.⁸ In general, the group of sarcoma patients with defined molecular events have been found to be younger with a defined histology, suggesting a clear line of differentiation. The defined molecular events include point mutations, a translocation causing overexpression of an autocrine growth factor or oncogenic fusion transcription factor. In contrast, sarcomas without currently identifiable genetic changes or expression profile signatures tend to occur in older patients exhibiting pleomorphic cytology and p53 dysfunction.⁸

Sarcomas occur more commonly within several hereditary cancer syndromes, including retinoblastoma, Li-Fraumeni syndrome, neurofibromatosis type I, and familial adenomatous polyposis.⁹ Germline mutations have been identified as causal in only a limited number of these disorders. Developments in the field of molecular biology have led to a better understanding of some of the basic cellular processes governed by oncogenes and tumor suppressor genes.

ONCOGENE ACTIVATION

Oncogenes are genes that can induce malignant transformation and tend to drive cells toward proliferation. Several oncogenes have been identified in association with soft tissue sarcomas, including *MDM2*, *N-myc*, *c-erbB-2*, and members of the *ras* family. These oncogenes produce specific oncoproteins that either play a role in nuclear function and cellular signal transduction or function as growth factors or growth factor receptors. Amplification of these genes has been shown to correlate with adverse outcome in several soft tissue sarcomas.¹⁰

Cytogenetic analysis of soft tissue tumors has identified distinct chromosomal translocations that seem to encode for oncogenes associated with certain sarcoma histologic subtypes. These specific genetic changes result in the in-frame fusion of genes and fused product codes for the expression of oncoproteins functioning as transcriptional activators or repressors.^{10,11} The best characterized gene rearrangements are found in Ewing's sarcoma (*EWS-FLI-1* fusion), clear-cell sarcoma (*EWS-ATF1* fusion), myxoid liposarcoma (*TLS-CHOP* fusion), alveolar rhabdomyosarcoma (*PAX3-FKHR* fusion), desmoplastic small round-cell tumor (*EWS-WT1* fusion), and synovial sarcoma (*SSX-SYT* fusion). It has been estimated that, in aggregate, fusion gene-related sarcomas may account for up to 30% of all sarcomas.¹² The oncogenic potential of

many of these genes has been demonstrated in vitro and in vivo. These fusion genes provide not only specific diagnostic markers but encode chimeric proteins, both of which may be potential therapeutic targets.

TUMOR SUPPRESSOR GENES

Tumor suppressor genes play a critical role in growth inhibition and can suppress growth in cancer cells. Inactivation of tumor suppressor genes (also known as *anti-oncogenes*) can occur through hereditary or sporadic mechanisms. The two genes that are most relevant to soft tissue tumors are the retinoblastoma (*Rb*) tumor suppressor gene and the p53 tumor suppressor gene. Mutations or deletions in *Rb* can lead to development of retinoblastoma or sarcomas of soft tissue and bone. Mutations in the p53 tumor suppressor gene are the most common mutations in human solid tumors and have been reported in 30 to 60% of soft tissue sarcomas.¹³ Patients with germline mutations in the tumor suppressor gene p53 (the Li-Fraumeni syndrome) have a high incidence of sarcomas. Mutant p53 expression is thought to correlate with overall survival.¹⁰ The p53 mutation also has been used as a therapeutic molecule in gene therapy strategies.

Neurofibromatosis is a neurocutaneous condition that exists in two forms. Neurofibromatosis type I, also known as *von Recklinghausen's disease*, occurs in approximately one of every 3000 people and is due to various mutations in the *NF-1* tumor suppressor gene located on chromosome 17. Patients with neurofibromatosis type I have an estimated 3 to 15% additional lifetime risk of malignant disease, including neurofibrosarcoma. Fifty percent of patients with neurofibrosarcomas have a mutation in *NF-1*.¹⁴

INITIAL ASSESSMENT

Clinical Presentation

Soft tissue sarcomas most commonly present as an asymptomatic mass. Another less common presentation of an extremity sarcoma may be a deep venous thrombosis, particularly in patients without significant risk factors for thrombosis.¹⁵ Tumor size at presentation usually is associated with the location of the tumor. Smaller tumors generally are located in the distal extremities, whereas tumors in the proximal extremities and retroperitoneum can grow quite large before becoming apparent. Often, an extremity mass is discovered after a traumatic event that draws attention to a pre-existing lesion.

Soft tissue sarcomas often grow in a centrifugal fashion and compress surrounding normal structures. Infrequently, their impingement on bone or neurovascular bundles produces pain, edema, and swelling. Retroperitoneal soft tissue sarcomas almost always present as large asymptomatic masses. Less frequently, patients present with obstructive GI symptoms or neurologic symptoms related to compression of lumbar or pelvic nerves.

The differential diagnosis of a soft tissue mass includes benign lesions such as lipomas (100 times more common than sarcoma), lymphangiomas, leiomyomas, and neuromas. In addition to sarcomas, other malignant lesions such as primary or metastatic carcinomas, melanomas, or lymphomas must be considered. Small lesions that have not changed for several years by clinical history may be closely observed. All other tumors should be considered for biopsy to establish a definitive diagnosis.

Diagnostic Imaging

Pretreatment radiologic imaging serves several purposes: (a) defines the local extent of a tumor, (b) stages malignant disease, (c) assists in percutaneous biopsy procedures, and (d) aids in the diagnosis of soft tissue tumors (benign vs. malignant or low grade vs. high grade). Imaging studies are also crucial in monitoring tumor changes after treatment,

especially preoperative chemotherapy or radiation therapy, and in detecting recurrences after surgical resection.

Radiographs provide useful information on primary bone tumors, but they are not useful in the evaluation of soft tissue sarcomas of the extremities unless underlying bone involvement from an adjacent soft tissue tumor is suspected. Chest radiography should be performed for patients with primary sarcomas to assess for lung metastases. For patients with high-grade lesions or tumors >5 cm (T2), computed tomography (CT) of the chest should be considered.

CT is the preferred technique for evaluating retroperitoneal sarcomas, whereas magnetic resonance imaging (MRI) often is favored for soft tissue sarcomas of the extremities.¹⁶ Both ultrasonography and CT can assist in guiding fine-needle aspiration, core biopsy for initial diagnosis, and at recurrence.

ULTRASONOGRAPHY

Ultrasonography may have a diagnostic role for patients who cannot undergo MRI. Ultrasonography also can be a useful adjunct to MRI when findings are indeterminate and for delineating adjacent vascular structures.

COMPUTED TOMOGRAPHY

Contrast-enhanced CT can assess the extent of soft tissue tumor burden and the proximity of the tumor to vital structures (Fig. 36-1). CT is the preferred imaging technique for evaluating retroperitoneal sarcomas.¹⁶ Current CT techniques can provide a detailed survey of the abdomen and pelvis and can delineate adjacent organs and vascular structures. For extremity sarcomas, CT may be useful if MRI is not available or cannot be used. CT of the abdomen and pelvis should be done when histologic assessment of an extremity sarcoma reveals a myxoid liposarcoma, because this subtype is known to metastasize to the abdomen.¹⁷

A 27-year-old man presented with symptoms of back pain. Computed tomography of the abdomen demonstrating a 4.1 x 3.3 cm hypodense mass in the retrocaval region involving the inferior vena cava. Subsequent biopsy of the tumor confirmed leiomyosarcoma.

MAGNETIC RESONANCE IMAGING

MRI accurately delineates muscle groups and distinguishes among bone, vascular structures, and tumor. Sagittal and coronal views allow evaluation of anatomic compartments in three dimensions (Fig. 36-2). Soft tissue sarcomas of the extremities usually present on MRI as heterogeneous masses. Their signal intensity tends to be equal to or slightly higher than that of adjacent skeletal muscle on T1-weighted images and heterogeneous and high on T2-weighted images. Hemorrhagic, cystic, or necrotic changes also may be observed in the tumor. Special MRI techniques, including magnetic resonance angiography, may be performed if adjacent vascular structures must be delineated.

Fig. 36-2.

A 55-year-old woman presented with right thigh pain and enlarging mass. Coronal image demonstrating an 18-cm mass within the adductor magnus musculature with evidence of necrosis and hemorrhage.

MRI has supplanted CT as the imaging technique of choice for evaluation of soft tissue sarcomas of the extremities. MRI also is valuable for assessing tumor recurrence after surgery (Fig. 36-3). A baseline image usually is obtained 3 months after surgery. Some clinicians believe that routine postoperative imaging of a primary extremity tumor site is not necessary for asymptomatic patients, citing the difficulties in detecting early recurrence in scarred, irradiated tissue.¹⁶ Others advocate routine imaging every 6 months for the first 2 years.

Fig. 36-3.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>

A 51-year-old woman, 30 months status postexcision of desmoid tumor of the left breast and chest wall. Magnetic resonance imaging of the chest demonstrating a 5.2 x 7.7 cm mass with both T2 signal and postcontrast T1 signal indicating a recurrent desmoid tumor in the anterior aspect of the left upper arm and shoulder.

MRI may be an important adjunct to cytologic analysis in distinguishing benign lesions such as lipomas, hemangiomas, schwannomas, neurofibromas, and intramuscular myxomas from their malignant counterparts. In the setting of preoperative chemotherapy, contrast-enhanced T1-weighted MRIs can be useful in evaluating intratumoral necrosis.

Biopsy Techniques

FINE-NEEDLE ASPIRATION

Fine-needle aspiration is an acceptable method of diagnosing most soft tissue sarcomas, particularly when the results correlate closely with clinical and imaging findings.¹⁸ However, fine-needle aspiration biopsy is indicated for primary diagnosis of soft tissue sarcomas only at centers where cytopathologists have experience with these types of tumors. Fine-needle aspiration biopsy is also the procedure of choice to confirm or rule out the presence of a metastatic focus or local recurrence. When tumor grading is essential for treatment planning, fine-needle aspiration biopsy is not the preferred technique.

Superficial lesions often are subjected to fine-needle aspiration biopsies in the clinic setting. Deeper tumors may require an interventional radiologist to perform the technique under sonographic or CT guidance. The technique generally involves the use of a 21- to 23-gauge needle that is introduced into the mass after appropriate cleansing of the skin and injection of local anesthetic. Negative pressure is applied, and the needle is pulled back and forth several times in various directions. After the negative pressure is released, the needle is withdrawn and the contents of the needle are used to prepare a smear.¹⁹ A cytopathologist then examines the slides to determine whether sufficient diagnostic material is present. When insufficient

diagnostic material is obtained, a core needle biopsy should be performed.

Diagnostic accuracy rates for fine-needle aspiration biopsy of primary tumors range from 60 to 96%. In general, the amount of material obtained from a fine-needle aspiration biopsy is small, and diagnostic accuracy clearly depends on the experience of the cytopathologist.

CORE NEEDLE BIOPSY

Core needle biopsy is a safe, accurate, and economical procedure for diagnosing sarcomas. The tissue sample obtained from a core needle biopsy is usually sufficient for several diagnostic tests such as electron microscopy, cytogenetic analysis, and flow cytometry. The reported complication rate for core needle biopsy is less than 1%.²⁰

CT guidance can enhance the positive yield rate of a core needle biopsy by more accurately pinpointing the location of the tumor. Precise localization in the tumor mass is particularly important to avoid sampling nondiagnostic necrotic or cystic areas of the tumor. CT guidance also permits access to tumors in otherwise inaccessible anatomic locations or when located near vital structures.

Dupuy and associates examined the accuracy of core needle biopsy in 221 patients with musculoskeletal neoplasms.²⁰ Core needle biopsy had an accuracy of 93% compared with the diagnosis given at the time of definitive treatment. Only 8% of patients had nondiagnostic or insufficient specimens.

INCISIONAL BIOPSY

Open biopsy is a reliable diagnostic method that allows adequate tissue to be sampled for definitive and specific histologic identification of bone or soft tissue sarcomas. When adequate tissue for diagnosis cannot be obtained by fine-needle aspiration biopsy or core biopsy, an incisional biopsy is indicated for deep tumors and for superficial soft tissue tumors >3 cm. Incisional biopsies usually are performed as a last resort when fine-needle aspiration or core biopsy specimens are nondiagnostic. Open biopsies should be performed only by surgeons experienced in the management of soft tissue sarcomas. In a series of 107 patients with soft tissue sarcomas, planned surgical treatments had to be changed due to prior, poorly oriented biopsies in 25% of the cases.²¹ Other series have reported complications in up to 16% of open biopsies.¹⁹

An open biopsy ideally should be performed in a designated treatment center and by the surgeon who will perform the definitive surgery. The biopsy incision should be oriented longitudinally along the extremity to allow a subsequent wide local excision that encompasses the biopsy site, scar, and tumor en bloc. A poorly oriented biopsy incision often mandates an excessively large surgical defect for a wide local excision. This, in turn, can result in a larger postoperative radiotherapy field to encompass all tissues at risk. Another mandate of surgical technique is that adequate hemostasis be achieved at the time of biopsy to prevent dissemination of tumor cells into adjacent tissue planes by hematoma.

An incisional or open biopsy is the most reliable of the diagnostic methods, providing accurate histologic diagnosis and grading in >95% of soft tissue sarcomas. In addition, the amount of tissue obtained often is sufficient for additional diagnostic studies if necessary.

EXCISIONAL BIOPSY

Excisional biopsy can be performed for easily accessible (superficial) extremity or truncal lesions <3 cm. Excisional biopsy should not be done for lesions involving the hands and feet, because definitive re-excision may not be possible after the biopsy. Excisional biopsy results have a 30 to 40% rate of recurrence when margins are positive or uncertain. Excisional

biopsies rarely provide any benefit over other biopsy techniques and may cause postoperative complications that could ultimately delay definitive therapy.

Pathologic Classification

Some experts have suggested that pathologic classification of soft tissue sarcomas has more prognostic significance than does tumor grade when other pretreatment variables are taken into account. Tumors with limited metastatic potential include desmoid, atypical lipomatous tumor (also called *well-differentiated liposarcoma*), dermatofibrosarcoma protuberans, and hemangiopericytoma. Tumors with an intermediate risk of metastatic spread usually have a large myxoid component and include myxoid liposarcoma and extraskeletal chondrosarcoma. Among the highly aggressive tumors that have substantial metastatic potential are angiosarcoma, clear-cell sarcoma, pleomorphic and dedifferentiated liposarcoma, leiomyosarcoma, rhabdomyosarcoma, and synovial sarcoma.

It recently has been noted that MFH is not associated with a distinct gene cluster, suggesting that MFH does not represent a separate tumor entity but rather a common morphologic appearance of various sarcoma subtypes.^{22,23} For example, most tumors initially diagnosed as MFH in the retroperitoneum have been reclassified using genomic profiling as dedifferentiated liposarcomas.²⁴

Expert sarcoma pathologists disagree about the specific histologic diagnoses and the criteria for defining tumor grade in 25 to 40% of individual cases.²⁵ The high rate of discordance emphasizes the need for more objective molecular and biochemical markers to improve conventional histologic assessment.

Staging and Prognostic Factors

The newly revised Seventh Edition of the American Joint Committee on Cancer (AJCC) staging criteria for soft tissue sarcomas relies on histologic grade, tumor size, and depth, and the presence of nodal or distant metastases (Table 36-2).²⁶ This system does not apply to GI stromal tumor, fibromatosis (desmoid tumor), Kaposi's sarcoma, and infantile fibrosarcoma.

Table 36-2 Seventh Edition American Joint Committee on Cancer Staging of Soft Tissue Sarcoma ¹⁷⁵				
Primary tumor (T)				
T1	Tumor ≤5 cm			
	T1a	Superficial tumor		
	T1b	Deep tumor		
T2	Tumor >5 cm			
	T2a	Superficial tumor		
	T2b	Deep tumor		
Regional lymph nodes (N)				
N0	No regional lymph node metastasis			
N1	Regional lymph node metastasis			
Distance metastasis (M)				
M0	No distant metastasis			
M1	Distant metastasis			
Histologic grade (G)				

G1	Well differentiated				
G2	Moderately differentiated				
G3	Poorly differentiated				
Stage grouping					
Stage IA	T1a, T1b	N0	M0	G1	Low
Stage IB	T2a	N0	M0	G1	Low
Stage IIA	T1a, T1b	N0	M0	G2–G3	High
Stage IIB	T2a	N0	M0	G2–G3	High
Stage III	T2b	N0 or N1	M0	G2–G3	High
Stage IV	Any T	Any N	M1	Any G	Any G

HISTOLOGIC GRADE

Histologic grade remains the most important prognostic factor for patients with sarcomas. For an accurate determination of tumor grade, an adequate tissue sample must be appropriately fixed, stained, and reviewed by an experienced sarcoma pathologist. The features that define grade are cellularity, differentiation, pleomorphism, necrosis, and the number of mitoses. Tumor grade has been shown to predict the development of metastases and overall survival.²⁷ The metastatic potentials have been estimated at 5 to 10% for low-grade lesions, 25 to 30% for intermediate-grade lesions, and 50 to 60% for high-grade tumors.

The number of grades varies according to the classification system used. The most common classification systems, those of the National Cancer Institute and the French Federation of Cancer Centers, use three tumor grades.²⁸ The National Cancer Institute system is based primarily on histologic tumor type, location, and amount of necrosis. The French Federation of Cancer Centers system generates a score based on tumor differentiation, mitotic rate, and the amount of tumor necrosis. A comparative analysis of the two grading systems suggested that the French Federation of Cancer Centers system may have better prognostic capability, predicting 5-year survival rates of 90%, 70%, and 40% for grade 1, 2, and 3 tumors, respectively.²⁸

Following the recommendation of the College of American Pathologists, the 2008 AJCC staging system reformatted the newest staging system from a four grade to a three grade system.²⁹ The three tumor grades are designated: well differentiated (G1), moderately differentiated (G2), and poorly differentiated (G3). In this three-tiered system, grade 1 is considered "low grade," and grades 2 and 3 are considered "high grade."

TUMOR SIZE

Tumor size has long been recognized to be an important prognostic variable in soft tissue sarcomas. Sarcomas have classically been stratified into two groups on the basis of size; T1 lesions are ≤ 5 cm, and T2 lesions are > 5 cm. Some authors have suggested that further stratification of patients on the basis of tumor size can provide more accurate prognostic information. For example, when 316 patients with soft tissue sarcomas were examined and grouped into four tumor-size subgroups (< 5 cm, 5 to 10 cm, 10 to 15 cm, and > 15 cm), each subgroup was found to have a different prognosis, with 5-year survival of 84, 70, 50, and 33%, respectively.³⁰

With respect to its association with the investing fascia of the extremity or trunk, anatomic tumor location was incorporated into the AJCC staging system in 1998. Soft tissue sarcomas above the superficial investing fascia of the extremity or trunk are designated "a" lesions in the T score, whereas tumors invading or deep to the fascia as well as all retroperitoneal, mediastinal, and visceral lesion tumors are designated "b" lesions.

NODAL METASTASIS

Lymph node metastases arising from soft tissue sarcomas are rare.³ A few histologic subtypes, including epithelioid sarcoma, rhabdomyosarcoma, clear-cell sarcoma, synovial sarcoma, MFH, and angiosarcoma, have a higher incidence of nodal involvement. In the newly revised AJCC staging system, nodal (N1) disease has been reclassified as stage III rather than stage IV disease.

A number of studies reporting better survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy compared to those with distant metastatic disease^{3,31–33} prompted a change in the AJCC staging system. Results of these studies support the benefit of therapeutic lymphadenectomy, including axillary and ilioinguinal dissections, for extremity soft tissue sarcoma metastatic to regional lymph nodes.³¹ Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed by preoperative fine-needle aspiration before radical lymphadenectomy.

DISTANT METASTASIS

Distant metastases occur most often in the lungs (Fig. 36-4). Selected patients with pulmonary metastases may survive for long periods after surgical resection and chemotherapy. Other potential sites of metastasis include bone, the brain, and the liver (Fig. 36-5). Visceral and retroperitoneal sarcomas have a higher incidence of liver and peritoneal metastases.

PROGNOSTIC FACTORS

Prognostic factors are important for identifying patients at high risk for recurrence and death from disease. Prognostic variables in soft tissue sarcoma include tumor characteristics such as size, grade, and depth, all of which have been incorporated into the staging system, as well as histology, tumor site, and locally recurrent presentation. Patient factors such as older age and gender also have been associated with recurrence and mortality in several studies.³⁴ A positive microscopic margin and early recurrence after resection of an extremity sarcoma have been shown to be associated with decreased survival.³⁴

The expression of markers for cell kinetics and regulatory proteins of the cell cycle also have been investigated as potential prognostic factors for soft tissue sarcoma. Several groups have reported that Ki-67, a proliferation marker, is correlated with a poor clinical outcome in high-grade extremity sarcomas.^{35,36} Others have investigated the correlation between expressions of various membrane proteins and clinical outcomes. E-cadherin and catenins, proteins essential for intercellular junctions, have been associated with poor outcome in patients with soft tissue sarcoma.³⁵ Similarly, higher CD100 expression in soft tissue sarcomas has been shown to correlate with higher proliferative potential and poorer outcome.³⁶

PROGNOSTIC NOMOGRAMS

Nomograms have recently been introduced for a variety of malignancies³⁷⁻³⁹ including soft tissue sarcoma⁴⁰ as a model in

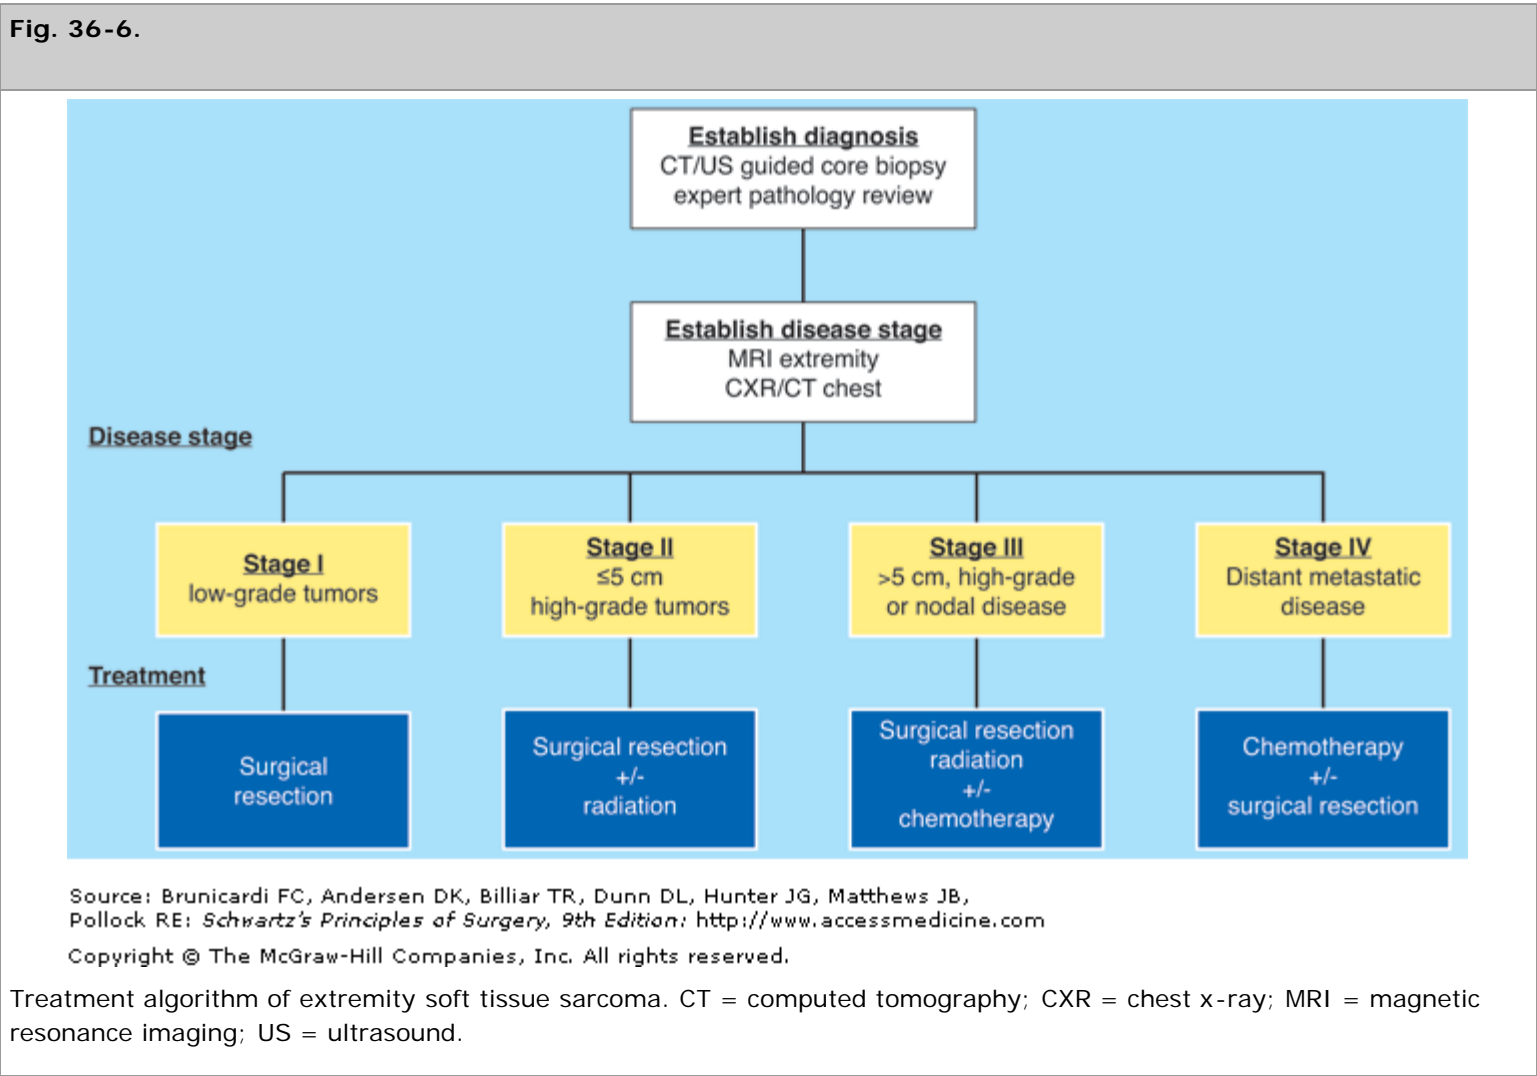

which identified prognostic factors can be combined and used to predict risk of disease-specific survival. One such nomogram was developed for 12-year disease-specific survival for general postoperative sarcoma and has been proposed as a useful tool for patient counseling, surveillance strategies, and consideration for clinical trials. This prognostic tool relies on patient age, tumor size, depth, site, grade, and histology. More recently, the same investigators developed a subtype-specific nomogram for patients with liposarcoma⁴¹ and demonstrated that the nomogram was more accurate in predicting disease specific survival.

TREATMENT OF EXTREMITY SARCOMA

(Fig. 36-6)

Accurate preoperative histologic diagnosis is critical when choosing a primary treatment strategy for soft tissue sarcomas. Presentation with gross disease after incisional biopsy, core-needle biopsy, or fine-needle aspiration biopsy allows the treatment planning team the best opportunity to evaluate the tumor's proximity to vital structures and the likelihood of being able to perform surgical resection with negative histologic margins. In addition, the tumor can serve as a biological marker of response if patients are to be enrolled in neoadjuvant treatment protocols.

Fig. 36-6.

In the past two decades, a multimodality treatment approach has improved survival and quality of life for patients with extremity sarcomas. For soft tissue sarcomas of the extremities, a multidisciplinary approach to management has resulted in local control rates up to and exceeding 90%. However, patients with abdominal sarcomas continue to have high rates of recurrence and poor overall survival. The overall 5-year survival for all stages of soft tissue sarcomas is 50 to 60%. Most

patients die of metastatic disease, which becomes evident within 2 to 3 years of initial diagnosis in 80% of cases. A brief summary of the recommendations for the evaluation and management of patients presenting with soft tissue masses is presented in Table 36-3.

Table 36-3 Recommendations for the Management of Soft Tissue Masses
1. Soft tissue tumors that are enlarging or >3 cm should be evaluated with radiologic imaging [ultrasonography or computed tomography (CT)] and a tissue diagnosis made by core needle biopsy.
2. Once a sarcoma diagnosis is established, obtain imaging (magnetic resonance imaging for extremity lesions and CT for other anatomic locations) and evaluation for metastatic disease with chest CT for intermediate/high-grade or T2 tumors.
3. A wide local excision with 2-cm margins is adequate therapy for low-grade lesions and T1 tumors.
4. Radiation therapy plays a critical role in the management of large (T2) tumors.
5. Patients with recurrent high-grade sarcomas or distant metastatic disease should be evaluated for chemotherapy.
6. An aggressive surgical approach should be taken in the treatment of patients with an isolated local recurrence or resectable distant metastases.

Surgery

Small (<5 cm) primary tumors with no evidence of distant metastatic disease are managed with local therapy consisting of surgery alone or in combination with radiation therapy, when wide pathologic margins are limited because of anatomic constraints. The type of surgical resection is determined by several factors, including tumor location, tumor size, depth of invasion, involvement of nearby structures, need for skin grafting or autogenous tissue reconstruction, and the patient's performance status. In 1985, the National Institutes of Health developed a consensus statement recommending limb-sparing surgery for most patients with high-grade extremity sarcomas.⁴² However, for patients whose tumor cannot be grossly resected with a limb-sparing procedure and preservation of function (<5%), amputation remains the treatment of choice.

Margin status after surgical resection has been shown to be an independent prognostic factor.^{43,44} Patients with microscopically positive surgical margins have an increased risk of local failure; however, neither a positive surgical margin nor local failure has been shown to adversely affect overall survival.⁴⁵ These data should be factored into the management plan when achieving clear surgical margins requires amputation or substantial functional compromise of an extremity.

WIDE LOCAL EXCISION

Wide local excision is the primary treatment strategy for extremity sarcomas. The goal of local therapy for extremity sarcomas is to resect the tumor with at least a 1- to 2-cm margin of surrounding normal soft tissue.⁴³ The tumors are generally surrounded by a zone of compressed reactive tissue that forms a pseudocapsule, which may mistakenly guide resection (enucleation) by an inexperienced surgeon. Extensions of tumor that go beyond the pseudocapsule must be considered in planning surgery and radiotherapy. In some anatomic areas, negative margins cannot be attained because of the tumor's proximity to vital structures. Soft tissue sarcomas abutting bone pose a particular dilemma in that obtaining a wide margin is not possible without excision of bone (Fig. 36-7). Although resection and reconstruction of skeletal defects is possible, the likelihood of postoperative complications may be increased and functional outcomes may not be as favorable. A recent analysis by Lin and colleagues⁴⁶ of 55 patients with soft tissue sarcomas abutting bone reported that, in the absence of frank cortical bone penetration, periosteum is an adequate surgical margin for sarcomas treated with wide excision and radiation. Bone invasion from extremity soft tissue sarcoma, which generally can be identified using high-quality cross-

sectional imaging such as MRI, has been estimated to occur in about 5% of patients. In such cases, bone resection is required to obtain an adequate surgical margin and to achieve local control. Tumor invasion into bone is associated with a reduction in overall survival.⁴⁷

Unclassified high-grade sarcoma of the left thigh measuring 21.7 x 7 x 5.2 cm abutting femoral cortex anteriorly and anteromedially with no evidence of medullary invasion.

Wide en bloc excision is seldom performed as a diagnostic procedure. When it is done for this purpose, the margin status often is not adequately evaluated in the pathologic assessment of the specimen. Unless detailed descriptions of the surgical procedure and the pathology specimen are provided, the margins should be classified as uncertain or unknown, a classification that carries the same prognosis as resection margins that are positive for tumor cells. In this setting, re-excision should be performed, if possible, to ensure negative margins. The biopsy site or tract (if applicable) should also be included en bloc with the re-resected specimen.

Soft tissue sarcomas arising in the distal extremities, particularly the hands and feet, present unique technical challenges. Although tumors of the distal extremities are often detected earlier (<5 cm) compared to proximal extremity tumors, resection and reconstruction techniques often are more complex, and preoperative planning is critical to obtaining favorable functional outcomes. Identifying the proximity of the tumor to underlying critical structures such as bone, tendon, or neurovascular structures using MRI is essential for surgical treatment planning. Radiation is almost always necessary as an adjunct to surgery, regardless of tumor size, given that it is rare that a 2- to 3-cm margin can be achieved in the distal

extremities without sacrificing important structures. For locally advanced tumors, reconstruction of bone defects, vascular reconstruction, tendon transfers, and soft tissue reconstruction using regional or free flaps have resulted in good functional outcomes.⁴⁸ Amputation remains a reasonable treatment option for patients with soft tissue sarcomas of the distal extremities when oncologic or functional outcomes cannot be achieved using available limb salvage techniques.

A number of studies have reported improved survival for patients with isolated regional lymph node metastases treated with radical lymphadenectomy.^{3,31–33} Patients with clinically or radiologically suspicious regional nodes should have metastases confirmed before radical lymphadenectomy. Current practice in our institution includes ultrasound evaluation with fine-needle aspiration biopsy of lymph nodes in selected patients with suspicious clinical or radiologic findings. The use of sentinel lymph node biopsy has been questioned for particular histologic subtypes of high-grade sarcoma with a propensity for lymph node metastases (e.g., epithelioid sarcoma, rhabdomyosarcoma, clear-cell sarcoma, synovial sarcoma, MFH, and angiosarcoma). However, there have been no prospective studies to adequately assess the sensitivity and specificity of sentinel lymph node biopsy techniques for these patients.

In the absence of appropriate surgery or combination treatment with surgery and radiation, the probability of local recurrence is >50%. With modern surgical and radiotherapy techniques, rates of limb preservation and local control have improved. A currently reported local failure rate of 10% after appropriate treatment is typical for soft tissue sarcomas of the extremity. Amputation is not required even for patients with locally advanced tumors involving major vascular structures, given that, in selected patients, vascular reconstruction has been shown to be feasible and often results in reasonable functional outcomes. In small series, en bloc tumor resection with vascular reconstruction resulted in increased postoperative complications. However, rates of local recurrence and 5-year survival were similar to those for patients who did not require vessel resection.^{49,50}

AMPUTATION

For the 5% of patients with primary or recurrent extremity tumors that cannot be grossly resected with a limb-sparing procedure and preservation of function, amputation is the treatment of choice. Historically, local excision of soft tissue sarcomas has resulted in local failure rates of 50 to 70%, even when a margin of normal tissue around the tumor was excised. As a consequence, radical resection or amputation has become the standard treatment. Because sarcomas usually spread along fascial planes or within muscle bundles, radical resection entails removal of all muscles in the involved compartment, along with nerves, vessels, and involved bone; it follows that this approach often requires amputation.

The addition of radiotherapy to less radical surgical resection has made limb salvage possible in many cases. A comparison of amputation vs. limb-sparing surgery followed by adjuvant radiation therapy was performed at the National Cancer Institute between 1975 and 1981.⁵¹ Forty-three patients were randomized; 27 to the limb-sparing group and 16 to the amputation group. The median follow up was 4 years and 8 months. Four local recurrences were experienced in the limb-sparing group and none in patients in the amputation group. No statistically significant difference was noted in the local recurrence rates or in the overall survival rates of the two groups. Potter and colleagues⁵² later reviewed the entire National Cancer Institute experience with 123 patients treated with conservative surgery plus radiotherapy and 83 treated with amputation. The difference in local control was statistically significant between groups with a local failure rate of 8% in the surgery and adjuvant radiotherapy group and no recurrences in the amputation group. However, survival rates did not differ significantly between the groups. Several large single-institution studies also have reported favorable local control rates with conservative resection combined with radiation therapy.^{53–55}

ISOLATED REGIONAL PERFUSION

Isolated regional perfusion is an investigational approach for treating extremity sarcomas, and found its greatest support in Europe. It has been attempted mainly as a limb-sparing alternative for patients with locally advanced or locally recurrent soft tissue sarcomas, and for patients with multifocal sarcomas. Additionally, it has served as a palliative treatment to achieve local control for patients with distant metastatic disease.

Limb perfusion involves isolating the main artery and vein of the perfused limb from the systemic circulation. The choice of anatomic approach is determined by tumor site; external iliac vessels are used for thigh tumors, femoral or popliteal vessels for calf tumors, and axillary vessels for upper-extremity tumors. The vessels are dissected, and all collateral vessels are ligated. The vessels are then cannulated and connected to a pump oxygenator similar to that used in cardiopulmonary bypass. Either a tourniquet or Esmarch band is applied to the limb to achieve complete vascular isolation. For the lower limb, the Esmarch band is anchored at the anterior–superior iliac spine with the aid of a pin inserted into the pelvic bones. For the upper limb, the pin is anchored at the scapular and pectoral levels. Chemotherapeutic agents are then added to the perfusion circuit and circulated for 90 minutes. Systemic leakage from the perfused limb is monitored continuously with ⁹⁹Tc-radiolabeled human serum albumin injected into the perfusate, and radioactivity is recorded above the precordial area with a Geiger counter. The temperature of the perfused limb is maintained during the entire procedure by external heating and warming the perfusate to 40°C (104°F). At the end of the procedure, the limb is washed out, the cannulas are extracted, and the blood vessels are repaired.

Despite a 40-year history of the use of isolated limb perfusion to treat extremity sarcomas, many questions remain to be answered. The choice of chemotherapeutic agent in the perfusion circuit, the benefits of hyperthermia, and the effectiveness of hyperthermic perfusion in the neoadjuvant or adjuvant setting remain to be elucidated. Studies published to date have involved heterogeneous patient groups and diverse chemotherapeutic agents. Despite these limitations, favorable response rates ranging from 18 to 80% and overall 5-year survival rates of 50 to 70% have been reported.^{56–60}

In 1974, McBride first reported results of 79 patients with extremity sarcomas who had been treated with isolated limb perfusion during the previous 14 years.⁵⁶ All patients had received melphalan and dactinomycin. The overall 5-year survival rate was 57%, and only 13 patients had subsequent amputation for recurrent disease. Over the next 20 years, isolated perfusion of the extremity to treat sarcoma fell out of favor for several reasons. Most notably, improved survival and decreased local recurrence rates could be obtained with less radical therapy. Conservative surgical excision was combined with radiation therapy or neoadjuvant chemotherapy to provide limb-sparing options to patients who were previously thought to require amputation. In view of the encouraging results of combination therapy, it is difficult to justify the technically challenging and expensive isolated perfusion procedure.

In 1992, a report by Lienard and associates⁶⁰ regenerated interest in isolated limb perfusion as a therapy for extremity tumors. Those investigators reported a 100% response rate among patients with extremity melanomas and sarcomas when high-dose recombinant tumor necrosis factor alpha plus interferon-γ and melphalan were given in an isolated perfusion circuit. This report led to larger studies geared specifically to patients with sarcoma. The largest of these studies, the European Multicenter Study, was reported by Eggermont and colleagues in 1996.⁵⁸ In that study of 186 patients, the overall tumor response rate was 82%. The clinical and pathologic complete response rate was 29%. Although all of the study participants were initially reported to be candidates for amputation, limb salvage following isolated limb perfusion was reported as 82%.⁵⁸

A similar study evaluated the role of hyperthermic isolated limb perfusion with tumor necrosis factor and melphalan for patients with extremity sarcomas. A complete response was seen in 26% of the patients, and an additional 30% had a partial response. Fourteen patients (32%) underwent amputation for progressive tumors, while the other 68% were able to undergo limb salvage surgery after isolated limb perfusion.⁵⁹ The inferior results in the United States–based studies are thought to be due to patient selection biases and the degree of pretreatment before limb perfusion.

Although melphalan has been reported to have minimal activity against soft tissue sarcomas when used as a systemic agent, it can produce significant responses with minimal toxicity when used in the limb perfusion circuit. Doxorubicin has been the most effective systemic agent for soft tissue sarcomas, but concerns about potential locoregional toxicity have limited its use in isolated limb perfusion. Rossi and associates⁶¹ performed a phase II trial of hyperthermic isolated limb perfusion with doxorubicin for 23 patients with extremity sarcomas. They reported a limb salvage rate of 91% and acceptable rates of grade 3 and 4 systemic (4%) and locoregional toxicity (22%).

Survival outcomes following isolated limb perfusion have not yet been directly compared with other more conventional treatment approaches, including wide local excision and radiation therapy or amputation.

Radiation Therapy

In the 1970s, 50% of patients presenting with extremity sarcomas underwent amputation for local control of their tumors. Despite a local recurrence rate of less than 10% after radical surgery, large numbers of patients died of metastatic disease. This realization prompted the development of local therapy involving conservative surgical excision combined with postoperative radiation therapy; these techniques offered local control rates of 80 to 90%. The evidence for adjunctive radiation therapy for patients eligible for conservative surgical resection comes from two randomized trials^{62,63} and three large single-institution reports.^{64–66} In a randomized trial by the National Cancer Institute, 91 patients with high-grade extremity tumors were treated with limb-sparing surgery followed by chemotherapy alone or radiation therapy plus adjuvant chemotherapy. A second group of 50 patients with low-grade tumors were treated with resection alone or with resection and radiation therapy. The 10-year rate of local control for all patients receiving radiation therapy was 98% compared with 70% for those not receiving radiation therapy ($P = .0001$).⁶² Similarly, in a randomized trial from the Memorial Sloan-Kettering Cancer Center, 164 patients underwent observation or brachytherapy after conservative surgery. The 5-year local control rate for patients with high-grade tumors was 66% in the observation group and 89% in the brachytherapy group ($P = .003$).⁶³ No statistically significant difference was observed between treatment groups for patients with low-grade tumors.⁶⁷

Until recently, the standard treatment guidelines required radiotherapy as an adjunct to surgery for all patients with intermediate or highly aggressive tumors of any size. However, small tumors (≤ 5 cm), in general, have not been associated with local recurrence, and radiation therapy may not be necessary. In a series of 174 patients reported by Geer and associates, postoperative radiation therapy did not improve 5-year local recurrence nor did it improve overall survival for patients with small soft tissue sarcomas.⁶⁸ Karakousis and colleagues reported a 5-year local recurrence rate of 6% for 80 patients with extremity sarcomas treated with wide local excision and observation, a rate similar to the 64 patients who underwent resection with more narrow surgical margins and adjuvant postoperative radiation.⁶⁹ These investigators argued that the high recurrence rates after less radical surgery were reported in the era before regular use of preoperative MRI and before the advent of improved surgical and pathologic techniques.

The optimal mode [external beam, brachytherapy, or intensity-modulated radiation therapy (IMRT)] and timing (preoperative, intraoperative, or postoperative) have yet to be defined. External-beam radiation therapy can be delivered by

photons or particle beams (electrons, protons, pions, or neutrons). Conventional fractionation is usually 1.8 Gy to 2 Gy/d. CT is an integral part of radiation therapy. It is used to define the gross tumor volume and to estimate a margin of tissue at risk of microscopic tumor involvement. The optimal margin is not well defined; a radiation margin of 5 to 7 cm is standard, although some centers advocate wider margins for tumors >15 cm. At most institutions the typical *preoperative* dose is 50 Gy, given in 25 fractions. *Postoperative* radiation therapy planning is based on tumor site, tumor grade, assessment of surgical margins, and on institutional preferences. The entire surgical scar and drain sites should be included in the field so that a near-full dose can be administered to the superficial skin. Metallic clips placed in the tumor bed during surgery can help define the limits of the resection and aid in radiation therapy planning. Doses of 60 to 70 Gy are usually necessary for postoperative treatment. Although postoperative radiation treatment of upper extremity sarcomas has been associated with a lower incidence of wound complications, the upper extremity site also is associated with a greater rate of local recurrence compared with the lower extremity.⁷⁰

No consensus exists on the optimal sequence of radiation therapy and surgery. The available data come largely from single-institution, nonrandomized studies. Proponents of preoperative radiation therapy cite several advantages. Multidisciplinary planning with radiation oncologists, medical oncologists, and surgeons is facilitated early in the course of therapy if the tumor is in situ; moreover, lower doses of preoperative radiation can be delivered to an undisturbed tissue bed with improved tissue oxygenation. In addition, Nielsen and associates⁷¹ demonstrated that the size of preoperative radiation fields is smaller and the number of joints included on those fields is fewer than in postoperative radiation fields, which may result in improved functional outcome. Critics of preoperative radiation therapy cite as deterrents the difficulty of pathologic assessment of margins and the increased rate of wound complications.⁷² However, plastic surgery techniques with advanced tissue transfer procedures are being used more often in these high-risk wounds, and reportedly result in better outcomes.

The only randomized comparison of preoperative and postoperative radiation therapy conducted to date was performed by the National Cancer Institute of Canada Clinical Trial Canadian Sarcoma Group.⁷³ This trial was designed to compare complications and the functional outcome of patients treated with preoperative and postoperative external beam radiation therapy. The 190 patients enrolled from October 1994 to December 1997 were randomized to receive preoperative radiotherapy (50 Gy) or postoperative radiotherapy (66 Gy). With a median follow-up of 3.3 years, the recurrence and progression-free survival rates were similar between groups, with the only statistically significant difference being in the rates of wound complications. That is, the incidence of wound complications was 35% in the patients who received preoperative therapy but just 17% in the patients who received postoperative radiation therapy.⁷³ Late radiation toxicity was higher in the postoperative group compared to the preoperative radiation group (48.2 vs. 31.5%) with larger field sizes predicting greater rates of fibrosis, joint stiffness, and edema.⁷⁴

Brachytherapy involves the placement of multiple catheters in the tumor resection bed. The primary benefit of brachytherapy is the shorter overall treatment time of 4 to 6 days compared with pre- or postoperative radiation therapy regimens, that can last 4 to 6 weeks. Brachytherapy produces less radiation scatter in critical anatomic regions (e.g., gonads or joints) and potentially improved function. A cost-analysis comparison of brachytherapy vs. external beam irradiation showed that costs were lower to undergo adjuvant irradiation with brachytherapy for soft tissue sarcomas.⁷⁵ Brachytherapy also can be used for recurrent disease previously treated with external beam radiation. Guidelines established at the Memorial Sloan-Kettering Cancer Center recommend spacing the afterloading catheters in 1-cm increments while leaving a 2-cm margin around the surgical bed.⁶³ After adequate wound healing is established, usually after the fifth postoperative day, the catheters are loaded with seeds containing iridium-192 that deliver 42 to 45 Gy of radiation to the tumor bed over 4 to 6 days. The

primary disadvantage of brachytherapy is that it requires an extended inpatient stay and bed rest.

IMRT recently has been introduced as a radiation technique that delivers radiation more precisely to the tumor while sparing surrounding tissues. The proposed benefits of preoperative IMRT include treatment delivery to tumors while minimizing the dose to superficial tissues (i.e., skin), thereby reducing postoperative wound infections⁷⁶ and underlying bone complications (i.e., femur) by achieving concave dose distributions.⁷⁷ Theoretically, treatment with IMRT would result in a lower risk of long-term femur fractures. The long-term outcomes following IMRT have not yet been established.

Local toxicity from radiation therapy varies according to radiation dose, field size, and timing (pre- or postoperative). With preoperative radiotherapy, the most frequent wound complications are wound dehiscence, wound necrosis, persistent drainage, infection, seroma formation, ulceration, and cellulitis.⁷³ Postoperative radiation treatment of free flaps often is associated with wound complications, and patients should be advised that secondary surgical repair may be necessary. Wound complication rates of 13 to 37% have been reported for patients receiving preoperative radiation therapy as compared with 5 to 20% for patients receiving postoperative treatment.⁷⁸ If catheters are loaded after the fifth postoperative day, rates of wound complications following brachytherapy are similar to those reported after postoperative radiation therapy.

Long-term (chronic) effects of radiation therapy (those occurring more than 1 year after completion of therapy) generally are related to fibrosis/contracture, lymphedema, neurologic injury, osteitis, and fracture, all of which can cause substantial functional impairment.⁷⁸ Variables associated with poorer functional outcome following radiation therapy include treatment of larger tumors, use of higher doses of radiation (>63 Gy), longer radiation fields (>35 cm), poor radiation technique, neural sacrifice, postoperative fractures, and wound complications.^{74,79} Additionally, complications of any kind are less likely following treatment for upper extremity sarcoma.^{72,73}

Systemic Therapy

Despite improvements in local control rates, metastasis and death remain significant problems for patients with high-risk soft tissue sarcomas. Patients considered at high risk of death from sarcoma include those presenting with metastatic disease, presenting with localized sarcomas at nonextremity sites, or presenting with sarcomas of intermediate- or high-grade histology >5 cm (T2).^{27,63} Treatment of patients with high-risk localized or metastatic disease often includes chemotherapy.

Results of conventional chemotherapy regimens have been poor for most patients with sarcoma. As a group, sarcomas include histologic subtypes that are responsive to cytotoxic chemotherapy and subtypes that are universally resistant to current agents. A spectrum of chemosensitivity has been demonstrated for various histologic subtypes. In particular, synovial sarcoma and fibrosarcoma have been noted to be highly sensitive to chemotherapy⁸⁰ and liposarcoma and myxofibrosarcoma as having intermediate sensitivity to chemotherapy; and GI stromal tumors and chondrosarcoma as being highly resistant to chemotherapy. Considering the variability of responses, it is not surprising that no overall survival benefit has been demonstrated.

Historically, only three drugs—doxorubicin, dacarbazine, and ifosfamide—have consistently demonstrated response rates of 20% or more for advanced soft tissue sarcomas. Doxorubicin and ifosfamide are the two most active agents, with consistently reported response rates of 20% or greater, and both agents have demonstrated positive dose-response curves.^{81,82} Response rates to ifosfamide have been reported to range from 20 to 60% in single-institution series using higher-dose regimens or in combination with doxorubicin.⁸² Over the last 5 years, several additional chemotherapeutic agents have been noted to be active. Single-agent response rates to gemcitabine in patients with advanced sarcoma have

been reported to be 18%⁸³ except for the specific histologic subtype leiomyosarcoma, in which response rates as high as 53% have been reported both alone or in combination with docetaxel.^{83,84} Gemcitabine combined with vinorelbine also has been associated with clinical benefit in patients with advanced sarcomas.⁸⁵ Other subtype-specific cytotoxic agents that have emerged include taxanes, docetaxel, and paclitaxel, which have been found to have specific activity in angiosarcomas.^{86,87}

Integrating Multimodality Therapy

The primary objective of multimodality treatment is cure; when this endpoint is not possible, the goal is palliation of symptoms. Patients with a suspected diagnosis of soft tissue sarcoma should be referred to multidisciplinary centers that specialize in treating this disease.⁸⁸ Patients with a deep soft tissue mass should be referred, even before a biopsy is performed, to a tertiary treatment center that offers care by a team of specialists. Such multidisciplinary teams typically include oncologists from several disciplines (medicine, pediatrics [if applicable], surgery, and radiation therapy), as well as a pathologist, radiologist, and ancillary staff. An analysis by Gutierrez and colleagues⁸⁹ reported that soft tissue sarcoma patients treated at high-volume centers have significantly better survival and functional outcomes. They conclude that particularly those with large, high-grade, or truncal/retroperitoneal tumors should be treated exclusively at specialized centers.

ADJUVANT CHEMOTHERAPY

The use of adjuvant chemotherapy for soft tissue sarcomas remains controversial. The average 5-year disease-free survival rate for patients initially presenting with localized disease is only about 50%. More than a dozen individual randomized trials of adjuvant chemotherapy have failed to demonstrate improvement in disease-free patients and overall survival in patients with soft tissue sarcomas. However, several limitations of these individual trials may explain the lack of observed improvement. First, the chemotherapy regimens used were suboptimal, relying on single-agent therapy (most commonly with doxorubicin) and insufficiently intensive dosing schedules. Second, the patient groups were not large enough to detect clinically significant differences in survival rates. Finally, most studies included patients at low risk of metastasis and death, namely those with small (<5 cm) and low-grade tumors.

The Sarcoma Meta-Analysis Collaboration analyzed 1568 patients from 14 trials of doxorubicin-based adjuvant chemotherapy to evaluate the effect of adjuvant chemotherapy on localized, resectable soft tissue sarcomas.⁹⁰ At a median follow-up of 9.4 years, doxorubicin-based chemotherapy significantly improved the time to local and distant recurrence and recurrence-free survival rates. However, the absolute benefit in overall survival for the sample was only 4%, which was not significant ($P = .12$). In a subset analysis, patients with extremity tumors had a 7% benefit in survival ($P = .029$).⁹⁰

Subsequent to this meta-analysis, additional randomized controlled trials of more modern (drugs, dose, and schedule) anthracycline/ifosfamide combinations for relatively small numbers of patients have yielded conflicting results. In an Italian cooperative trial, apparent improvement was seen in median disease-free and overall survival times in patients with high-risk extremity soft tissue sarcomas.⁹¹ In that study, 104 patients with high-grade tumors ≥ 5 cm were randomized to undergo definitive local therapy (surgery) vs. local therapy plus adjuvant chemotherapy consisting of epirubicin (60 mg/m² per day on day 1 and 2) and ifosfamide (1.8 g/m² per day on days 1 to 5) for five cycles. At a median follow-up of almost 5 years, disease-free survival times were 16 months in the surgery-alone group and 48 months in the combined-treatment group ($P = .04$), and median overall survival times were 46 months vs. 75 months ($P = .03$) for those treated with surgery vs. surgery plus chemotherapy, respectively.⁹¹ However, several years later a convergence in both relapse rates (28 and 32% in chemotherapy and control groups respectively) and deaths (22 vs. 29%) was observed that resulted in statistically similar

overall survival.⁹² Other randomized studies have failed to confirm such benefit.

In an effort to further assess the role of chemotherapy in patients with stage III extremity sarcoma, a cohort analysis of the combined databases from both the University of Texas M. D. Anderson and Memorial Sloan-Kettering was recently performed. The data on 674 patients with stage III extremity sarcoma who received either preoperative or postoperative doxorubicin-based chemotherapy were reviewed to determine their outcomes (5-year disease-specific survival as well as 5-year local and distant recurrence rates) from systemic therapy. The 5-year disease-specific survival rate was 61%.⁹³ Cox regression analysis showed a time-varying effect of chemotherapy with an associated benefit during the first year. However, the clinical benefits of doxorubicin-based chemotherapy in patients with high-risk extremity sarcomas were not sustained beyond 1 year after therapy. Grobmyer and colleagues also compared the outcome of a cohort of patients treated at two institutions (1990 to 2001) with surgery only or neoadjuvant chemotherapy containing doxorubicin and ifosfamide. In this analysis, there was an improvement in 3-year disease-specific survival, which was most pronounced in patients with tumors >10 cm (62 vs. 83% for surgery alone vs. neoadjuvant chemotherapy and surgery, respectively).⁹⁴

Because the evidence addressing treatment of stage III disease is inconclusive, considerable variation still exists in treatment standards. It may be that there are subsets of high-risk patients based on tumor size or histology with extremity soft tissue sarcoma who derive significant benefit from systemic chemotherapy. Specifically, retrospective cohort analyses have noted a benefit in disease-specific survival in patients with large (T2), high-grade liposarcomas and synovial sarcomas of the extremity treated with combination ifosfamide and doxorubicin compared with patients who received no chemotherapy.⁹⁵

A major deterrent to the use of adjuvant chemotherapy has been the risk of adverse toxic effects in patients who do not respond to therapy. To optimize the use of doxorubicin and ifosfamide, investigators have tried to escalate the drug doses with combination regimens with the aim of maximizing tumor-cell kill. The ultimate goal is to achieve an incremental response rate and improve the quality of response sufficiently to influence survival. However, the limits to this approach are becoming apparent even when treatment includes support with hematopoietic growth factors. The advent of growth factors like granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor has helped minimize the morbidity related to neutropenia; however, dose-limiting thrombocytopenia continues to pose a challenge for treatment. Use of high-dose doxorubicin has been limited by myelotoxicity, epithelial toxicity, painful hand-foot syndrome, and potentially severe cardiac toxicity. The toxicity profile for systemic regimens with gemcitabine has been mild, primarily related to hematologic toxicity. This regimen is of particular clinical interest for patients with limited options due to (a) prior exposure to full therapeutic doses of doxorubicin and ifosfamide, (b) advanced age, and (c) significant comorbidities.

NEOADJUVANT/PREOPERATIVE CHEMOTHERAPY

The rationale for using neoadjuvant and preoperative chemotherapy for soft tissue sarcomas is the belief that only 30 to 50% of patients will respond to standard (postoperative) chemotherapy. Neoadjuvant chemotherapy enables oncologists to identify patients whose disease responds to chemotherapy by assessing that response while the primary tumor is in situ. Patients whose tumors do not respond to short courses of preoperative chemotherapy are, thus, spared the toxic effects of prolonged postoperative or adjuvant chemotherapy.

Treatment approaches that combine systemic chemotherapy with radiosensitizers and concurrent external beam radiation may improve disease-free survival by treating microscopic disease and enhancing the treatment of macroscopic disease. Concurrent chemoradiotherapy with doxorubicin-based regimens reportedly produces favorable local control rates for patients with sarcoma.⁹⁵ Since those findings were published, several groups have attempted to evaluate the optimal route of

administration, alternative chemotherapeutic agents, and the toxicity of combined therapies.

Theoretical advantages of concurrent treatment notwithstanding, use of concurrent local and systemic therapy decreases the total treatment time for patients with high-risk sarcoma. This decrease represents a substantial advantage over current sequential combined-method treatment approaches, for which the total duration of treatment for radiation, chemotherapy, surgery, and rehabilitation frequently exceeds 6 to 9 months.

Surveillance

In general, it is believed that early recognition and treatment of recurrent local or distant disease can prolong survival in patients with soft tissue sarcoma. This is primarily based on a few reports involving small numbers of patients that have indicated salvage after recurrent local disease is possible by performing radical re-excision with or without radiation therapy.^{96,97} Similarly, several groups have reported that survival can be prolonged after resection of pulmonary metastases. These limited data form the basis for use of aggressive surveillance strategies for all patients with soft tissue sarcoma.

History and physical examination are the most useful components of follow-up in evaluating for local recurrence after definitive treatment. CT and MRI are useful for evaluating less accessible regions, such as the retroperitoneum, and in assessing equivocal changes on examination. Most recurrences of soft tissue sarcomas occur in the first 2 years after completion of therapy. Patients should be evaluated with a complete history and physical examination and chest radiography every 3 to 6 months during the 2- to 3-year period of highest risk. Most experts recommend that the tumor site should be evaluated every 6 months by performing MRI for extremity tumors or CT for intra-abdominal or retroperitoneal tumors. Guidelines have been established for using MRI to distinguish recurrences from typical postsurgical changes. A discrete nodule with low signal intensity on T1-weighted images and higher signal intensity on T2-weighted images that enhances after administration of IV contrast is strongly suggestive of recurrence and should be sampled for biopsy. In some circumstances, ultrasonography can be used to assess recurrence of tumor in the extremities.

Recurrence after surgery for abdominal soft tissue sarcomas is common. CT is useful for detecting recurrences at primary and distant anatomic sites in the abdomen and pelvis. After surgery, cross-sectional imaging every 3 to 6 months during the first 2 years and every 6 months for 3 years thereafter has been recommended. However, many experienced surgeons are advocating less aggressive imaging for asymptomatic patients, particularly after a second recurrence of retroperitoneal sarcoma arguing that no evidence exists to suggest that survival is improved by earlier detection.

Because most metastases to distant sites occur within 2 to 3 years of initial diagnosis, general guidelines are that follow-up intervals can be lengthened to every 6 months, with annual imaging, for years 2 through 5. After 5 years, patients should be evaluated and undergo chest radiography annually.

Whooley and associates reviewed the efficacy of the surveillance strategy used at Roswell Park Cancer Institute for 174 patients with soft tissue sarcomas of the extremities.⁹⁸ Patients were evaluated every 3 months for the first 2 years, every 4 to 6 months during year 3, and every 6 months through year 5. Local recurrence occurred in 18% of patients at a median interval of 14 months, and all but one of the recurrences was detected by physical examination alone. Fifty-seven patients had distant recurrences (at a median of 18 months after treatment), of which 36 were asymptomatic and diagnosed by surveillance radiographic imaging. Those investigators determined that the positive predictive value of chest radiography in follow-up was 92%.⁹⁸ However, evaluation of the primary site by CT or MRI and routine laboratory assessment was ineffective in detecting recurrences. The authors of this report cautioned that their study did not conclusively demonstrate

that CT and MRI should not be used. Rather, patient characteristics, location of the primary tumor, previous treatment, and physician familiarity with changes after surgery and radiation therapy should all be considered in determining the need for radiographic imaging.

Recurrent Sarcoma

The pattern of recurrence is related to the anatomic site of the primary tumor. Up to 20% of patients with extremity sarcoma develop locally recurrent disease. Patients with microscopically positive surgical margins are at increased risk of local recurrence. In a series of 179 patients with locally recurrent extremity soft tissue sarcoma at Memorial Sloan-Kettering Cancer Center, the median interval to local recurrence was noted to be 16 months; 65% developed a local recurrence by 2 years and 90% by 4 years.⁹⁶ The majority of patients (89%) were treated with additional limb-sparing surgery, and 73% received additional adjuvant therapy with a disease-specific survival of 55% at 4 years. Independent prognostic factors for disease-specific survival after local recurrence included histologic tumor grade, local recurrence size, and local recurrence-free interval. These data indicate that surveillance of patients for the first 4 years after resection of their primary extremity sarcoma is warranted.

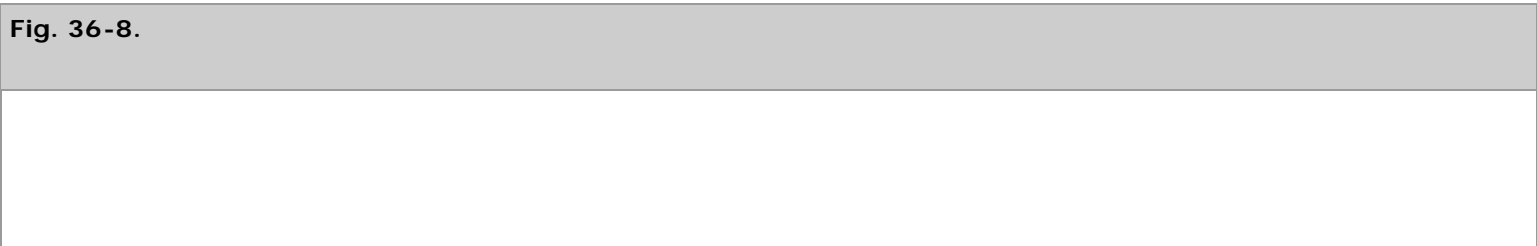

An isolated local recurrence should be treated aggressively with margin-negative resection. For patients with extremity sarcomas, this frequently requires amputation. However, some patients with recurrent extremity sarcoma can undergo function-preserving resection combined with additional radiation therapy, with or without chemotherapy, with acceptable rates of local control.^{99–101} Nori and colleagues reported a local control rate of 69% among 40 patients with recurrent tumors treated with re-excision and brachytherapy to a median dose of 45 Gy.¹⁰¹ In a similar series, limb-sparing conservative surgery was possible in 24 of 36 patients (66%), and the 5-year local recurrence-free survival rate was 72%.⁹⁹

The primary determinant of survival in patients with soft tissue sarcoma is development of distant metastases. Patients with extremity sarcomas generally have recurrence as distant pulmonary metastases, whereas patients with retroperitoneal or intra-abdominal sarcomas tend to have local recurrences.⁹⁸ Other less common sites of metastasis include bone (7%), liver (4%),⁵² and lymph nodes.³ Myxoid liposarcoma of the extremity is known to metastasize to the abdomen and pelvis and requires staging CT of these regions before definitive local therapy.¹⁷

SURGICAL RESECTION FOR METASTATIC SARCOMA

The most common initial site of metastasis of soft tissue sarcomas is the lung. Selected patients with a limited number of pulmonary nodules (fewer than four), long disease-free intervals, and no endobronchial invasion may become long-term survivors after pulmonary resection (Fig. 36-8); 15 to 40% of patients with complete resection of metastatic disease confined to the lung are long-term survivors.^{98,102} In a retrospective multi-institutional study of 255 patients, the 5-year overall survival rate after metastasectomy was reported to be 38%.¹⁰³ Favorable prognostic factors in that study included microscopically free margins, age younger than 40 years old, and grade I or II tumors.¹⁰³ For patients who are surgical candidates, pulmonary resection alone also has been shown to be the most cost-effective treatment strategy compared to no treatment, chemotherapy alone, and surgery combined with chemotherapy.¹⁰⁴

CHEMOTHERAPY FOR METASTATIC SARCOMA

The only available treatment for most patients with metastatic disease is chemotherapy. Historically, response rates for patients with stage IV soft tissue sarcoma have been low. Several prognostic factors have been defined for patients undergoing chemotherapy, including performance status, previous response to chemotherapy, younger age, absence of hepatic metastases, low-grade tumors, and long disease-free interval.¹⁰⁵ Isolated liver metastases, if stable over several months, may be amenable to resection, radiofrequency ablation, or chemoembolization.

PALLIATIVE RADIATION THERAPY

Definitive radiation therapy has been described as a treatment option to be considered in clinical situations where there is no acceptable surgical option available (e.g., patient with significant medical comorbidities). A window of therapeutic radiation dose benefit has been reported in this clinical setting in the range of 63 Gy to 67 Gy; higher radiation doses (greater than 63 Gy) yielded superior tumor control while doses over 68 Gy yielded increased rates of major complications.¹⁰⁶

SPECIAL SITUATIONS

Myxoid Liposarcomas

Myxoid liposarcomas belong to the group of soft tissue sarcomas with lipomatous differentiation. However, these tumors have very distinct morphology with myxoid stroma and lipomatous differentiation and clinical behavior that differs from the other liposarcoma subtypes. Myxoid liposarcomas frequently present as slow-growing, deep tumors in the lower extremity.

Distinct from other soft tissue sarcomas that metastasize to the lungs, metastases arising from myxoid liposarcoma often are detected in other soft tissue locations, including the retroperitoneum or extremities.^{107,108} For this reason, CT of the chest, abdomen, and pelvis are recommended for the adequate staging and surveillance of patients with myxoid liposarcoma.

Specific chromosomal translocation has been identified in myxoid liposarcoma that consists of the fusion of the SUF and CHOP genes [(t12;16)(q13;p11)] in 90% of tumors and fusion of the EWS and CHOP [(t12;22)(q13;q12)] genes in greater than 5% of tumors.¹⁰⁹ These translocations can be detected using polymerase chain reaction techniques for diagnostic purposes.

Retroperitoneal Sarcomas

Most retroperitoneal tumors are malignant, and about one third are soft tissue sarcomas. Also included in the differential diagnosis are primary germ cell tumor, lymphoma, or metastatic testicular cancer. Ten to 15% of adult soft tissue sarcomas, or about 1000 new cases, of retroperitoneal sarcoma are diagnosed annually in the United States. The most common sarcomas occurring in the retroperitoneum are liposarcomas, MFHs, and leiomyosarcomas. In contrast to extremity sarcomas, many retroperitoneal sarcomas present as large tumor masses abutting or involving vital structures, making margin-free resection difficult. As a result, locoregional recurrence is common (72% at 5 years), and prognosis for patients with retroperitoneal sarcoma is poor with 5-year survival estimated at 36 to 58%.¹¹⁰

Retroperitoneal sarcomas generally present as large masses; nearly 50% are >20 cm at the time of diagnosis. They typically do not produce symptoms until they grow large enough to compress or invade contiguous structures. The evaluation for a patient with a retroperitoneal mass begins with an accurate history that should exclude signs and symptoms associated with lymphoma (e.g., fever and night sweats). Complete physical examination, with particular attention to all nodal basins and testicular examination in men, is critically important. Laboratory assessment can be helpful; an elevated lactate dehydrogenase level may suggest lymphoma, and elevated beta human chorionic gonadotropin levels or alpha-fetoprotein levels can indicate a germ cell tumor.

Radiologic assessment should include CT of the abdomen and pelvis to define the extent of the tumor and its relationship to surrounding structures, particularly vascular structures. Imaging should also encompass the liver for the presence of metastases, the abdomen for discontinuous disease, and the kidneys bilaterally for function. Angiography or magnetic resonance arteriography/venography also can be used to delineate vascular anatomy in selected patients when involvement of critical vascular structures is suspected. Thoracic CT is indicated to detect lung metastases. For patients presenting with an equivocal history, an unusual appearance of the mass, an unresectable tumor, or distant metastasis, CT guided core needle or laparoscopic biopsy is appropriate to obtain a sample for tissue diagnosis.

Complete surgical resection is the most effective treatment for primary or recurrent retroperitoneal sarcomas (Fig. 36-9). En bloc resections for these tumors often include sacrificing contiguous structures such as the small bowel, colon, kidney, inferior vena cava, and aorta. In a review of 141 patient who underwent resection of retroperitoneal sarcoma with major blood vessel involvement, postoperative morbidity and mortality were 36 and 4% respectively, and vessel patency rates were greater than 88% at a median follow-up of 19.3 months.¹¹¹ With favorable rates of local control and survival reported in their cohort of patients with tumor-free resection margins, the authors concluded that vascular resection is the treatment of choice in sarcomas that involve major blood vessels in the retroperitoneum.¹¹¹

A. Computed tomography image of the abdomen for a 50-year-old woman with a massive retroperitoneal tumor with

anterior displacement of left kidney. **B.** Gross specimen, en bloc resection of retroperitoneal liposarcoma with spleen, left kidney, left adrenal gland, and transverse and sigmoid colon.

In several retrospective assessments of patients with retroperitoneal sarcoma, complete surgical excision was achieved in only 40 to 60% of patients.^{112,113} In an analysis of 500 patients with retroperitoneal soft tissue sarcomas treated at Memorial Sloan-Kettering Cancer Center, the median survival time for those who underwent complete resection was 103 months vs. 18 months for those who underwent incomplete resection, or observation without resection.¹¹⁴ In general, surgical resection should not be offered to patients unless radiographic evidence indicates the potential for complete resection, although palliative surgical procedures may be considered to reduce the symptoms of intestinal obstruction, pain, or bleeding.¹¹⁵ In particular, patients with atypical lipomatous tumors, also termed *well-differentiated liposarcomas*, may benefit symptomatically from repeated tumor debulking.

Tumor stage at presentation, high histologic grade, unresectability, and grossly positive resection margins are strongly associated with rates of death from retroperitoneal sarcoma.^{114,116,117} Survival rates at 5 years are typically reported to be 40 to 50%. The best chance for long-term survival for patients with retroperitoneal sarcoma is achieved with a margin-negative resection, however, this often is not possible. In one series, the 5-year disease-free survival rate was 50% for patients who had margin-negative resection as compared with 28% for patients undergoing incomplete resection.¹¹² In the series reported by Lewis and associates,¹¹⁴ about 75% of patients died of locally recurrent disease without distant metastasis. As is true for extremity lesions, tumor grade is also a significant predictor of outcome for patients with retroperitoneal sarcoma. In the series reported by Jaques and colleagues,¹¹³ patients with high-grade tumors ($n = 65$) had a median survival time of only 20 months compared with 80 months for patients with low-grade tumors ($n = 49$).

ADJUVANT THERAPY

Most studies have failed to show a survival advantage for adjuvant chemotherapy for retroperitoneal sarcomas.^{118–120} However, adjuvant chemotherapy has been advocated for some of the more uncommon histologic variants of retroperitoneal sarcoma including dedifferentiated liposarcoma, MFHs, and primitive neuroectodermal tumors.^{121,122}

Because of the high rates of local recurrence, adjuvant radiation therapy has been proposed as a potential means of treating microscopic residual disease following the surgical resection of retroperitoneal sarcomas. However, the optimal technique and timing of delivery continues to evolve as clinicians weigh the potential benefits with the increased risk of treatment-related toxicity. Treatment of retroperitoneal sarcomas is complex because tumors are usually large, requiring large fields, and due to the proximity of radiosensitive structures (i.e., bowel). Several techniques have been used, including preoperative and postoperative external beam radiation, intraoperative radiation therapy, and brachytherapy.¹²³ Preoperative radiotherapy is emerging as a technique that is feasible and well tolerated. Toxicity may be lower with preoperative radiation given that (a) the tumor borders are definable, (b) the tumor acts as an expander, displacing radiosensitive viscera away from the treatment field, and (c) effective doses of radiation may be lower preoperatively.¹²⁴

There are a number of studies that report favorable local control rates for intermediate and high-grade retroperitoneal sarcomas treated with preoperative radiotherapy plus complete resection compared to historical data.¹²³ However, most studies have failed to show a survival benefit for such patients.¹²⁵ This body of evidence prompted the initiation of a multicenter, randomized trial sponsored by the American College of Surgeon's Oncology Group to compare surgery alone with preoperative radiation therapy plus surgery (ACOSOG Z9031). Unfortunately, the study was closed prematurely in 2006 because of lack of patient accrual. There are no consensus guidelines for the use of radiation in patients with primary or recurrent retroperitoneal sarcomas. The optimal balance between acceptable radiation toxicity and effective local control is

yet to be determined.

Current recommendations for radiation therapy for patients with retroperitoneal sarcoma at MDACC are based on presentation of disease.¹¹⁷ For high-risk patients, defined as those with large, high-grade tumors or recurrent low-grade tumors, 50-Gy preoperative radiation therapy followed by surgical resection is recommended. In the preoperative setting, the tumor often displaces the bowel out of the field of radiation and treatment may be delivered with less toxicity. Postoperative radiation is discouraged unless the resected tumor bed is clearly away from dose-limiting structures.

RECURRENCES

Retroperitoneal sarcomas recur in two thirds of patients. In addition to recurring locally in the tumor bed and metastasizing to the lungs, retroperitoneal leiomyosarcomas frequently spread to the liver. Retroperitoneal sarcomas can also recur diffusely throughout the peritoneal cavity (sarcomatosis). The approach to resectable recurrent disease after the treatment of a retroperitoneal sarcoma is similar to the approach taken after the recurrence of an extremity sarcoma. However, the ability to resect a recurrent retroperitoneal sarcoma declines precipitously. In a large series of patients treated at Memorial Sloan-Kettering Cancer Center, the authors were able to resect recurrent tumors in 57% of patients with a first recurrence, but in only 20% after a second recurrence, and 10% after a third recurrence.³⁵ Of note is that in as many as 25% of patients, well-differentiated liposarcoma may recur in a poorly differentiated form or develop areas of dedifferentiation. Dedifferentiated retroperitoneal liposarcoma is more aggressive with a greater propensity for distant metastasis than its well-differentiated precursor.

Gastrointestinal Sarcomas

Patients with GI sarcomas most often present with nonspecific GI symptoms that are determined by the site of the primary tumor. In a series from Memorial Sloan-Kettering Cancer Center, early satiety and dyspepsia were noted in patients with upper GI tumors, whereas tenesmus and changes in bowel habits were common in those with tumors of the lower GI tract.¹²⁶ In a series of 80 patients with various smooth muscle tumors of the GI tract, Chou and associates¹²⁷ identified the most common presenting symptoms and signs as GI bleeding (44%), abdominal mass (38%), and abdominal pain (21%).

Establishing the diagnosis of a GI sarcoma preoperatively is often difficult. Radiologic assessment, including CT of the abdomen or pelvis, is sometimes useful to determine the anatomic location, size, and extent of disease. Patients with localized disease frequently present with a large intra-abdominal mass but no radiographic evidence of the regional lymph node metastases that would be typical of an adenocarcinoma of comparable size and anatomic location. In patients with advanced disease, CT may demonstrate disseminated intra-abdominal masses with or without concomitant ascites and possible invasion of tissue planes.

Endoscopy (esophagoduodenoscopy or colonoscopy) has become the mainstay for evaluating symptoms related to the GI tract. For tumors involving the stomach, upper endoscopy with endoscopic ultrasonography and biopsy are important diagnostic tests used to distinguish adenocarcinoma from GI sarcomas. This distinction is clinically significant because the extent of resection (local excision vs. gastrectomy) and the role of regional lymph node dissection differs for these two conditions. Lymphatic spread is not the primary route of metastasis for GI sarcomas. Consequently, lymphadenectomy is not routinely performed as part of resection. Based on published data and the primary pattern of distant (vs. local) failure, the general recommendation is to perform a margin-negative resection with a 2- to 4-cm margin of normal tissue. However, some cases may be technically challenging because of the tumor's anatomic location or size. For example, for gastric tumors located near the gastroesophageal junction, achieving adequate surgical margins may not be possible without a total or

proximal subtotal gastrectomy. Similarly, large leiomyosarcomas arising from the stomach with invasion of adjacent organs should be resected together with the adjacent involved viscera en bloc.

Segmental bowel resection is the standard treatment for sarcomas of the small or large intestine. For the jejunum, ileum, and colon, the tumor is excised en bloc with the involved segment of intestine and its mesentery; radical mesenteric lymphadenectomy is not attempted. For sarcomas originating in the rectum, the technique used for tumor resection is based on the anatomic location and size of the tumor. For small, low rectal lesions, it may be possible to achieve clear margins with a transanal excision. Large or locally invasive lesions may require more extensive operations for complete tumor extirpation.^{128,129} Meijer and colleagues¹²⁹ reviewed the experience with 50 patients with primary colorectal sarcoma at Memorial Sloan-Kettering Cancer Center. In 32 cases, the primary tumor was located in the rectum, and 18 tumors involved the colon. Of the rectal lesions, 15 were treated with abdominoperineal resection and 12 were treated with local excision. Distant metastasis was the first recurrence in 11 of the 32 patients who underwent curative resection.¹²⁹

GASTROINTESTINAL STROMAL TUMOR

Gastrointestinal stromal tumors (GISTs), which constitute the majority of GI sarcomas, have distinctive molecular features of GISTs that have been characterized over the last decade. These tumors share phenotypic similarities with the intestinal pacemaker cell known as the *interstitial cells of Cajal*.¹³⁰ The interstitial cells of Cajal and GIST cells express the hematopoietic progenitor cell marker CD34 and the growth factor receptor c-Kit (CD117).¹³¹ c-Kit is a transmembrane glycoprotein receptor with an internal tyrosine kinase component that, when activated, triggers a cascade of intracellular signals regulating cell growth and survival.¹³² The expression of the c-Kit gene protein product CD117 has emerged as an important defining feature of GISTs. Using these diagnostic criteria, the incidence of GIST has been estimated at 6–15 cases per 1 million population.^{133–135}

Kit mutation site has emerged as a prognostic factor of progression-free and overall survival in patients with GIST. Patients with Kit exon 11 mutation have a superior progression-free and overall survival on imatinib therapy compared to those patients whose tumors have an exon 9 mutation or wild-type Kit. Current clinical practice in many centers is to perform mutation analysis of the Kit gene in all new patients for both prognostic and therapeutic consideration.

RADIOLOGIC ASSESSMENT

Positron emission tomography (PET) using ¹⁸F-fluorodeoxyglucose has been reported as useful for preoperative staging of GISTs, as it may reveal early metastases and establish baseline metabolic activity. PET has been shown to be highly sensitive in detecting early response to imatinib treatment and predicting long-term response in patients with metastatic GIST. Because PET imaging is still not widely available and, in some lesions, insensitive, and because glucose uptake is not sufficient, predictive criteria for assessment of GISTs using CT imaging also have been proposed.¹³⁶

MANAGEMENT OF LOCALIZED DISEASE

Surgery remains the only potentially curative treatment for patients with localized GISTs. Complete resection with negative margins, even of locally advanced tumors, is associated with improved survival.¹³⁷ The extent of surgery required to produce a complete resection does not seem to influence survival. The 5-year survival rate for all patients with GISTs ranges from 20 to 44% and up to 75% for early-stage tumors that have been completely excised.¹³⁷ However, a more recent analysis of 200 patients by DeMatteo and colleagues noted a disease-specific survival rate of only 54% for patients in whom a grossly complete resection of primary GISTs had been achieved, and the median survival duration for patients with metastatic

disease was only 20 months.¹³⁸

As with other soft tissue sarcomas, tumor size has consistently been identified as an important prognostic factor for GISTs. Mitotic activity also has been identified as an important prognostic factor and is generally categorized as <5, 5 to 10, and 10 or more mitotic counts per high-power field. Based primarily on these prognostic variables, tumor size, and mitotic count, the National Institutes of Health¹³⁹ and the Armed Forces Institute of Pathology¹⁴⁰ have proposed prognostic criteria for the risk stratification (i.e., low risk, intermediate risk, high risk, and very high risk) for surgically treated localized primary GISTs. The Armed Forces Institute of Pathology also includes tumor site as a prognostic variable. Accurate risk stratification is essential to select patients most likely to benefit from adjuvant treatment.

MANAGEMENT OF LOCALLY ADVANCED OR METASTATIC DISEASE

Until recently, systemic treatment options for a patient with unresectable or metastatic GIST were of little therapeutic benefit. Treatment with imatinib (Gleevec, ST1571), a selective c-Kit inhibitor, has resulted in impressive clinical responses in a large percentage of patients with unresectable or metastatic GISTs. Based on the initial treatment results from a single patient with metastatic GIST, a phase I study was initiated by the European Organization for Research and Treatment of Cancer Soft Tissue and Bone Sarcoma Group to test the safety and efficacy of imatinib.¹⁴¹ In that study, 53% of patients with GISTs had confirmed partial responses; investigators concluded that imatinib is safe and effective against GISTs.¹⁴¹ A multicenter, international trial was begun in July of 2000 at four treatment centers: Dana-Farber Cancer Institute, Oregon Health Sciences University, Fox Chase Cancer Center, and University Hospital of Helsinki, Finland.¹⁴² A total of 147 patients with unresectable or metastatic GISTs were randomized to receive one of two doses of imatinib (400 mg or 600 mg daily) for planned treatments of up to 24 months. Overall objective response was demonstrated in 79 patients (54%); all had partial responses and no significant difference was found between imatinib doses.¹⁴³ Fourteen percent of patients had disease progression. The toxicity profile was acceptable, with the predominant effects being GI toxicity and periorbital edema, cramps, and fatigue. However, 21% of patients experienced serious adverse events (grade 3 or 4 toxicity), including GI bleeding (5%) likely related to the rapid tumor response of mural lesions.

A phase III randomized Intergroup trial was simultaneously performed to assess the clinical activity of imatinib at two dose levels for patients with unresectable or metastatic GISTs expressing the c-Kit tyrosine kinase.¹⁴⁴ Between December 15, 2000, and September 1, 2001, 746 patients were accrued and randomized to receive low-dose (400 mg/d) or high-dose (800 mg/d) imatinib. The primary endpoint of the trial was survival. Preliminary toxicity data from 325 patients revealed a 23% incidence of grade 3 or 4 adverse events, including nausea and vomiting, GI bleeding, abdominal pain, edema, fatigue, and rash. The European Organization for Research and Treatment of Cancer Soft Tissue and Bone Sarcoma Group, in conjunction with the Italian Sarcoma Group and the Australasian Gastro-Intestinal Trials Group, has accrued 753 patients with GISTs to another randomized phase III trial.¹⁴⁵ Response data from the trial are currently maturing.

In February 2002, the U.S. Food and Drug Administration approved imatinib for treatment of GISTs based on the results of these promising clinical trials. In addition, there continues to be little known about the optimal length of treatment, the duration of benefit, or the long-term toxicity of imatinib therapy. It has become evident that, when feasible, imatinib should be continued in the absence of disease progression. A randomized trial has reported worse progression-free survival in patients that stopped imatinib after 1 year of treatment compared to those who continued beyond 1 year (6 months vs. 18 months, respectively).¹⁴⁶ Less than 4% of patients with GISTs have experienced serious adverse events with imatinib. Mild GI toxicity is the most frequently reported adverse event, but GI tract hemorrhage, presumably from rapid tumor necrosis, also has been reported. Thus, all patients with GISTs treated on clinical protocols should be evaluated and followed by a

team of medical professionals that includes a surgeon.

In 2006, sunitinib malate (Sutent, Pfizer), an inhibitor of a broad spectrum of tyrosine kinases, emerged as an alternative systemic treatment for patients unable to tolerate imatinib or with imatinib-refractory GIST. Sunitinib is a tyrosine kinase inhibitor that targets multiple kinases, including the vascular endothelial growth factor receptors, PDGFR- β , KIT, and FLT3. It has both antiangiogenic and antiproliferative activity. Oral administration as 50 mg daily for 4 weeks followed by no treatment for 2 weeks and then repeated as 6-week cycles for treatment of imatinib-resistant GISTs resulted in objective responses in 7% of patients while 58% had stable disease.¹⁴⁷ Many other tyrosine kinase inhibitors are in development, many of which target more than one family of protein kinases.¹⁴⁸ Among these include sorafenib, dasatinib, and AMG-706, which are actively being investigated for the treatment of imatinib-resistant GIST.¹⁴⁹ Several other new agents, everolimus (RAD001) and protein kinase C, are being investigated as synergistic agents that may maximize the extent and duration of response to imatinib by blocking potential pathways of resistance.

MULTIDISCIPLINARY APPROACH

With the emergence of effective systemic treatment for GIST, so has the emergence of the multidisciplinary approach to managing locally advanced and metastatic disease. Although imatinib has improved survival of patients with advanced GISTs, most patients are not cured. There are groups of patients who develop secondary resistance to imatinib with one or more sites of disease progression after 6 months of clinical response. The mechanisms of imatinib resistance are areas of active investigation. Surgery has been shown to be of benefit for selected patients on imatinib with isolated progression of disease.^{150–153} Surgical resection of residual metastatic disease responding to kinase inhibitor therapy also has been demonstrated to result in favorable progression-free survival in 70 to 96% of patients with imatinib- or sunitinib-sensitive GISTs.^{152–154} The optimal timing of surgery for a patient with metastatic disease in relation to imatinib therapy remains to be determined. Comparison of nonrandomized outcomes for patients treated with kinase inhibitors alone to those treated with combination kinase inhibitors and surgical resection is not possible given the heterogeneity of patients and bias associated with those selected for surgical resection.

Given the promising results of imatinib therapy for metastatic or locally advanced GISTs, the logical next step is to study the efficacy of imatinib as adjuvant (postoperative) and neoadjuvant (preoperative) in patients with surgically resectable disease, particularly those who are at high risk for recurrence because of large tumor size or high mitotic count. The American College of Surgeons Oncology Group (ACOSOG Z9001) has conducted a phase III randomized double-blind study of adjuvant imatinib vs. placebo after complete resection of primary GISTs. Eligible patients included those with a primary c-Kit–expressing GIST 3 cm or larger, with tumor rupture before or during surgery, intraperitoneal hemorrhage, or one to four multifocal tumors. Patients were randomized to receive 400 mg/d imatinib or placebo for 1 year. The trial was suspended to accrual when an interim analysis demonstrated a relapse-free survival rate of 97% in the imatinib-treated group vs. 83% in the placebo group.¹⁵⁵ All placebo-treated patients were allowed to take imatinib. There are also two ongoing randomized trials in Europe in which imatinib is being given following surgical resection of GIST; the Scandinavian Sarcoma Group (SSG XVIII) is comparing 12 months vs. 36 months of imatinib and the European Organization for the Research and Treatment of Cancer (EORTC 62024) is comparing imatinib vs. no treatment for 24 months. A neoadjuvant trial also is being conducted by the Radiation Treatment Oncology Group (RTOG S0132), in which patients with potentially resection primary or recurrent tumors are being treated with imatinib for 8 to 10 weeks preoperatively and then 24 months postoperatively.¹⁵⁶

Sarcomas of the Breast

Sarcomas of the breast are rare tumors, accounting for <1% of all breast malignancies and <5% of all soft tissue sarcomas. A variety of histologic subtypes have been reported to occur within the breast, including angiosarcoma, stromal sarcoma, fibrosarcoma, and MFH.

Angiosarcoma of the breast accounts for about 50% of all sarcomas of the breast and increasingly has been associated with radiation therapy for the treatment of primary breast cancer.⁵ The latency period for radiation-associated sarcomas has been reported to range from 3 years to 20 years with an incidence of 0.3% at 10 years and 0.5% at 15 years.¹⁵⁷ In a retrospective study of 55 patients with angiosarcoma of the breast, patients with radiation therapy–associated angiosarcoma were on average 30 years older and less likely to present with distant metastatic disease than radiation-naïve patients. Clinically, angiosarcoma of the breast associated with radiation therapy may occur in the irradiated chest wall after mastectomy or in the remaining breast after breast conservation followed by radiation. The presentation of cutaneous angiosarcoma often includes an expanding erythematous patch, red papular eruptions, bluish-black lesions, or bruise-like discoloration overlying an area of induration. Mammography is often nonspecific. Diagnosis requires punch or incisional biopsy.

Cystosarcoma phyllodes generally are not considered to be sarcomas because these tumors are thought to originate from hormonally responsive stromal cells of the breast and the majority are benign. Tumors with infiltrating tumor margin, severe stromal overgrowth, atypia, and cellularity have been identified as high risk for metastases.¹⁵⁸

As with sarcomas at other anatomic sites, the histopathologic grade and size of the tumor are important prognostic factors. Likewise, the likelihood of local recurrences increases as the tumor size increases; tumors <5 cm are associated with better overall survival. Local and distant recurrence are more common in patients with high-grade lesions. Complete excision with negative margins is the primary therapy. Simple mastectomy carries no additional benefit if complete excision can be accomplished by segmental mastectomy. Because of low rates of regional lymphatic spread, axillary dissection is not routinely indicated. Neoadjuvant chemotherapy or radiation therapy may be considered for patients with large, high-risk tumors.

Uterine Sarcomas

Sarcomas account for <5% of all uterine malignancies. They have been classified into three main histologic subgroups: endometrial stromal sarcoma, leiomyosarcoma, and mixed müllerian tumor. Five-year overall survival rates for patients with uterine sarcoma is poor at 30 to 50%.¹⁵⁹ Total abdominal hysterectomy is the treatment for local disease. Because of the rarity of the uterine sarcomas, the benefits of adjuvant therapy (e.g., radiation therapy to the pelvis, chemotherapy, and hormonal therapy) have not been adequately evaluated. Gemcitabine plus docetaxel has been noted to be well tolerated and highly active with a response rate of 53% in patients with unresectable leiomyosarcoma of the uterus.⁸⁴

Endometrial stromal sarcomas comprise about 7 to 15% of uterine sarcomas. Mitotic count is used to classify tumors either as low-grade (<10 mitoses per 10 high-power field) or high-grade (>10 mitoses per 10 high-power field). In general, low-grade tumors demonstrate an indolent clinical course while high-grade tumors are more aggressive with a poorer prognosis. Distinct from other uterine sarcoma subtypes, endometrial stromal sarcomas express progesterone receptors and have been found to be responsive to hormonal manipulation as an adjuvant therapy or treatment of recurrent disease.^{160,161}

Desmoids

Desmoid tumors are low-grade sarcomas that do not metastasize. Approximately half of these tumors arise in the

extremities, with the remaining lesions located on the trunk or in the retroperitoneum. Abdominal wall desmoids are associated with pregnancy and are thought to arise as the result of hormonal influences. Patients with Gardner's syndrome may have retroperitoneal desmoids as an extracolonic manifestation of the disease. Surgical resection with wide local excision should be the primary therapy for desmoid tumors. Local recurrence may occur in up to one third of patients. Adjuvant radiation therapy has been associated with a reduced incidence of local recurrence.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a rare, low-grade sarcoma arising in the dermis. The overall annual incidence has been estimated at 4.2 cases per million population¹⁶² with a higher incidence among blacks than whites (6.5 vs. 3.9 per million). Approximately 40% arise on the trunk, with most of the remaining tumors distributed between the head and neck and extremities. The lesion presents as a nodular, cutaneous mass that shows slow and persistent growth. Satellite lesions may be found in patients with larger tumors. Standard treatment of DFSPs is wide local excision, with expected local recurrence rate of <10%. Although recurrence rates have been reported as high as 30 to 50% in population-based series, associated 5-year survival is >99%.¹⁶²

The pathogenesis of DFSP arises from a specific chromosomal translocation involving chromosomes 17 and 22, in which the collagen1alpha1 gene is fused to the gene for platelet-derived growth factor (PDGF) β chain.¹⁶³ The resultant deregulated expression of PDGF β leads to continuous activation of the PDGF receptor protein-tyrosine kinase that promotes DFSP tumor cell growth. The identification of this chromosomal translocation in >90% of DFSPs has led to the application of targeted therapy. Inhibiting PDGF receptors with imatinib has been shown to induce clinical and radiologic improvement in patients with unresectable DFSP.⁸ These data have resulted in the approval by the U.S. Food and Drug Administration for imatinib treatment in patients with locally advanced DFSP.

Pediatric Sarcomas

Soft tissue sarcomas account for 7 to 8% of all pediatric cancers, totaling approximately 600 new cases per year.¹⁶⁴ Pediatric sarcomas traditionally have been divided into two groups: rhabdomyosarcoma and nonrhabdomyosarcoma soft tissue sarcomas. The most common nonrhabdomyosarcomas are synovial sarcoma, malignant peripheral nerve sheath tumor, and fibrosarcoma. Associated with skeletal muscle, rhabdomyosarcomas are the most common soft tissue tumors among children <15 years old and can occur at any site that has striated muscle. These tumors generally present as a painless enlarging mass; about 24% in the genitourinary system, 20% in the extremities, 20% in the head and neck, 16% in the parameningeal region, and 22% in miscellaneous other sites.¹⁶⁵ Regional lymphatic spread of tumor occurs frequently in extremity tumors and in paratesticular tumors. About 15 to 20% of cases have metastasis at presentation, most commonly (40 to 50%) involving the lungs, followed by bone marrow and bone. However, all patients are considered to have micrometastatic disease at presentation, which is the rationale for universal chemotherapy.

Rhabdomyosarcoma is classified as a small, round cell tumor that demonstrates muscle differentiation upon light microscopy and immunohistochemical analysis. Two primary histologic subtypes account for 90% of cases, an embryonal subtype (7%) and an alveolar (20%). Alveolar rhabdomyosarcoma is associated with cytogenetic translocation [t(2;13)(q35;q14)] in 85 to 90% of cases and [t(1;13)(p36;q14)] in 10% of cases.¹⁶⁶ These translocations affect biologic activity at the levels of protein function and gene expression affecting the control of cell growth, apoptosis, differentiation, and motility, ultimately contributing to tumorigenic behavior.¹⁶⁷ In contrast to the specific translocations found in alveolar rhabdomyosarcomas, most embryonal rhabdomyosarcomas have an allelic loss at chromosome 11p15.5 that is thought to inactivate a tumor

suppressor gene.^{167,168} Both of these distinct molecular subtypes of rhabdomyosarcomas are thought to affect similar downstream targets, such as the p53 and Rb pathways.¹⁶⁷ Further insight into these genetic alterations may lead to a better understanding of the pathogenesis of rhabdomyosarcoma and provide novel targets for therapeutic approaches.

Extent of disease is the strongest predictor of long-term outcome. Several staging systems for rhabdomyosarcoma are available; that of the Intergroup Rhabdomyosarcoma Study Group is based on surgical-pathologic groupings (Table 36-4). Multidisciplinary evaluation including pediatric oncologists, surgical subspecialists, and radiation oncologists is critical for treatment planning to achieve favorable long-term outcomes with the goal of maximizing local tumor control and minimizing long-term treatment effects.

Table 36-4 Surgical-Pathologic Grouping of Soft Tissue Sarcoma (Intergroup Rhabdomyosarcoma Study Group)

Clinical Group		Definition
I	a	Localized, completely resected, confined to site of origin
	b	Localized, completely resected, contiguous involvement beyond site of origin
II	a	Localized, grossly resected, microscopic residual tumor
	b	Regional disease, involved lymph nodes, completely resected
	c	Regional disease, involved lymph nodes, grossly resected but with evident of microscopic residual tumor
III	a	Local or regional grossly visible disease after biopsy only
	b	Grossly visible disease after >50% resection of primary tumor
IV		Distant metastases at diagnosis

Intergroup Rhabdomyosarcoma Committee. *J Clin Oncol* 8:443–52, 1990. Copyright © American Society of Clinical Oncology. All rights reserved.

Complete surgical resection is the treatment of choice for rhabdomyosarcoma, when function and cosmesis can be preserved. Patients who are able to undergo a complete tumor resection with negative (group I) or microscopic surgical margins (group II) are able to undergo less intensive systemic therapy with overall survival rates approaching 90%.¹⁶⁹ Given the morbidity associated with resections at some anatomic sites, in particular the head and neck and genitourinary systems, surgery often is not undertaken. Recent findings suggest that chemotherapy can adequately control several such tumors without additional local therapy. In the second International Society of Paediatric Oncology study of rhabdomyosarcoma (MMT84), the choice of local treatment was based on response to initial chemotherapy such that radical surgery and radiotherapy were avoided in 6% of patients. Among the patients who subsequently developed local relapse, the 5-year overall survival rate after salvage therapy was 46%.¹⁶⁹

Unlike other soft tissue sarcomas, rhabdomyosarcomas have a high propensity for lymph node metastasis, with rates of up to 20 to 30% for sites such as the extremities, paratesticular nodes, and prostate. Lymph node sampling and, more recently, sentinel lymph node mapping have been used to evaluate regional node status in children with rhabdomyosarcoma.

Multiagent chemotherapy is recommended for all patients with rhabdomyosarcoma. Combination regimens including vincristine, actinomycin D, and cyclophosphamide continue to be the basis of effective curative therapy.¹⁶⁵ Although various combinations including doxorubicin, ifosfamide, cisplatin, and etoposide have been active against rhabdomyosarcoma, they have not improved outcomes.^{169,170} Radiation therapy is given to most patients with microscopic residual disease (group II) after resection.

The prognosis for children with rhabdomyosarcomas is related to tumor site, surgical-pathologic grouping, and tumor histology. The 5-year, disease-free survival rate for all patients has been reported as 65%. Disease-free survival by group (see Table 36-4) has been reported as 84%, 74%, 62%, and 23% for groups I, II, III, and IV, respectively.¹⁷¹

RESEARCH PERSPECTIVES

Experimental Therapeutics

As the molecular alterations associated with various sarcoma subtypes are elucidated, many potential pathways for therapeutic development will become available. A wide variety of DNA alterations have been observed in sarcoma resulting in mutated genes encoding various proteins ranging from transcription factors, mutated tyrosine kinases, and mutated cytokines.¹⁴⁹ The challenge in identifying targets in sarcomas is to identify those that are specifically important to cellular function. The ideal therapeutic target has been described as one that is (a) a single molecule critical for pathogenesis, (b) expressed and active, (c) involved in a single pathway which is amenable to blockade (i.e., no alternative bypass pathways), and (d) critical for sarcoma cell survival.¹²

The translocations and mutations of tyrosine kinases have allowed the development of drugs targeting crucial proteins involved in the neoplastic transformation of sarcoma cells. Tyrosine kinases are enzymes that bind adenosine triphosphate and transfer phosphates from adenosine triphosphate to the tyrosine residues on substrate proteins. These enzymes have long been considered attractive targets for selective pharmacologic inhibition because many human cancers display deregulated kinase pathways.¹⁷² In the early 1980s, it was recognized that constitutively activated tyrosine kinase is important in the pathogenesis of chronic myelogenous leukemia. The BCR-ABL gene, which is the result of a reciprocal exchange of genetic material between chromosomes 9 and 22, was identified as the causative molecular abnormality in chronic myelogenous leukemia. The genetic translocation was found to lead to the constitutive activation of a specific BCR-ABL tyrosine kinase protein, resulting in the malignant expansion of myeloid cells, disruption of regulatory control by stromal cells, and inhibition of apoptosis.¹⁷² In the late 1980s, Ciba-Geigy identified a series of compounds with kinase inhibitory activity and subsequently developed a compound, [4-[(4-methyl-1-piperazinyl)methyl]-N-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl]amino]-phenyl]benzamide-methanesulfonate], that specifically blocked the tyrosine kinase activity of ABL.¹⁷³ Formerly referred to as STI571 (signal transduction inhibitor 571), imatinib mesylate, marketed as Gleevec, selectively inhibits several structurally similar tyrosine kinases, including all ABL tyrosine kinases, the PDGF receptor, and the c-Kit tyrosine kinase.

Mutations of c-Kit are common in GISTs, and most of the mutations result from an inframe deletion or a point mutation in exon 11 (the juxtamembrane domain). These mutations, which occur predominantly in malignant GISTs, lead to ligand-independent activation of the tyrosine kinase of c-Kit. The resulting constitutive c-Kit tyrosine kinase activity has been shown to promote tumor growth in vitro and may be the key molecular pathway in the pathogenesis of GISTs. Imatinib has been shown to selectively inhibit c-Kit tyrosine kinase activity, resulting in decreased GIST cellular proliferation and increased induction of apoptosis. These results have provided the rationale for clinical trials of imatinib for patients with solid tumors that are dependent on the activity of wild-type or mutant c-Kit for proliferation. GI stromal tumors are a rare subtype of sarcoma in which GIST cells harbor an activating mutation of the KIT resulting in tumor progression in 85% of cases.

Insight into the mechanisms of tumor resistance to imatinib, such as the acquisition of secondary mutation of the KIT and PDGF receptors, has provided insight for the development of many new agents.¹⁷⁴ There are a number of emerging second-generation receptor tyrosine kinase inhibitors, including sunitinib, sorafenib, nilotinib and AMG-706, that have shown

therapeutic potential in imatinib-resistant patients.¹⁷⁴ Understanding of the molecular pathways and mediators with the introduction of new systemic treatments will hopefully improve survival for additional soft tissue sarcomas in the near future. It has become increasingly apparent that soft tissue sarcoma is a heterogeneous disease comprised of unique subtypes and the promise for future therapies is connecting specific sarcoma subtypes to novel therapeutics.

CONCLUSIONS

Soft tissue sarcomas are a family of rare tumors, constituting approximately 1% of adult malignancies. The etiology in the vast majority of patients is sporadic. The management of such diverse tumors is complex. Diagnosis by light microscopy is inexact. Molecular diagnosis, although still in its infancy, holds great promise for the future.

In spite of these confounding issues, the natural history of soft tissue sarcomas is well established. Approximately two thirds of cases arise in the extremities, whereas the remaining one third is distributed between the retroperitoneum, trunk, abdomen, and head and neck. The management algorithm for soft tissue sarcomas is complex and depends on tumor stage, site, and histology. The most common site of metastasis is the lungs and generally occurs within 3 years of diagnosis.

Progress in the understanding of soft tissue sarcoma biology is crucial for the development of new therapeutic targets. Drug engineering will enable molecular-based therapies to become increasingly incorporated into clinical trials and, with success, treatment strategies in the near future.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 37. Inguinal Hernias >

KEY POINTS

1. A proficient understanding of groin anatomy is essential to successful inguinal hernia treatment.
2. Conservative management of asymptomatic inguinal hernias is acceptable.
3. Elective repair of inguinal hernias can be undertaken using a laparoscopic or open approach.
4. Laparoscopic inguinal hernia repair results in less pain and faster recovery, yet requires specialized training and equipment.
5. The use of prosthetic mesh as a reinforcement significantly improves recurrence rates, whether the repair is open or laparoscopic.
6. Recurrence, pain, and quality of life are important outcome factors.

HISTORY

The treatment of inguinal hernias is integral to the history and current status of general surgery; evolution in the treatment of inguinal hernias has paralleled technologic developments in the field. The most significant advances to impact inguinal hernia repair have been the addition of prosthetic materials to conventional repairs and the introduction of laparoscopy to general surgical procedures.

Evidence of surgical repair of inguinal hernias can be traced back to civilizations of ancient Egypt and Greece.¹ Early management of inguinal hernias involved a conservative approach using trusses; however, the inefficacy of this approach prompted the initiation of a surgical approach to the problem. As a consequence of the primitiveness of the techniques, the treatment was often worse than the disease itself. Surgery often involved routine excision of the testicle, and wounds were closed with cauterization or left to granulate on their own. Considering these procedures were performed before the advent of the aseptic technique, it is safe to assume that mortality was quite high. For those that did survive the operation, recurrence of the hernia was commonplace.

Failure of these early techniques of hernia repair was based on inadequate knowledge of groin anatomy and poor understanding of the natural history of hernia formation. As the anatomy of the human body was described via dissection study, the anatomy of the groin became defined. From the late 1700s to the early 1800s, physicians such as Hasselbach, Cooper, Camper, Scarpa, Richter, and Gimbernat identified vital components of the inguinal region, and their contributions are reflected in the current nomenclature. The progress in anatomic understanding, coupled with the development of the aseptic technique, led surgeons such as Marcy, Kocher, and Lucas-Championnière to enter the inguinal canal and perform sac dissection, high ligation, and closure of the internal ring. Results had improved, but recurrence rates remained high with prolonged follow-up.

By demonstrating a comprehensive understanding of inguinal anatomy, Bassini (1844–1924) transformed inguinal hernia repair into a successful venture with minimal morbidity to the patient. His operation involved dissection of the layers of the inguinal canal to the transversalis fascia and then a reconstruction of the floor of the inguinal canal in several layers. The success of the Bassini repair over any of its predecessors ushered in an era of tissue-based repairs. Modifications of the Bassini repair were manifest in the McVay repair, as well as the Shouldice repair. All three of these techniques are currently practiced: the Shouldice repair, namely at the institution that bears its name (Shouldice Hernia Centre) and the McVay and Bassini in situations when prosthetic materials are contraindicated.

The era of tissue-based repairs was supplanted by tension-free repairs with the widespread acceptance of prosthetic materials for inguinal floor reconstruction. Initially described by Lichtenstein, the repair involved placement of a Marlex mesh over the entire floor of the inguinal canal. The repair capitalized on the concept of the myopectineal orifice of Fruchaud, which was based on the notion that

whatever the type of inguinal hernia, the defect lay in the integrity of the transversalis fascia. This was superior to previous tissue-based repairs in that the weakness of the transversalis fascia could be restored by bridging the defect with mesh, rather than placing tension between tissues to close the defect. Superior results could be achieved by nonexpert hernia surgeons. The concept of prosthetic reconstruction of the inguinal floor was also furthered by Stoppa, Rives, and Wantz, who developed a preperitoneal mesh placement over the transversalis fascia.

With the advent of minimally invasive surgery, inguinal hernia repair underwent its most recent transformation. Laparoscopic inguinal hernia repair has added to the armamentarium of the general surgeon, providing a technique that lessens postoperative pain and improves recovery. Since the initial description by Ger, the laparoscopic method of hernia repair has become significantly more sophisticated. Refinements in approach and technique have led to the development of the intraperitoneal onlay mesh (Fitzgibbons and Toy 1990), the transabdominal preperitoneal (TAPP) repair (Arregui 1991), and the totally extraperitoneal (TEP) repair (Duluq 1991). Furthermore, an array of prosthetic materials has been introduced to further lower recurrence rates and provide the patient with the utmost quality of life.

Irrespective of the approach to hernia repair, be it open or laparoscopic, the current state of surgical treatment of inguinal hernia depends on a sound foundation of the inguinal anatomy. The application of current technologies to this anatomic knowledge has fostered successful treatment of inguinal hernias with minimal morbidity heretofore unknown to surgical practice.

EPIDEMOLOGY

Inguinal hernia repair is one of the cornerstones of a general surgery practice and is one of the most commonly performed procedures in the United States, owing to a significant lifetime incidence and variety of successful treatment modalities. Although there are no exact figures totaling the number of inguinal hernia repairs performed annually, it has been estimated that approximately 800,000 cases were performed in 2003, not including recurrent or bilateral hernias.² A vast majority of these procedures were performed on an outpatient basis. Advancements in perioperative anesthesia and the increase in proportion of laparoscopic treatment of inguinal hernias have combined to increase the percentage of ambulatory inguinal hernias. In a survey of 17 states in 2003, 89% of the total number of inguinal hernia repairs were performed on an outpatient basis.³ However, the preponderance of laparoscopic inguinal hernia repair is relatively low (14%) when compared to percentage of open inguinal hernia repair (86%).⁴

The majority of abdominal wall hernias occur in the groin, totaling approximately 75% of the total incidence. It is difficult to estimate the exact prevalence of inguinal hernias in the population, but an overwhelming majority of inguinal hernias occur in males vs. females. Of inguinal hernia repairs, 90% are performed in males and 10% in females. Approximately 70% of femoral hernia repairs are performed on female patients; however, females undergo nearly five times the number of inguinal hernia repairs as femoral hernia repairs. The most common type of groin hernia presenting in females remains the indirect inguinal hernia.⁵

Classical teaching has been that most unilateral hernias originate on the right side. However, it has been recognized that up to one third of patients that undergo unilateral inguinal hernia repair may develop a contralateral inguinal hernia. Physical examination, although dependable in confirming the presence of symptomatic hernias, is beset with limitations when a small hernia is present. Therefore, although patients were diagnosed with unilateral inguinal hernias, they may, in fact, have had bilateral hernias. With the advent of laparoscopic techniques, the contralateral side can be examined without additional incisions or trocars. In a study examining only patients with primary unilateral inguinal hernias, 22% were found to have an occult contralateral hernia during laparoscopic inguinal hernia repair.⁶ Although asymptomatic at time of diagnosis, these hernias have the potential to become clinically significant as the patient ages.

Incidence of inguinal hernias in males has a bimodal distribution with peaks before 1 year of age and then again after age 40. The age-dependence of inguinal hernias was demonstrated in an oft-cited study by Abramson. Males >25 years old ($n = 1883$) were studied and constituted 91% of the total males settled in western Jerusalem. Between the years 1969–71, the participants were first interviewed regarding the presence of an inguinal hernia and subsequently examined by a physician. A total of 459 men with 637 hernias between

them were identified. The results were limited to those that had not previously undergone an inguinal hernia operation. The current prevalence rate was 18%, and the lifetime risk of developing an inguinal hernia was 24%. When subdivided into age groups, those aged 25 to 34 years had a lifetime prevalence rate of 15% whereas those aged 75 years and over had a rate of 47% (Table 37-1).⁷ In a later study of California males aged 14 to 62, significantly decreased "current" prevalence rates were noted in most age groups; however, lifetime prevalence rates were largely similar between both studies. A notable drawback of this study was the reliance on self-reporting and the absence of physical examination to confirm findings.

Table 37-1 Inguinal Hernia Prevalence by Age						
Age (Y)	25–34	35–44	45–54	55–64	65–74	75+
Current prevalence (%)	12	15	20	26	29	34
Lifetime prevalence (%)	15	19	28	34	40	47

Current = repaired hernias excluded; Lifetime = repaired hernias included.

ETIOLOGY

Inguinal hernias may be considered congenital or acquired diseases. Although there is debate, in all likelihood, inguinal hernias in the adult are acquired defects in the abdominal wall. A number of studies have attempted to delineate the precise causes of inguinal hernia formation; however, the risk factors are likely multifactorial, the common denominator being a weakness in the abdominal wall musculature (Table 37-2). Congenital hernias, which make up the majority of pediatric hernias, can be considered an impedance of normal development, rather than an acquired weakness. During the normal course of development, the testes descend from the intra-abdominal space into the scrotum in the third trimester. Their descent is preceded by the gubernaculum and a diverticulum of peritoneum, which protrudes through the inguinal canal and ultimately becomes the processus vaginalis. Between 36 and 40 weeks, the processus vaginalis closes and eliminates the peritoneal opening at the internal inguinal ring.⁸ Failure of the peritoneum to close results in a patent processus vaginalis (PPV) and thus explains the high incidence of indirect inguinal hernias in preterm babies. It should be noted that the processus vaginalis continues to close as the child ages, with most closing within the first few months of life. Children with congenital indirect inguinal hernias will present with a PPV; however, its presence does not necessarily indicate an inguinal hernia (Fig. 37-1). In a study of nearly 600 adults undergoing laparoscopy for reasons not related to inguinal hernia repair, bilateral inspection of the internal inguinal rings revealed an incidence of 12% of PPV. None of these patients had clinically significant symptoms of a groin hernia.⁹ However, in a group of 300 patients undergoing unilateral laparoscopic inguinal hernia repair, 12% were found to have a contralateral PPV. Over the next 5 years, they developed inguinal hernias at a rate four times more than counterparts that had a closed ring.¹⁰

Varying degrees of closure of the processus vaginalis (PV). **A.** Closed PV. **B.** Minimally patent PV. **C.** Moderately patent. **D.** Scrotal hernia.

The presence of a PPV likely predisposes the patient to the development of an inguinal hernia. This likelihood depends on the presence of other risk factors such as inherent tissue weakness, family history, and strenuous activity. Overall, there is limited data pertaining to the etiology of inguinal hernia development. Several studies have documented strenuous physical activity as a predisposing risk factor to acquiring an inguinal hernia.^{11,12} Repeated physical exertion may increase intra-abdominal pressure; however, whether this process occurs in combination with a PPV or through age-related weakness of abdominal wall musculature is unknown. A case-controlled study of over 1400 male patients with inguinal hernia revealed that a positive family history was eight times as likely to lead to development of a primary inguinal hernia. Chronic obstructive pulmonary disease significantly increased the risk of direct inguinal hernias.¹³ Interestingly, several studies have noted a protective effect of obesity. In a large, population-based prospective study of American individuals (First National Health and Nutrition Examination Survey), the risk of inguinal hernia development in obese men was only 50% that of normal weight males, while the risk in overweight males was 80% that of nonobese men. A possible explanation is the increased difficulty in detecting inguinal hernias in obese individuals.¹⁴

One of the most intriguing areas under study is the role of tissue biology in hernia formation. Epidemiologic studies have identified risk factors that may predispose to a hernia, but there are limited data specifically related to the molecular basis of these hernias. Early experiments involving iatrogenic laythirism resulted in hernia formation. Furthermore, microscopic examination of skin of inguinal hernia patients demonstrated significantly decreased ratios of type I to type III collagen. Type III collagen does not contribute to wound tensile strength as significantly as type I collagen. Additional analyses of similar skin revealed disaggregated collagen tracts with decreased collagen fiber density.¹⁵ Collagen disorders such as Ehlers-Danlos syndrome also are associated with an increased incidence of hernia formation (Table 37-3). Tissue analysis has revealed that there is a relationship between the aneurysmal component and hernias, owing to a pathologic extracellular matrix metabolism.¹⁶ Although a significant amount of work remains to elicit the biologic nature of hernias, studies such as these provide compelling evidence for the presence of a genetic collagen defect.

ANATOMY

It cannot be overstated that proficient knowledge of inguinal anatomy is necessary to produce a lasting surgical cure of the inguinal hernia. The groin region is a complex network of muscles, ligaments, and fascia that are interwoven in a multiplanar fashion. To understand the anatomy of the groin, it is best to first consider its components and then conceptualize them according to operative approach. Because the vast majority of inguinal hernias occur in men, general descriptions of groin anatomy contained herein will pertain to males. The inguinal canal is approximately 4 to 6 cm long and is situated in the anteroinferior portion of the pelvic basin (Fig. 37-2). Shaped like a cone, its base is at the superolateral margin of the basin, with its apex pointed inferomedially toward the symphysis pubis. The canal begins intra-abdominally on the deep aspect of the abdominal wall, where the spermatic cord passes through a hiatus in the transversalis fascia (in females, this is the round ligament). This hiatus is termed the *deep or internal inguinal ring*. The canal then concludes on the superficial aspect of the abdominal wall musculature at the superficial or external inguinal ring, the point at which the spermatic cord crosses the medial defect of the external oblique aponeurosis. In the normal situation, parietal peritoneum covers the intra-abdominal portion of the spermatic cord, as well as the internal ring. Anteriorly, the boundary of the canal is comprised of the external oblique aponeurosis and internal oblique muscle laterally. Posteriorly, the floor of the inguinal canal is formed by the fusion of the transversalis fascia and transversus abdominus muscle, although up to one fourth of subjects are found to have only the transversalis fascia forming the posterior floor. The superior boundary is an arch formed by the fibers of the internal oblique muscle.

Lastly, the inferior margin consists of the inguinal ligament. The spermatic cord consists of three arteries, three veins, and two nerves. As well, it contains the pampiniform venous plexus anteriorly and the vas deferens posteriorly, with connective tissue and remnant of the processus vaginalis between. The cord is then enveloped in layers of spermatic fascia.

Fig. 37-2.

Location and orientation of the inguinal canal within the pelvic basin. Boundaries of the canal include: posteriorly the transversus abdominus and transversalis fascia; superiorly the internal oblique muscle; anteriorly is the external oblique aponeurosis; inferiorly is the inguinal ligament. m. = muscle.

Additional structures that are important to the conceptualization of the inguinal canal include the inguinal ligament, Cooper's ligament, iliopubic tract, lacunar ligament, and conjoined area (Fig. 37-3). The inguinal ligament is also known as *Poupart's ligament* and is comprised of the inferior fibers of the external oblique aponeurosis. The ligament stretches from the anterior superior iliac spine to the pubic tubercle. The ligament serves an important purpose as a readily identifiable boundary of the inguinal canal, as well as a sturdy structure used in various hernia repairs. Cooper's ligament is otherwise known as the *pectineal ligament*, although controversy exists as to whether it is, in fact, a ligament at all. Its anatomic site predisposes the structure to varied explanations of its nature and relationships to contiguous structures. For all intents and purposes, it can be considered as the lateral portion of the lacunar ligament that is fused to the periosteum of the pubic tubercle. It also may include fibers from the transversus abdominus, iliopubic tract, internal oblique, and rectus abdominus. The iliopubic tract is an aponeurotic band that begins at the anterior superior iliac spine and inserts into Cooper's ligament from above. It often is confused with the inguinal ligament secondary to common origin and insertion points. However, the iliopubic tract forms on the deep side of the inferior margin of the transversus abdominus and transversalis fascia. The inguinal ligament is on the superficial side of the musculoaponeurotic layer of these structures. The shelving edge of the inguinal

ligament is a structure that more or less connects the iliopubic tract to the inguinal ligament. The iliopubic tract helps form the inferior margin of the internal inguinal ring as it courses medially, where it continues as the anterior and medial border of the femoral canal. The lacunar ligament, or ligament of Gimbernat, is the triangular fanning out of the inguinal ligament as it joins the pubic tubercle. Controversy exists as to whether the lateral edge of the lacunar ligament forms the medial border of the femoral canal. Controversy also exists as to the nature of the conjoint tendon. It is commonly described as the fusion of the inferior fibers of the internal oblique and transversus abdominis aponeurosis, at the point where they insert on the pubic tubercle. This exact anatomic entity is hard to describe consistently. More likely, the conjoint area is a combination of the transversus abdominis aponeurosis, transversalis fascia, lateral edge of the rectus sheath, and internal oblique muscle or its fibers.

Fig. 37-3.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>

Ligaments that contribute to the inguinal canal include the inguinal ligament, which spans the anterior superior iliac spine to the pubic bone. Cooper's ligament is seen as the lateral extension of the lacunar ligament, which is the fanning out of the inguinal ligament as it joins the pubic tubercle. The iliopubic tract originates and inserts in a similar fashion to the inguinal ligament, yet it is deep to it. m. = muscle.

Nerves of interest in the inguinal region are the ilioinguinal, iliohypogastric, genitofemoral, and lateral femoral cutaneous nerve (Figs. 37-4 and 37-5). The ilioinguinal and iliohypogastric nerve arise together from the first lumbar nerve (L1). The ilioinguinal nerve emerges from the lateral border of the psoas major and passes obliquely across the quadratus lumborum. At a point just medial to the anterior superior iliac spine, it crosses the internal oblique muscle to enter the inguinal canal between the internal and external oblique muscles and exits through the superficial inguinal ring. The nerve supplies the skin of the upper and medial thigh. In males, it also supplies the penis and upper scrotum, while supplying the mons pubis and labium majus in females. The iliohypogastric nerve arises from T12–L1 and follows the ilioinguinal nerve. After the iliohypogastric nerve pierces the deep abdominal wall in its downward course, it courses between the internal oblique and transversus abdominis, supplying both. It then branches into a lateral cutaneous branch and an anterior cutaneous branch, which pierces the internal oblique and then external oblique aponeurosis above the superficial inguinal ring. A common variant is for the iliohypogastric and ilioinguinal nerves to exit around the superficial inguinal ring as a single entity. The genitofemoral nerve arises from L1–L2, courses along the retroperitoneum, and emerges on the anterior aspect of the psoas. It then divides into the genital and femoral branches. The genital branch remains ventral to the iliac vessels and iliopubic tract as it enters the

inguinal canal just lateral to the inferior epigastric vessels. In males, it travels through the superficial inguinal ring and supplies the scrotum and cremaster muscle. In females, it supplies the mons pubis and labia majora. The femoral branch courses along the femoral sheath, supplying the skin anterior to the upper part of the femoral triangle. The lateral femoral cutaneous nerve arises from L2–L3, but emerges from the lateral border of the psoas muscle at the level of L4. It crosses the iliacus muscle obliquely toward the anterior superior iliac spine. It then passes inferior to the inguinal ligament where it divides to supply the lateral aspect of the thigh (Fig. 37-6).

Anterior view of the five major nerves of the inguinal region.

Fig. 37-6.

Anterior Perspective

The aforementioned borders of the inguinal canal can be readily appreciated when approaching an inguinal hernia in an open, anterior fashion. Once the subcutaneous tissue is passed, the oblique fibers of the external oblique aponeurosis are encountered. The external oblique muscle originates on the lower eight ribs (Fig. 37-7). The course of the fibers runs inferiorly from lateral to medial and is commonly referred to as *hands in the pockets* as they are parallel to one's fingers in this orientation. As the fibers approach the inguinal canal, they are no longer comprised of muscle, only tendinous aponeurosis. Once the aponeurosis is exposed, the superficial inguinal ring and inguinal ligament may be identified. The superficial ring consists of two crura. The medial crus is formed by the fibers of the external oblique aponeurosis and join with the lateral border of the rectus sheath. The inferior crus is formed by the inguinal ligament, which inserts into the pubic bone. The iliohypogastric nerve generally pierces the external oblique aponeurosis above the superficial inguinal ring. The spermatic cord, genitofemoral and ilioinguinal nerves are seen passing through the superficial inguinal ring. One layer deep to the external oblique aponeurosis, these same structures are visualized, as well as the deep inguinal ring. The inferior border of the internal inguinal ring is formed by the iliopubic tract, while the rest of the ring is formed by fibers of the transversalis fascia. Structures that are seen entering the internal inguinal ring include the spermatic cord and genital branch of the genitofemoral nerve.

The abdominal wall musculature. A. External oblique muscle. B. Internal oblique muscle. C. Transversus abdominis muscle.

The cord structures are enveloped by three fascial layers. The internal fascial layer is derived from the internal oblique muscle and contains the cremaster muscle. The external layer is adhered to the fascia of the external oblique muscle and must be dissected to mobilize the cord. The superficial fascia is also known as the *fascia of Gallaudet* or *innominate fascia*. Superior to the cord, the arch of the internal oblique muscle is seen fanning out to form the roof of the inguinal canal. The superior fibers are oriented perpendicular to the external oblique aponeurosis; however, the lower fibers run parallel with it, as they course toward the pubic bone (Fig. 37-8).

Fig. 37-8.

Anterior perspective of posterior inguinal canal musculature. The external oblique aponeurosis has been removed to display the internal ring and inguinal canal floor. m. = muscle.

Continuing posteriorly through the inguinal canal, the transversus abdominis muscle is encountered deep to the inguinal ring. It arises from the iliac crest, iliopsoas fascia, thoracolumbar fascia, and lower six costal cartilages. Regardless of site of origin, the fibers run in a lateral to medial fashion and it becomes less muscular and more aponeurotic medial, where it contributes to the rectus sheath and falx inguinalis. It is a commonly held belief that the integrity of the transversus abdominis muscle is the most important determinant to hernia formation. As its fibers contract, the arch of the transversus abdominis closes off the internal inguinal ring, thereby serving as a shutter mechanism. One layer deep to the transversus abdominis is the anterior and posterior lamina of transversalis fascia. Inferior to the arcuate line, the posterior covering of the anterior abdominal wall consists only of transversalis fascia, as the fascia of the external and internal oblique muscles fans out anteriorly to constitute the anterior layer of the rectus sheath. Deep to the transversalis fascia, the next layer encountered is the preperitoneal areolar tissue and fat. Dissection of this tissue and progression through the next layer, the peritoneum, allows one to enter into the peritoneal space. Therefore, the preperitoneal space is in actuality a potential space, bordered by the peritoneum on the deep aspect and transversalis fascia superficially.

The inferior epigastric vessels are best visualized from a posterior approach. The inferior epigastric artery is responsible for the blood supply to the rectus abdominis and connects the vasculature of the upper extremity to the lower extremity. The internal thoracic artery offshoots to form the superior epigastric artery, which anastomoses with the inferior epigastric artery, and is derived from the external iliac artery. The epigastric veins run with the arteries within the rectus sheath, posterior to the rectus muscles. Inspection of the internal inguinal ring will reveal the deep location of the inferior epigastric vessels. Inguinal hernias that protrude lateral to the inferior epigastric vessels, through the deep inguinal ring, are referred to as *indirect inguinal hernias*. Direct hernias, on the contrary, are protrusions

medial to the inferior epigastric vessels, in Hesselbach's triangle. The borders of the triangle are as such: the inguinal ligament forms the inferior margin, the edge of rectus abdominis is the medial border, and the inferior epigastric vessels are the superior or lateral border.

From an anterior perspective, the femoral space can be visualized below the inguinal ligament. The iliopectineal arch is a fibrous band of fused iliac and psoas fascia that subdivides the space beneath the inguinal ligament into a lateral muscular space, housing the iliopsoas, femoral nerve, and lateral femoral cutaneous nerve, and a medial vascular space, containing the femoral vessels and femoral branch of the genitofemoral nerve. In addition to these components, the vascular space also houses a medial potential space known as the *femoral canal* and is the site of possible femoral hernia formation. The canal is shaped like a cone pointed inferiorly, extending to the fossa ovalis; the opening of the fascia lata for the great saphenous vein. The femoral ring is bordered by sturdy structures that lend to its inflexibility. The posterior boundary consists of the iliacus fascia and Cooper's ligament, and the anterior boundary is the iliopubic tract and inguinal ligament, internally and externally, respectively. Medially, the border is made up of the aponeurosis of transversus abdominis and the transversalis fascia and laterally, the canal is bordered by the femoral vein and its connective tissue. Normal contents of the femoral canal include areolar preperitoneal tissue and fat and lymph nodes, most notably the node of Cloquet at its upper end. The distal end of the canal is closed by fatty tissue called the *septum femorale*. Once the integrity of this septum is lost, femoral herniation occurs. Due to its small size and limited flexibility, the femoral ring is usually the site of incarceration. Reduction of incarcerated contents of a femoral hernia can thus be effected by splitting the inguinal ligament.

Posterior Perspective

Since laparoscopic procedures have been adapted as a treatment for inguinal hernias, surgeons have been required to reconceptualize the groin anatomy from the posterior perspective (Fig. 37-9). The large visual field and familiarity with intra-abdominal anatomy result in easier identification of the posterior groin region when inguinal hernias are approached intraperitoneally compared to the preperitoneal approach. Initial points of reference intraperitoneally are the five peritoneal folds, bladder, inferior epigastric vessels, and psoas muscle (Fig. 37-10). Beginning at the midline, the median umbilical fold can be easily identified in the lower midline. The fold represents the fibrous remnant of the fetal allantois, but may persist in the adult as a patent urachus. As one follows the median peritoneal fold from the umbilicus inferiorly, one encounters the pubic symphysis and bladder. Radiating down bilaterally, just lateral to this fold, is the medial umbilical fold, which represents the obliterated portion of the fetal umbilical artery. Less likely, a superior vesicular artery will persist within this fold, supplying the superior and lateral edge of the bladder, which is often found immediately medial to the medial umbilical fold, adjacent to the lateral edge of the bladder. Lateral to the medial umbilical ligament, the paired lateral umbilical fold contains the inferior epigastric vessels. The inferior epigastric artery is the lateral border of Hesselbach's triangle and thus provides a useful landmark to differentiate between direct and indirect hernias. A defect medial to the inferior epigastric vessels is considered direct, whereas a lateral defect is an indirect hernia. The type of hernia also can be elucidated by referring to the series of depressions that exist between the peritoneal folds. Progressing from midline laterally, one can identify the supravescical, medial, and lateral fossae. The supravescical fossa is found between the median and medial umbilical ligaments and leads to hernias of the same name. The medial fossa is located between the medial and lateral umbilical folds and is the site of direct hernias. The lateral fossa is found lateral to the lateral umbilical ligament and is the site of the internal inguinal ring and thus the location for indirect inguinal hernias. The superficial inguinal ring is not visualized from the peritoneal perspective. Most laterally, the psoas muscle is seen coursing inferiorly along the retroperitoneum. The anterior superior iliac spine is not readily apparent, but may be elucidated by palpating outside the abdomen. Identification of the internal inguinal ring then permits identification of the spermatic cord. Further inferior to the cord, the iliac vessels are identified deep to the peritoneum. Two potential spaces exist deep to the peritoneum, and these are encountered once the peritoneal flap is created. Between the peritoneum and the posterior lamina of the transversalis fascia is Bogros's space. This area contains preperitoneal fat and areolar tissue. A less prominent space exists between the posterior and anterior laminae of the transversalis fascia termed the *vascular space*, as this is the location of the inferior epigastric vessels.

Once the peritoneum is reflected to expose Bogros's space, the pertinent structures of preperitoneal inguinal anatomy can be identified. The most medial aspect of the preperitoneal space, that which lies superior to the bladder, is alternately known as the *Retzius space*. The pubic symphysis is identified by its midline location, white periosteum, and rigidity to palpation. The vasculature of the groin is much more apparent from the posterior perspective than from the anterior perspective. The inferior epigastric vessels are found in the same longitudinal plane as the iliac vessels. A common finding is the corona mortis, which is found overlying Cooper's ligament and represents a connection between the inferior epigastric and obturator vessels. The deep circumflex iliac vessels arise from the external iliac vessels and must be protected, as they may be intimately associated with the medial portion of the iliopubic tract. Exposure of the iliac vessels allows identification of the genital branch of the genitofemoral nerve as it courses with the external iliac artery. At the internal inguinal ring, the nerve joins the spermatic cord as it enters the inguinal canal.

The femoral branch of the genitofemoral nerve is found lateral to the genital branch and is seen leaving the retroperitoneum underneath the iliopubic tract. Also found laterally, and sometimes in association with the femoral branch of the genitofemoral nerve, is the lateral cutaneous nerve of the thigh. After emerging from the lateral edge of the psoas muscle, it, too, leaves the retroperitoneum inferior to the iliopubic tract to innervate the anterolateral skin of the thigh. The femoral nerve is not routinely seen during laparoscopic inguinal hernia repair but can be demonstrated lateral to the external iliac vessels between the iliacus and psoas muscles. The nerve courses beneath the iliopubic tract and inguinal ligament as it enters the thigh. The iliohypogastric and ilioinguinal nerves are more easily demonstrated via the anterior perspective because they do not cross into the operative space established by the preperitoneal approach.

The structures of the spermatic cord come together shortly before the cord enters through the internal inguinal ring. The vas deferens is of special note as it courses cephalad out from the pelvis and then crosses the inferior epigastric arteries to enter the spermatic cord inferomedially. Slightly inferior to the internal inguinal ring, the iliopubic tract is identified as it attaches to the iliac crest. On the medial side of the internal inguinal ring, Cooper's ligament can be demonstrated inserting inferolaterally into the pubic ramus. The pectineal

ligament can also be identified on the medial aspect of the inferior epigastric vessels, along with the medial aspect of the femoral ring. The remainder of the boundaries of the femoral ring are also visualized. From the posterior perspective, this includes the iliopubic tract superiorly, Cooper's ligament inferiorly, and the femoral vein laterally.

The posterior perspective also allows excellent appreciation of the myopectineal orifice of Fruchaud (Fig. 37-11). The arch of the internal oblique muscle and transversus abdominis muscle constitute the superior margin, the iliopsoas muscle the lateral margin, the lateral edge of rectus abdominis medially, and the pubic pecten medially. The iliopubic tract divides the orifice into a superior portion housing the spermatic cord and an inferior portion containing the iliac vessels. The posterior perspective has also resulted in the characterization of important areas to avoid, known as the *triangle of doom*, *triangle of pain*, and the *circle of death* (Fig 37-12).¹⁷ The triangle of doom is bordered medially by the vas deferens and laterally by the vessels of the spermatic cord, thereby pointing its apex superiorly. The contents of the space include the external iliac vessels, deep circumflex iliac vein, femoral nerve, and genital branch of the genitofemoral nerve. The triangle of pain can be conceptualized as the space bordered by the iliopubic tract and gonadal vessels. The structures within this space include nerves such as the lateral femoral cutaneous, femoral branch of the genitofemoral, and femoral. The circle of death is a vascular continuation formed by the common iliac, internal iliac, obturator, aberrant obturator, inferior epigastric, and external iliac vessels. Basic knowledge of the boundaries of these triangles allows one to avert the dangers associated with injury to their contents.

CLASSIFICATION

A number of classification systems have been developed relating to inguinal hernias. The classification systems allow for standardization in comparing outcomes of various hernias, yet their clinical significance to date is limited. A common clinical classification system relates to location and subdivides hernias into indirect, direct, and femoral, although this system does not take into account the complexity of the hernia. Even this system has undergone considerable transformation with the concept of the myopectineal orifice of Fruchaud. Instead of examining the various locations of herniation independently, Fruchaud determined that a common site of weakness, the transversalis fascia, predisposes to all three hernias. With hernia treatment directed at restoring the integrity of this area, recurrences of all three hernias can be reduced. An ideal classification system would also be able to preoperatively stratify hernias and allow for the most appropriate approach to repair, rather than making management decisions based on intraoperative findings. However, preoperative classification relies heavily upon physical examination and the inherent subjectivity of it. Intraoperative classification is also complicated by the fact that certain components of an inguinal hernia cannot be assessed via the laparoscopic method.

A number of authors, including Rutkow, Robbins, Gilbert, Nyhus, and Schumpelick, have attempted to devise a standardized classification system. Gilbert's classification requires intraoperative assessment and divides hernias into five types, three indirect and two direct (Table 37-4). Type 1 hernias have a small internal ring, type 2 have a moderately dilated internal ring, and type 3 have a ring that is greater than two fingerbreadths. A type 4 direct hernia involved complete disruption of the inguinal floor, and type 5 represented direct hernias with a small diverticular opening of no more than one fingerbreadth.¹⁸ Rutkow and Robbins further expanded the Gilbert classification to include a type 6 pantaloon hernia, which is a combination of a direct and indirect hernia sac, and type 7 femoral hernia.¹⁹

Table 37-4 Gilbert Classification System	
Type 1	Small, indirect
Type 2	Medium, indirect
Type 3	Large, indirect
Type 4	Entire floor, direct
Type 5	Diverticular, direct
Type 6	Combined (pantaloon)
Type 7	Femoral

The Nyhus classification is more detailed and assesses not only the location and size of the defect, but also the integrity of the inguinal ring and inguinal floor (Table 37-5). Consequently, this is one of the most widely used classifications. The system divides hernias into four types, with three subgroups for type III. A type I hernia has a normal size and configuration of the internal ring and occurs primarily as a congenital hernia. Type II hernias have a distorted and enlarged internal ring, without encroachment into the inguinal floor, and small hernia sac. Type IIIA hernias include small- to moderate-sized direct hernias without any sac component through the internal ring. Type IIIB hernias consist of large indirect hernias with defects that encroach on the inguinal canal floor, usually secondarily affecting the structure of the floor. Femoral hernias are classified as type IIIC, and recurrent inguinal hernias are type IV, with A representing direct, B indirect, C femoral, and D any combination of the previous three.²⁰ Despite its general acceptance, the Nyhus classification scheme is limited by its subjectivity in assessment of distortion of the inguinal ring and posterior floor, especially laparoscopically.

Table 37-5 Nyhus Classification System	
Type I	Indirect hernia; internal abdominal ring normal; typically in infants, children, small adults
Type II	Indirect hernia; internal ring enlarged without impingement on the floor of the inguinal canal; does not extend to the scrotum
Type	Direct hernia; size is not taken into account

IIIA	
Type IIIB	Indirect hernia that has enlarged enough to encroach upon the posterior inguinal wall; indirect sliding or scrotal hernias are usually placed in this category because they are commonly associated with extension to the direct space; also includes pantaloon hernias
Type IIIC	Femoral hernia
Type IV	Recurrent hernia; modifiers A–D are sometimes added, which correspond to indirect, direct, femoral, and mixed, respectively

A third major classification system was created by Schumpelick and enjoys greater application in Europe compared to North America. The major feature is the addition of orifice sizing to traditional systems. An L represents a lateral indirect site, M represents medial direct, and F for femoral. The defects are then graded according to size with type I being <1.5 cm in diameter, type II being 1.5 to 3 cm, and type III being >3 cm.²¹ Although the system purports to be more objective, differences in the extent of abdominal distention during pneumoperitoneum may affect measurements. A significant amount of other classification systems exist, although no single system has been widely embraced by all surgeons. Future systems will have to take into account ease of use, objectivity, and account for varying anatomic perspectives between open and laparoscopic surgery.

DIAGNOSIS

History

Inguinal hernias present along a spectrum of scenarios. These range from incidental findings to symptomatic hernias to surgical emergencies such as incarceration and strangulation of hernia sac contents. Asymptomatic inguinal hernias are frequently diagnosed incidentally on physical examination or may be brought to the patient's attention as an abnormal bulge. In addition, these hernias can be identified intra-abdominally during laparoscopy. Inspection of the pelvis following mobilization of intestinal contents into the upper abdomen will reveal the myopectineal orifice and allow facile identification of the peritoneum herniating through the direct, indirect, or femoral space.

Patients who present with a symptomatic groin hernia will frequently present with groin pain. Less commonly, patients will present with extrainguinal symptoms such as change in bowel habits or urinary symptoms. Regardless of size, an inguinal hernia may impart pressure onto nerves in the proximity, leading to a range of symptoms. These include generalized pressure, local sharp pains, and referred pain. Pressure or heaviness in the groin is a common complaint, especially at the conclusion of the day, following prolonged activity. Sharp pains tend to indicate an impinged nerve and may not be related to the extent of physical activity performed by the patient. Lastly, neurogenic pains may be referred to the scrotum, testicle, or inner thigh. Questions also should be directed to elucidating the extrainguinal symptoms. A change in bowel habits or urinary symptoms may indicate a sliding hernia consisting of intestinal contents or involvement of the bladder within the hernia sac.

Important considerations of the patient's history include duration and progressiveness of the symptoms. Hernias will often increase in size and content over a protracted time. Much less commonly, a patient will present with a history of acute inguinal herniation following a strenuous activity. However, it is more likely that an asymptomatic, previously unknown, inguinal hernia became evident once the patient experienced symptoms associated with the circumstances of the acute event. Notwithstanding the type of presentation, specific questions should be focused as to whether the hernia is reducible. Oftentimes, patients will reduce the hernia by pushing the contents of the bulge back into the abdomen, thereby providing temporary relief. As the size of a hernia increases and a larger amount of intra-abdominal contents fill the hernia sac, the bulge may become harder to reduce.

Physical

Although the history may be tremendously indicative of an inguinal hernia, the physical examination is essential to forming the diagnosis. A significant drawback exists in morbidly obese patients, where delineation of external groin anatomy is difficult and may

obscure the findings of a groin hernia. Ideally, the patient should be examined in a standing position, with the groin and scrotum fully exposed. The standing position has the advantage over the supine position in that intra-abdominal pressure is increased, and thereby, the hernia can be more easily elicited. Inspection is performed first, with the goal of identifying an abnormal bulge along the groin or within the scrotum. If an obvious bulge is not detected, physical examination is performed to confirm the presence of the hernia.

Palpation is performed by placing the index finger into the scrotum, aiming it toward the external inguinal ring (Fig. 37-13). This allows the inguinal canal to be inspected. The patient is then asked to cough or bear down (i.e., Valsalva's maneuver) to protrude the hernia contents. Reproduction of patient symptoms, namely vague, generalized pressure sensations, will not usually be reproduced by these maneuvers, as they are a product of prolonged pressure on the cord contents. However, a Valsalva's maneuver will reveal an abnormal bulge and allow the clinician to determine whether the bulge is reducible or not. Examination of the contralateral side affords the clinician the opportunity to compare the extent of herniation between sides. This is especially useful in the case of a small hernia. The magnitude of the bulge on the affected side can be compared to the normal bulging of muscle on the nonaffected side, when the abdomen is placed under strain. However, the results may be misleading if there is a latent contralateral hernia that is discovered during this examination.

Digital examination of the inguinal canal.

Certain techniques of the physical examination have classically been used to differentiate between direct and indirect hernias. The inguinal occlusion test involves placement of a finger over the internal inguinal ring and the patient is instructed to cough. If the cough impulse is controlled, then the hernia is indirect. If the cough impulse is still manifest, the hernia is direct. As well, with a finger in the inguinal canal, the cough impulse can be used to determine the type of hernia. If the cough impulse is felt on the fingertip, the hernia is indirect; if felt on the dorsum of the finger, it is deemed direct. However, when results of clinical examination are compared against operative findings, there is a probability somewhat higher than chance (i.e., 50%) of correctly diagnosing the type of hernia.^{22,23}

Therefore, the utility of these tests should not be used to diagnose the type of inguinal hernia insomuch as they should be used to determine the presence or absence of one.

A further challenge to the physical examination is the identification of a femoral hernia. The anatomic position of a femoral hernia dictates that it should be palpable below the inguinal ligament, lateral to the pubic tubercle. As a consequence of increased subcutaneous tissue, a femoral hernia may be missed or misdiagnosed as a hernia of the inguinal canal. In contrast, a prominent fat pad in a thin patient may prompt an erroneous diagnosis of femoral hernia, otherwise known as a *femoral pseudohernia*.

In addition to inguinal hernia, a number of other diagnoses may be considered in the differential of a groin bulge (Table 37-6). The diagnosis is ambiguous; radiologic investigation may provide the answer.

Table 37-6 Differential Diagnosis of Groin Hernia

Cyst of the canal of Nuck (female)
Saphenous varix
Psoas abscess
Hematoma
Ascites

Imaging

A number of situations can make the usually straightforward diagnosis of inguinal hernia ambiguous. These scenarios include obese patients, hernias that cannot be elicited on physical examination, and recurrent inguinal hernias. In these situations, radiologic investigations may be used as an adjunct to history and physical examination. The most common radiologic modalities include ultrasonography (US), computed tomography (CT), and magnetic resonance imaging (MRI). Each technique has certain advantages over physical examination alone; however, each also is associated with potential pitfalls.

Ultrasound is the least invasive technique and does not impart any radiation to the patient. Anatomic structures can be more easily identified by the presence of bony landmarks; however, because there are few in the inguinal canal, other structures such as the inferior epigastric vessels are used to define groin anatomy. Positive intra-abdominal pressure is used to elicit the herniation of abdominal contents. Movement of these contents is essential to making the diagnosis with US, and lack of this movement may lead to a false negative. In thin patients, normal movement of the spermatic cord and posterior abdominal wall against the anterior abdominal wall

may lead to false-positive diagnoses of hernia.²⁴

CT and MRI provide static images that are able to delineate the groin anatomy and demonstrate not only the presence of groin hernias, but also rule out differential diagnoses that may cloud the clinical picture (Fig. 37-14). Although CT scan is useful in ambiguous clinical presentations, little data exist to support its routine use in diagnosis. The use of MRI in assessing groin hernias was examined in a group of 41 patients scheduled to undergo laparoscopic inguinal hernia repair. Preoperatively, all patients underwent US and MRI. Laparoscopic confirmation of the presence of inguinal hernia was deemed the gold standard. Physical examination was found to be the least sensitive, whereas MRI was found to be the most sensitive. False positives were low on physical examination and MRI (one finding), but higher with US (four findings). With further refinement of technology, radiologic techniques will continue to improve the sensitivity and specificity rates of diagnosis, thereby serving a supplementary role in cases of uncertain diagnosis.

Computed tomography scan depicting a large right inguinal hernia (arrow). A smaller left inguinal hernia is also visualized.

ANESTHESIA

Local, regional, and general anesthesia are all viable options for open anterior hernia repairs. Laparoscopic repairs, on the other hand, usually are performed using general anesthesia for optimal abdominal expansion and patient comfort. This limitation of laparoscopic surgery becomes a consideration in high-risk patients that cannot tolerate general anesthesia and the effects of pneumoperitoneum. In contrast, there are relatively few side effects of local anesthesia, which can facilitate operative tolerance by the patient, especially when combined with an IV sedative or anxiolytic agent.

Local anesthesia is applied by the surgeon before the initial groin incision. Common anesthetic agents include lidocaine and the longer-acting bupivacaine, both with optional epinephrine. Patients with a history of coronary artery disease have a relative contraindication to epinephrine use. The maximum dose should be calculated according to the patient's weight during preparation of the injection. In advance of the initial incision, usually before the prep and drape, a variable amount of anesthetic is injected one fingerbreadth medial and inferior to the anterior superior iliac spine to block the ilioinguinal nerve. In addition, anesthetic is injected along the cutaneous

course of the skin incision and underlying subcutaneous tissue. The remaining amount is reserved for repeated applications to affected areas during the course of the operation. A combination of the two agents provides for a quick onset and prolonged control of pain, in the range of 18 hours.

Regional anesthesia, such as epidural, is another option reserved for patients that cannot tolerate general anesthesia. It also has a greater margin of patient comfort. Additional advantages of local and regional anesthesia include the ability of the patient to cough or Valsalva to test the repair. The versatility of anesthesia choices is a common argument for proponents of open inguinal hernia repairs. Nonetheless, the majority of procedures are performed using general anesthesia, which provides the greatest margin of patient comfort of all three choices. Advances in perioperative care have allowed for extensive general anesthesia use in an ambulatory surgery setting. Long- or short-acting local anesthetics can be applied to the incisions at the end of the procedure to prolong pain control. Common cardiorespiratory complications of anesthesia include myocardial depression, infarct, and aspiration pneumonia. The risk of these complications is reduced by using local anesthesia; however, anesthesiologists may prefer to completely sedate the patient and thereby control the airway. It should be noted that most procedures using only local anesthesia are performed at specialty hernia centers.

TREATMENT

The treatment of inguinal hernias can be subdivided according to approach (i.e., open vs. laparoscopic). Open inguinal hernias can be further subdivided according to whether the repair is performed anterior or posterior to the inguinal floor. A large number of open inguinal hernia repairs have been described over time; however, the most commonly performed and clinically pertinent procedures will be described herein.

Open Approach

Before the widespread use of prosthetic material, inguinal hernia repairs were based on restoring tissue strength through the use of sutures. Upon the introduction of prosthetics in the tension-free repair, these procedures came to be known as *tension repairs*; however, this would imply that these procedures do not adhere to basic surgical principles of avoiding tension between tissues. Therefore, these will be referred to as *tissue repairs*. Despite the advantages of the tension-free prosthetic repair, tissue repairs occupy an important place in the choice of inguinal hernia repair, especially in situations where prosthetic material is contraindicated. This includes a contaminated operative field or concern regarding possible azoospermia secondary to long-term effects of mesh on the vas deferens.²⁵

Exposure of the inguinal region is common to open approaches to inguinal hernia repair. An oblique or horizontal incision is performed over the groin (Fig. 37-15). A point two fingerbreadths inferior and medial to the anterior superior iliac spine is chosen as the most lateral point of the incision. It is then progressed medially for approximately 6 to 8 cm. Electrocautery is then used to divide the subcutaneous tissue. Fascia of Camper is not routinely encountered; however, Scarpa's fascia generally is identified and then divided, thereby exposing the aponeurosis of the external oblique muscle. A vein coursing in a vertical fashion through the subcutaneous tissue frequently is encountered and is ligated and divided between hemostat clamps. The fibers of the external oblique muscle are then sharply divided parallel to the direction of fibers. Metzenbaum scissors are then advanced immediately beneath the fibers, laterally and then medially toward the external inguinal ring, and spread as they are retracted to create a space and avoid inadvertent dissection of the ilioinguinal nerve. The scissors are then used to incise the aponeurosis, splitting the external inguinal ring, exposing the inguinal canal and its contents. The aponeurosis is divided superior to the inguinal ligament as consideration should be made for its reapproximation once the repair is complete.

A. Layers of the abdominal wall in an anterior open approach to hernia repair. **B.** Identification of indirect and direct hernia sacs once the spermatic cord has been isolated and the ilioinguinal nerve has been retracted away. Ex. = external; SQ = subcutaneous.

MOBILIZATION OF THE CORD STRUCTURES

Hemostat clamps are then applied to the superior and inferior edges of the aponeurosis and elevated from the inguinal canal. Blunt dissection is then performed to separate the superior flap of the external oblique aponeurosis from the internal oblique muscle. Likewise, the inferior flap of the external oblique aponeurosis is bluntly dissected to reveal the shelving edge of the inguinal ligament. The iliohypogastric and ilioinguinal nerves are identified and may be retracted from the operative field by placing a hemostat beneath their course and then grasping one of the edges of the aponeurosis. Some surgeons routinely divide these nerves to avoid possible entrapment; however, the sequelae involve permanent paresthesia to sites of their cutaneous distribution. The pubic tubercle is then identified and the surgeon's index finger and thumb are placed around the cord as it passes the tubercle. A Penrose drain or metal cord ring may then be placed around the cord and its contents to permit its elevation from the floor of the inguinal canal. With the cord elevated at the external inguinal ring, cremasteric fibers are visualized connecting the floor of the inguinal canal to the posterior aspect of the cord. The cremasteric fibers can then be divided bluntly or through the use of electrocautery to initiate skeletonization of the cord. Once the cremasteric fibers are completely divided between the external and internal inguinal rings, the floor of the inguinal canal can be fully assessed for direct hernias. Care must be taken to avoid injury to cord structures during the division of the cremasteric muscle.

IDENTIFICATION AND REDUCTION OF THE SAC

With the contents of the inguinal canal completely encircled, identification of cord contents and the hernia sac can be effected. Direct hernias will become evident as the floor of the inguinal canal is dissected. Even in tension-free repairs, the floor of the inguinal canal may be imbricated with stitches to reduce the direct hernia sac. An indirect hernia sac will generally be found on the anterolateral surface of the spermatic cord. In addition to sac identification, the vas deferens and vessels of the spermatic cord must be identified to allow dissection of the sac from the cord. At the leading edge of the sac, the two layers of peritoneum will fold upon themselves and reveal a white edge, which may help in the identification of the sac. This peritoneum can then be grasped with a tissue forceps and bluntly dissected from the cord. The dissection is carried proximally toward the deep inguinal ring.

The reduction of the hernia sac into the preperitoneal space is commonly known as *high ligation of the sac*. Some surgeons will routinely open the sac and inspect it to ensure there is no incarceration of intra-abdominal contents. As well, the decision must be made whether to excise the sac at the internal inguinal ring or simply invert it into the preperitoneum. Both methods are effective in reducing the sac; however, in a large prospective randomized study, patients undergoing high ligation and excision of the sac had significantly increased postoperative pain in the first week.²⁶ A densely adherent sac, which may result in injury to cord structures, does not necessarily

deserve dissection; however, division at the internal inguinal ring is necessary. Likewise, an inguinal hernia sac that extends into the scrotum may require division within the inguinal canal. Attempts to reduce such sacs may be met with postoperative complications related to injury of the pampiniform plexus, including testicular atrophy and orchitis.

WOUND CLOSURE

Once the reconstruction of the inguinal canal is complete, the cord contents are returned to their anatomic position. The external oblique aponeurosis is then reapproximated. A useful starting position is at the external inguinal ring. Using an absorbable suture, the external inguinal ring is reconstructed and the external oblique fascia is then closed using a running stitch that progresses laterally. Avoidance of an overly constricting external ring will prevent compression of cord structures at that point. However, it should be small enough to contain the contents of the inguinal canal and prevent a future false-positive diagnosis of recurrent hernia. Scarpa's fascia may then be closed with a series of interrupted absorbable sutures. Lastly, skin is closed with a subcuticular stitch to preserve cosmesis of the incision.

ANTERIOR REPAIRS, NONPROSTHETIC

Before the introduction of mesh prostheses, open anterior inguinal hernia repairs were performed by reapproximating tissue using only sutures. Despite their shortcomings, specific procedures such as the Bassini, Shouldice, and McVay repair continue to occupy a minor, yet important role in the overall treatment of inguinal hernias. The introduction of the Bassini repair was superior to previously performed procedures in that, not only was the hernia reduced and the defect oversewn, but now an attempt was made to reconstruct the site of weakness, although these tissue-based repairs tend to place tension on the reconstructed tissue. The Shouldice repair is an exception because the multilayer reconstruction distributes the tension, effectively resulting in a tension-free repair. Hernia exposure and reduction are common to all open anterior repairs; however, the mode of restoration of inguinal canal integrity differs according to procedure.

Bassini Repair

The Bassini repair was a major advancement in the treatment of inguinal hernias owing to significantly reduced recurrence rates as compared to other operations of the day. Current use of the Bassini repair is limited because other tissue-based operations such as the Shouldice repair have demonstrated lower recurrence rates. The importance of the Bassini repair lies in the paradigm shift it promoted, which included dissection of the spermatic cord, dissection of the hernia sac with high ligation, and extensive reconstruction of the floor of the inguinal canal (Fig. 37-16). Following division of the cremasteric muscle and ligation of the hernia sac deep to the internal inguinal ring, the transversalis fascia is incised from the pubic tubercle to the internal inguinal ring, thereby entering the preperitoneal space. Preperitoneal fat is bluntly dissected from the upper margin of the posterior side of the transversalis fascia to permit adequate tissue mobilization. A triple-layer repair is then performed to restore integrity to the floor. The medial tissues, including the internal oblique muscle, transversus abdominis muscle, and transversalis fascia, are fixed to the shelving edge of the inguinal ligament and pubic periosteum with interrupted sutures. The lateral border of the repair is the medial border of the internal inguinal ring, which subsequently is reinforced by the repair. Adoption of the Bassini technique in North America resulted in injury to neurovascular structures and high recurrence rates because the posterior floor was not routinely opened. Nevertheless, the significant advances promulgated by Bassini still resulted in a recurrence rate that could be further improved. Numerous modifications of the technique by successive surgeons accomplished a lower recurrence rate, namely with the addition of the relaxing incision and the Shouldice technique. Current use of the Bassini technique is limited, although a modification may be useful in large direct hernias approached via an open approach. In these cases, imbrication of the posterior floor may be added to a tension-free repair with mesh.

Bassini repair. **A.** The transversalis fascia is opened from the internal inguinal ring to the pubic tubercle exposing the preperitoneal fat. **B.** Reconstruction of the posterior wall by suturing the transversalis fascia (TF), the transversus abdominis muscle (TA), and the internal oblique muscle (IO) (Bassini's famous "triple layer") medially to the inguinal ligament (IL) laterally. EO = external oblique aponeurosis.

Shouldice Repair

The principles of the Bassini repair were revitalized within the Shouldice repair, resulting in superior recurrence rates. Although the Shouldice repair is generally grouped with open tissue-based repairs, its success rates are equivalent to that of tension-free repairs in many studies comparing the two approaches. As with the Bassini repair, the primary tenets of the procedure involve extensive dissection and reconstruction of inguinal canal anatomy. The use of a continuous suture in multiple layers resulted in the dual advantage of distributing tension over several layers and preventing subsequent herniation between interrupted sutures (Fig. 37-17). Original descriptions of the Shouldice technique involved the use of a stainless steel wire; however, modern modifications have resulted in the use of a synthetic nonabsorbable suture. With the posterior inguinal floor exposed, an incision in the transversalis fascia is performed

between the pubic tubercle and internal ring. Care is taken to avoid injury to any preperitoneal structures, and these are bluntly dissected to mobilize the upper and lower fascial flaps. The first layer of repair begins at the pubic tubercle where the iliopubic tract is sutured to the lateral edge of the rectus sheath, then progressing laterally. The inferior flap of the transversalis fascia, which includes the iliopubic tract, is sutured continuously to the posterior aspect of the superior flap of the transversalis fascia until the internal ring is encountered. At this point, the internal ring has been reconstituted. The suture is not tied here, but rather is continued back upon itself in the medial direction. At the internal ring, the second layer is the reapproximation of the superior edge of the transversalis fascia to the inferior fascial margin and the shelving edge of the inguinal ligament. The suture is then tied to the tail of the original stitch. A third suture is started at the tightened inguinal ring, joining the internal oblique and transversus abdominis aponeuroses to external oblique aponeurotic fibers just superficial to the inguinal ligament. This layer is continued to the pubic tubercle where it reverses upon itself to create a fourth suture line, which is similar and superficial to the third layer. Unique to this operation is the routine division of the genital branch of the genitofemoral nerve. The consequence of loss of skin sensation is countered by the observed decrease in recurrence rate at the pubic tubercle. The Shouldice technique is readily apparent in common practice, especially in specialized hospitals treating inguinal hernias.

The Shouldice repair. **A.** The iliopubic tract is sutured to the medial flap, which is made up of the transversalis fascia and the internal oblique and transverse abdominis muscles. **B.** This is the second of the four suture lines. After the stump of the cremaster muscle is picked up, the suture is reversed back toward the pubic tubercle approximating the internal oblique and transversus muscles to the inguinal ligament. Two more suture lines will eventually be created suturing the internal oblique and transversus muscles medially to an artificially created "pseudo" inguinal ligament developed from superficial fibers of the inferior flap of the external oblique aponeurosis parallel to the true ligament.

McVay Repair

The advantage of the McVay (Cooper's ligament) repair is the ability to address both inguinal and femoral canal defects. Femoral hernias that are approached via a suprainguinal ligament approach, or situations where the use of prosthetic material is contraindicated, are amenable to this type of repair. The operation was popularized by McVay, who also added the concept of the relaxing incision as a tension reducing maneuver (Fig. 37-18). Once the cord has been isolated, a transverse incision is performed through the transversalis fascia, thereby entering the preperitoneal space. A small amount of dissection of the posterior aspect of the fascia is performed to allow mobilization of the upper margin of the transversalis fascia. The floor of the inguinal canal is then reconstructed to restore its strength. Cooper's ligament is identified medially, and it is bluntly dissected to expose its surface. The upper margin of the transversalis fascia is then sutured to Cooper's ligament. The repair is continued laterally along Cooper's ligament, occluding the femoral canal.

McVay Cooper ligament repair.

Once the femoral canal has been passed, a transition stitch is performed by now suturing the transversalis fascia to the inguinal ligament. The transition stitch helps obliterate the femoral canal, but more importantly, avoids injury to the femoral vessels. The transversalis fascia is subsequently sutured to the inguinal ligament, the lateral margin being the internal inguinal ring, which consequently undergoes transformation to a smaller, tighter ring. The repair can be performed using either interrupted sutures or a continuous stitch. An essential component of the procedure is the relaxing incision, which helps reduce the considerable amount of tension that normally results. Before suturing the transversalis fascia to Cooper's and the inguinal ligament, an incision in the anterior rectus sheath is made. The incision begins at the pubic tubercle and is extended superiorly for approximately 2 to 4 cm.

Potential consequences of the relaxing incision include increased postoperative pain and less likely herniation at the anterior abdominal wall. Disadvantages of routinely performing the McVay Cooper's ligament repair include elevated recurrence rates due to the tissue-based nature of the operation. Furthermore, the procedure requires extensive dissection and may result in injury to the underlying femoral vessels.

ANTERIOR REPAIRS, PROSTHETIC

Outside of specialized centers dealing with inguinal hernias, recurrence rates of tissue-based repairs continued to be high, owing to the tension placed on reconstructed tissues. To circumvent this problem and adhere to no-tension principles of effective surgical repair, mesh herniorrhaphies were developed. The addition of a mesh prosthesis effected a reconstruction of the posterior inguinal canal, without placing tension on the floor itself, hence a tension-free repair, as championed by Lichtenstein. Further refinements have included the addition of a plug through the internal ring, resulting in the plug and patch repair. The consistently superior recurrence rates over the long-term, along with the ease of reproducibility of these techniques, resulted in the wide acceptance of tension-free repairs for inguinal hernias.

Lichtenstein Tension-Free Repair

Initial exposure and mobilization of cord structures is identical to other open approaches. Particular attention must be paid to blunt

dissection of the inguinal canal to expose the shelving edge of the inguinal ligament and pubic tubercle, as well as provide a large area for mesh placement. Unlike the tissue-based repairs, the Lichtenstein repair does not include routine division of the transversalis fascia, thereby preventing the identification of a latent femoral hernia. However, in the case where a clinically significant hernia is not visualized upon entrance into the inguinal canal, an argument can be made to enter the preperitoneal space and evaluate the femoral canal. The lack of inguinal floor division also indicates that the internal inguinal ring is not reconstructed using canal structures (Fig. 37-19). Instead, the floor and internal ring are reinforced through the application of the mesh.

Lichtenstein tension-free hernioplasty. **A.** Medially, the prosthesis (P) is sutured to the anterior rectus sheath 2 cm medial to the pubic tubercle. Laterally, a continuous suture is used to fix the prosthesis to the shelving edge of the inguinal ligament. The tails of the mesh are placed around the cord and secured with an interrupted suture. **B and C.** A lateral view demonstrates that the prosthesis is situated between the cord and the hernia defect (HD). The hernia defect has been imbricated to allow for facile prosthesis placement only (this does not affect the strength of the repair). EOA = external oblique aponeurosis.

The mesh is rectangular in shape, with a rounded edge at its apex, corresponding to the medial edge. At the other end, the mesh will be split to accommodate the spermatic cord. The mesh prosthesis must be large enough to adequately cover the posterior wall of the inguinal canal and can be sized accordingly when placed into the field. The rounded edge is attached to the anterior rectus sheath just medial to the pubic tubercle, ensuring that there is an adequate overlap medially to prevent recurrence. The suture is then continued in a running fashion to secure the mesh around the pubic tubercle. Care must be taken to avoid placing sutures directly into the periosteum of the pubic tubercle, which may result in persistent postoperative pain. The inferior margin of the mesh is then sutured to the shelving edge of the inguinal ligament, as the repair is continued laterally. The stitch is then tied at the internal ring. The mesh is then tailored to fit around the cord at the internal ring. The slit in the lateral end of the mesh may require expansion to accommodate the cord and prevent strangulation of cord contents. The superior and inferior flaps of the prosthesis are then placed around the base of the cord, lateral to the internal ring and near the anterior superior iliac spine, and sutured together with a single interrupted stitch. This allows the internal ring to be reinforced by a synthetic valve, helping to prevent recurrences of indirect inguinal hernias.

A flap closure that is too loose may lead to higher indirect hernia recurrences; however, one that is too tight may impart significant pressure on the spermatic cord, leading to the injury of its contents. The superior edge of the mesh is then fixed to the posterior aspect of the internal oblique aponeurosis and rectus sheath, using either interrupted or continuous sutures. Fixation of the upper and lower margin of the mesh too superficially to the internal and external oblique aponeuroses may shorten the superior and inferior flaps of the external oblique aponeurosis, making closure of the inguinal canal difficult. In the case of a femoral hernia, the inferior margin of the mesh is sutured to Cooper's ligament medially and inguinal ligament laterally, similar to McVay's repair. Nonabsorbable or long-term absorbable sutures generally are used with mesh repairs.

Plug and Patch Technique

A modification of the Lichtenstein repair, known as the *plug and patch technique*, was developed by Gilbert and later popularized by Rutkow and Robbins.²⁷ In addition to placement of the prosthesis in a similar fashion to the Lichtenstein repair (i.e., the patch), the technique includes placement of a prosthesis (i.e., the plug) through the internal ring (Fig. 37-20). The internal ring is therefore reinforced by the leaflets of the patch as well as the plug. Initial technique described rolling a flat piece of polypropylene into a tight cylinder and placing it alongside the spermatic cord as it passes through the internal ring. Further modifications have involved shaping the plug into a flower or umbrella configuration, with the apex pointed intra-abdominally, in effect serving as a preperitoneal prosthesis. Increased abdominal pressure acts on the plug, opening its leaflets and creating a protective valve. Original descriptions of the plug and

patch procedure emphasized a pure tension-free approach in that the plug and patch could be placed in their anatomic positions without sutures. Normal scarring would then fix the prostheses in place and provide reconstituted strength to the inguinal canal. Currently, preformed plugs in various sizes are available and are usually fixed to the margins of the internal ring with one or several interrupted sutures.²⁸ Direct defects may also be plugged; however, in the absence of inguinal floor division and dissection, suture fixation of the plug to the margins of the defect is necessary. In this case, the plug is fixed to Cooper's and the inguinal ligament inferiorly and the internal oblique aponeurosis superiorly. Numerous modifications of the plug and patch technique have occurred with various extents of prosthesis fixation. Considerations unique to the plug include intra-abdominal migration and erosion into contiguous structures.

A. A plug may be created from a flat piece of mesh, or a preformed, commercially available plug is placed in the internal ring. **B.** Final

view of the repair following placement of the plug and patch. A common modification is to use the flat mesh to overlap the plug, after it is placed.

PREPERITONEAL REPAIRS

As previously noted in the Bassini Repair section, the preperitoneal space can be entered using the anterior approach by dividing the transversalis fascia; however, wide exposure of the preperitoneal space is limited. Therefore, a number of surgeons have approached the preperitoneal space posterior to the transversalis fascia. Cheatele was the first to perform posterior preperitoneal repair of a groin hernias, usually through a lower midline and later using a Pfannenstiel incision. Nonprosthetic preperitoneal repairs were also described by Nyhus; however, the superior results achieved by mesh use lend them to historical significance only. The placement of a widely overlapping prosthesis in the preperitoneal space using the open approach eventually became the basis of laparoscopic surgery. The strength of the transversalis fascia is reinforced by the addition of the prosthesis deep to it. The perceived advantage of the preperitoneal approach is that the prosthesis can be placed between hernia contents and the hernia defect. Furthermore, increases in intra-abdominal pressure serve to push the mesh against the floor of the inguinal canal, unlike in anterior mesh placement where the mesh is pushed away. The posterior approach to preperitoneal repairs avoids entry into the inguinal canal and permits optional closure of the hernia defect. Therefore, nerves that course through the inguinal canal are avoided, and there is minimal manipulation of the spermatic cord. A Pfannenstiel or lower midline incision is generally used to gain access to the preperitoneal space, taking care not to disturb the peritoneum. The preperitoneal space can also be accessed intra-abdominally; however, this approach is optimal if a laparotomy is being performed for other purposes. A notable example is a laparotomy performed for bowel obstruction that results in the identification of an inguinal hernia as the cause of obstruction.

Read-Rives Repair

The anterior approach to preperitoneal repairs, as described by Read and Rives, accesses the groin using a standard groin incision (Fig. 37-21). The transversalis fascia is incised and a wide blunt dissection of the preperitoneal space is performed to accommodate a large prosthesis. The spermatic cord is identified at the internal ring and dissected from the peritoneum proximally to the pelvic portion of the vas deferens. The vas deferens is separated from the spermatic vessels during the course of cord parietalization. Cooper's ligament must also be identified medially and dissected free to expose its surface. Dissection to this extent frees the peritoneum from the iliac fossa and provides an adequate space for placement of a large prosthesis. An unsplit piece of mesh, approximately 16 x 12 cm is then placed in the preperitoneal space over the spermatic cord, ensuring overlap medial to Cooper's ligament, laterally to the anterior superior iliac spine and inferiorly to the margin of the preperitoneal dissection. The mesh is secured using three sutures, to Cooper's ligament, the pubic tubercle, and the psoas muscle. The transversalis fascia is then reclosed, and the inguinal canal is closed routinely as per the open approach.

View of mesh placement in posterior repairs. A large piece of mesh is used to overlap the myopectineal orifice. Sutures are placed at the pubic tubercle, Cooper's ligament, and psoas muscle.

Giant Prosthetic Reinforcement of the Visceral Sac

The giant prosthetic reinforcement of the visceral sac is also known as the *Rives*, *Stoppa*, or *Wantz* repair, although minor modifications exist between them. Ideal access is provided by a Pfannenstiel or lower transverse incision, which is more medial than a standard groin incision in anterior open approaches. The incision ranges 8 to 10 cm from the midline laterally, above the level of the internal ring. The intent is to expose the lateral aspect of the rectus sheath and divide it and the oblique muscles for a distance of 10 cm. Abdominal wall muscles are then retracted to expose the transversalis fascia, allowing it to be incised. The peritoneum is left intact to maintain the procedure within the preperitoneal space. Wide dissection is then performed posterior to the rectus sheath and inferior epigastric vessels (Fig. 37-22). The dissection begins on the contralateral side of the midline and continues laterally to beyond the anterior superior iliac spine. Inferiorly, the peritoneum is dissected to the division of the spermatic vessels and vas deferens. The posterior approach requires identification of Cooper's ligament medially and the iliopubic tract running laterally. A direct hernia will be identified and reduced during the course of initial dissection. Care must be taken to separate the hernia sac from the overlying transversalis fascia because an incorrect plane of dissection may be entered, resulting in dissection of the anterior abdominal wall. Direct defects can be ignored, or conversely, the defect can be imbricated or obliterated by suturing the transversalis fascia to Cooper's ligament. An indirect hernia will be identified at the internal ring and usually will require additional directed dissection. The advantage to the preperitoneal approach is minimal interaction with the spermatic cord. Therefore, in the case of large or densely adherent indirect hernia sacs that pose a problem during cord parietalization, ligation of the sac may be undertaken. The distal sac is left untouched, and the sac, at its insertion at the internal ring, is dissected from the spermatic cord. The resulting defect in the peritoneum is then closed to restore the peritoneal lining. Because the sac is bilayered, it can be opened on the side not adherent to the cord and dissected away until it can be circumferentially freed and divided.

Fig. 37-22.

Extensive dissection of the preperitoneal space on both sides will eventually accommodate the large prosthesis shown replacing the transversalis fascia.

A large mesh is then aseptically prepared for placement into the dissected space. The width of the mesh should span a distance between the umbilicus and anterior superior iliac spine, minus 1 cm, and the height should be approximately 14 cm. Variations of mesh preparation include an intact mesh vs. a slit mesh. A slit in the lateral aspect accommodates the spermatic cord, similar to mesh placement in the Lichtenstein tension-free repair. Splitting of the mesh creates a small defect in its integrity, which may predispose it to a hernia recurrence. Proponents for a slit or keyhole argue that mesh positioning is optimal and obviates the need for fixation sutures. Fixation is an important consideration when avoiding preperitoneal structures such as the lateral femoral cutaneous nerve and inferior epigastric vessels. Wantz's technique advocates the placement of three absorbable sutures that attach the superior border of the mesh to the anterior abdominal wall above the level of the indirect or direct defect. The location of fixation sutures includes the linea alba, linea semilunaris, and anterior superior iliac spine. Long clamps placed along the inferior border of the prosthesis facilitate flat placement along the inferior margin of the preperitoneal space (Fig. 37-23). The clamps are placed along the lower corners of the mesh and one in between. The mesh should be placed in a flat, taut position, avoiding any scrolling of the inferior border. The medial clamp is directed into the space of Retzius, the middle clamp over the pubic ramus and iliac vessels, and the lateral clamp is placed into the iliac fossa to provide coverage of the spermatic cord. The clamps are removed as the peritoneum is brought into apposition with the prosthesis. In the case of bilateral hernias, Stoppa advocates the use of a single large mesh spanning the area between the two anterior superior iliac spines minus 2 cm. The height is the distance between the umbilicus and the pubis. The large mesh requires the application of eight clamps to the lower border to facilitate proper placement. Although the approach provides excellent coverage and reinforcement of the preperitoneal space, postoperative pain and recovery is a significant consideration (Fig. 37-24).

Final appearance of Wantz's unilateral giant prosthetic reinforcement of the visceral sac.

Iliopubic Tract Repair

The iliopubic tract repair was popularized by Nyhus and Condon following extensive anatomic study detailing the importance of the iliopubic tract. The preperitoneal approach does not allow for visualization of the inguinal ligament; however, the iliopubic tract serves an analogous function in the preperitoneal space by providing a strong point of fixation. The repair combines a preperitoneal tissue-based repair with the implantation of mesh. Access to the preperitoneum is gained through a transverse abdominal incision two fingerbreadths above the pubic symphysis. The anterior rectus sheath is incised and the rectus abdominis is retracted medially to expose the posterior aspect of the sheath. The internal and external oblique muscles and the transversus abdominis muscle are also incised to reach the transversalis fascia (Fig. 37-25). The preperitoneal exposure and dissection is similar to other open preperitoneal techniques. Reconstruction of the inguinal floor is then enacted by suturing the transverse aponeurotic arch to Cooper's ligament and the iliopubic tract using interrupted sutures (Fig. 37-26). By suturing the transversalis fascia to Cooper's ligament, the femoral canal is obliterated. Around the internal ring, the leaflets of the transversalis fascia are sutured to the iliopubic tract to tighten the ring. The nature of the repair therefore specifically addresses femoral, direct, and indirect hernia defects. A mesh prosthesis is then implanted over the posterior aspect of the transversalis fascia and fixed to Cooper's ligament and above the iliopubic tract.

Fig. 37-25.

Iliopubic tract repair. Initial incision. The lateral side of the anterior rectus sheath has been opened, and the rectus muscle is visible. The external oblique, internal oblique, and transversus abdominis muscles are incised to expose the transversalis fascia.

Fig. 37-26.

Iliopubic tract repair. Direct hernia. The key to the repair is to suture the transverse aponeurotic arch to the iliopubic tract inferiorly. In this case, the internal ring is particularly large, so a suture is also placed lateral to the internal ring.

Kugel Repair

The Kugel repair aims to maximize on the preperitoneal approach while minimizing on the length of the skin and fascia incision.²⁹ An oblique skin incision is made approximately 2 to 3 cm above the internal ring, which is estimated to be halfway between the anterior superior iliac spine and the pubic tubercle. The 3- to 4-cm incision is made one third lateral and two thirds medial between these two structures. The abdominal wall is opened using a series of muscle splitting incisions similar to open appendectomy. The external oblique aponeurosis is incised, the internal oblique muscle is bluntly divided, and the transversalis fascia is opened vertically for 3 cm, avoiding the internal ring. Blunt dissection is then performed within the preperitoneal space, deep to the inferior epigastric vessels. Cooper's ligament, the pubic tubercle, the iliac vessels, and the hernia sac are palpated to aid in anatomic identification. Hernia sac dissection and division, if necessary, is similar to other open preperitoneal approaches. Similarly, dissection along the spermatic cord should be carried proximally enough to accommodate a mesh that will adequately cover the internal ring. In Kugel's view, placing the patch sufficiently posterior is the most critical part of preventing recurrences; however, the preperitoneal pocket should be dissected only up to the point that it barely accepts the mesh prosthesis. The pocket should extend 3 cm medial to the pubic tubercle and lateral to the lateral extent of the transversalis incision. The procedure is inextricably linked to a specially designed mesh. The 8 x 12 cm mesh is composed of two sheets of polypropylene, with a slit in the anterior layer that accommodates a single digit or instrument during mesh positioning. The mesh can be deformed to fit through the small incision, yet the self-retaining single monofilament fiber around the periphery of the mesh allows the mesh to spring open, assuming its normal shape. Additional features of the mesh promote anchoring and incorporation of tissue into the mesh. The mesh is oriented parallel to the inguinal ligament, with three fifths sitting above the level of the inguinal ligament. The transversalis fascia is closed with a single absorbable stitch, incorporating the anterior surface of the mesh to prevent

migration. The remainder of the wound is closed in successive layers using absorbable sutures. Kugel's experience of nearly 1500 patients demonstrates excellent recurrence rates (0.4%); however, these have not been reproduced owing to a steep learning curve associated with blind placement of the patch.³⁰

Prolene Hernia System

The Prolene hernia system technology was constructed to take advantage of the benefits of the anterior and preperitoneal repair using an open approach. The mesh consists of two large flaps (an onlay and an underlay patch) with an intervening connector (Fig. 37-27). The underlay is positioned in the preperitoneal space while the overlay rests along the floor of the inguinal canal. Exposure of the inguinal canal is identical to standard open approaches. The preperitoneal space is entered according to the site of the defect. Indirect hernia sacs are dissected from the spermatic cord and sponge dissection of the preperitoneal space is subsequently performed through the internal ring. In the case of direct defects, the transversalis fascia is opened to provide for preperitoneal dissection. The underlay portion of the mesh is then placed through the hernia defect, thereby overlapping direct, indirect, and femoral site defects. The overlay flap reinforces the inguinal floor similar to a tension-free repair. Only the anterior layer of the mesh is secured, using three to four interrupted sutures to the pubic tubercle, inguinal ligament, and internal oblique muscle. As well, the overlay flap contains a slit to accommodate the spermatic cord. The bilayer connector prevents mesh migration and ensures correct positioning. The greatest advantage to this technique is that it adds a preperitoneal reinforcement to an otherwise open tension-free repair.

Fig. 37-27.

The Prolene hernia system consists of two large flaps of mesh with an intervening connector.

Laparoscopic

Laparoscopic inguinal hernia repairs capitalize on the preperitoneal approach using a series of small incisions. The predominant techniques include transabdominal preperitoneal (TAPP) and totally extraperitoneal (TEP) repair, with intraperitoneal only mesh (IPOM) performed the least. The operating room setup is identical for both TAPP and TEP procedures. Mobilization of intra-abdominal and preperitoneal contents is optimally achieved by placing the patient in a Trendelenburg position. To this end, the monitors are placed at the foot of the bed, allowing the surgeon and assistant to view the procedure in a direct line of sight with instrumentation. The surgeon generally is positioned on the contralateral side to the hernia in question, although bilateral hernias can be repaired from either side. An assistant will occupy a position opposite the surgeon. The patient's arms are tucked at their sides and efforts must be made to adequately secure the patient during mobilization to the Trendelenburg position. Before performing the surgical prep, the bed should be tested to ensure the patient is fully secured and can hemodynamically tolerate being in Trendelenburg during the procedure. The scrub nurse and instrumentation table can be positioned on either side of the bed or at the foot of the bed. Figure 37-28 demonstrates a typical operating room setup for laparoscopic inguinal hernia.

Room setup and positioning of the patient and surgical team.

TRANSABDOMINAL PREPERITONEAL PROCEDURE

Unilateral or bilateral inguinal hernias can be assessed and repaired using a combination of three trocars. The authors' preference is for a 12-mm trocar in the umbilicus and one 5-mm trocar in each lower quadrant, slightly below the level of the umbilicus. Care must be taken to avoid injuring the inferior epigastric arteries when placing the 5-mm trocars (Fig. 37-29). Initially, a 12-mm trocar is placed through the umbilicus. The 12-mm trocar allows use of a 10-mm camera and allows for easy introduction of a prosthetic material into the abdominal cavity. A 12-mm vertical incision is performed through the umbilicus and sharp dissection is performed to clear the subcutaneous attachments around the umbilical ring. A Kelly hemostat is then inserted through the umbilical ring and gently widened to allow placement of a blunt 12-mm trocar. The surgeon's fifth finger is then swept circularly beneath the umbilical ring to ensure no adhesions or intestinal contents are present. Sutures are placed in the fascia around the umbilical ring to anchor the trocar. Once the trocar is fixed in place, pneumoperitoneum is instilled to a level of 15 mmHg. A 5-mm trocar is then placed in each lower quadrant. The patient is then placed in a Trendelenburg position and the pelvic anatomy is inspected.

Trocar placement for **(A)** transabdominal preperitoneal repair and **(B)** totally extraperitoneal repair.

Initial inspection relies on identification of the bladder, median and medial umbilical ligaments, external iliac, and inferior epigastric vessels. The inguinal hernia can then be identified in relation to this anatomy. The peritoneum at the medial umbilical ligament is then grasped and incised with endoscopic scissors. The incision should be at least 3 to 4 cm above the hernia defect to allow placement of a large mesh and allow for closure of the peritoneal defect at the conclusion of the procedure. The incision is then carried laterally along a horizontal plane until the anterior superior iliac spine is reached. The peritoneum is retracted inferiorly to reveal the areolar tissue of the preperitoneum. Sharp and blunt dissection is then performed to dissect free the preperitoneal space, the goal being to expose cord structures. Rarely is electrocautery necessary to aid in dissection. The symphysis pubis can then be used to identify Cooper's ligament lateral to it. Direct hernia sacs are reduced during the creation of the peritoneal flap. Indirect hernia sacs must be dissected free from the cord structures. Before handling the cord and hernia sac, the vessels of the spermatic cord and vas deferens must be identified. Care is taken to avoid grasping these structures, as permanent injury may ensue. The hernia sac, which is usually located anterior to cord structures, is grasped and elevated superiorly from the cord. A space inferior to the cord is created through blunt dissection. The sac is then dissected from the cord and the cord is skeletonized, including removal of any lipomas of the cord. Densely adherent hernia sacs may need to be divided to avoid injury to cord structures. The peritoneum must be dissected inferiorly to the level of divergence of the vas deferens and spermatic vessels to allow a large, flat coverage of mesh.

Once the preperitoneum has been adequately dissected, the mesh prosthesis can be placed. The mesh usually measures 10 x 15 cm (4 x 6 in), to completely cover the myopectineal orifice, and can be scrolled in a lengthwise fashion to facilitate easier handling. The mesh is then rolled lengthwise and placed through the 12-mm trocar with the aid of an instrument. The mesh is then unrolled in the preperitoneal space and secured to Cooper's ligament medially using a spiral tacker. The surgeon places the spiral tacker on the mesh and directs it into the abdominal wall. The other hand is able to palpate the end of the instrument and thus stabilizes the groin from the exterior. The mesh is then pulled relatively taut and fixed lateral to the anterior superior iliac spine, above the level of the iliopubic tract. The mesh can be further fixed along its superior edge, above the iliopubic tract, with great care taken to avoid fixation near the

inferior epigastric vessels. Being able to palpate a spiral tacker with the surgeon's other hand avoids placement of spiral tacks below the iliopubic tract, thereby avoiding injury to the lateral cutaneous nerve of the thigh or the femoral branch of the genitofemoral nerve. Variations of this technique include the absence of fixation in situations where the mesh is preformed to the preperitoneal space or is very large. As well, some prostheses are fashioned with an extra amount of mesh to place around the cord structures, mimicking an open tension-free approach. The mesh can also be split by the surgeon if this is desired.

The mesh is then manipulated to lay flat within the preperitoneal space. The peritoneal edge is then grasped and returned to its normal anatomic position, while the mesh is stabilized. Closure of the peritoneal defect can be performed using intracorporeal suturing or through the use of spiral tacks. One of the greatest difficulties encountered in the TAPP procedure is the reapproximation of the peritoneum. Through the course of dissection, the peritoneum may become denuded and prevent complete reconstruction and complete coverage of the mesh implant. Any tears in the peritoneum, especially if the hernia sac was divided, should be repaired to avoid direct contact of mesh with intestinal contents or acute obstruction of intestinal contents within these defects. The abdomen is desufflated, the trocars are removed, and the umbilical ring is reconstructed to avoid future umbilical herniation.

Despite the shortcomings of the TAPP procedure, namely injury to intra-abdominal organs and difficulty in closing the peritoneal dissection, there are a number of clinical scenarios where the usefulness of the procedure is evident. These include the possibility of repairing an inguinal hernia during the course of a laparoscopic procedure for an unrelated ailment. Furthermore, large hernias, ambiguous diagnoses, and a history of lower abdominal procedure may make TAPP more attractive than TEP. Lastly, the inguinal anatomy associated with TAPP is more obvious than that of its counterpart, TEP, and the presence of a large working space affords the surgeon a greater degree of motion.

TOTALLY EXTRAPERITONEAL PROCEDURE

The authors' preference is the TEP, as it is superior to TAPP on a number of levels. The TEP procedure allows the surgeon to work within the preperitoneal space, between the posterior aspect of the rectus abdominis and posterior rectus sheath, thereby circumventing penetration of the abdominal cavity. Inherent to this approach is a decrease in the possibility of injury to intra-abdominal organs and vascular structures. As well, the incidence of trocar site herniation is decreased owing to the preservation of the posterior rectus sheath. As importantly, TEP obviates the need for peritoneal closure and therefore may be performed faster than a TAPP. In situations involving large inguinal hernias or densely adherent tissue from previous abdominal operations, rents may result in the peritoneum, inadvertently exposing the intra-abdominal environment. These defects may be simply closed using tacks, sutures, or an endoloop. When the operation is wholly performed within the preperitoneal space, the incidence of bowel obstruction and mesh erosion into bowel in the proximity is insignificant compared to that of TAPP.

The preperitoneal dissection in TEP is identical to TAPP; however, access to the preperitoneal space is what makes the TEP unique and superior to TAPP. The initial incision is made horizontally, slightly inferior to the umbilicus. Subcutaneous tissue is dissected until the anterior rectus sheath is exposed. The anterior rectus sheath is opened away from the linea alba to expedite identification of the rectus abdominis. The muscle is then retracted laterally and superiorly to allow placement of a dissecting balloon. The balloon is advanced toward the symphysis pubis and then insufflated under direct vision, with the assistance of a 30° laparoscope. The dissecting balloon is inflated slowly to provide the initial dissection of the preperitoneal space (Fig. 37-30). The dissecting balloon is then replaced with a 12-mm trocar containing a balloon that maintains pneumoperitoneum. Carbon dioxide is then insufflated to a level of 15 mmHg. Two additional 5-mm trocars are placed in the lower midline (see Fig. 37-29). One is placed suprapubically, while the other is placed immediately distal to the structural balloon. The patient is then placed in a Trendelenburg position and the operation proceeds in an identical fashion to a TAPP (Figs. 37-31 and 37-32). During the course of the operation, an inadvertent rent may result in the peritoneum leading to loss of working space. Usually, the intra-abdominal and preperitoneal pressure will equilibrate with no loss of exposure. However, if the preperitoneal space becomes limited from billowing of the peritoneum, the defects may be closed using an endoloop. Alternatively, the operation can be converted to a TAPP; however, this is rarely necessary. The tears in the peritoneum should be repaired before conclusion of the operation to prevent mesh erosion or bowel obstruction. Following mesh placement, the

preperitoneal space is desufflated slowly and in a deliberate manner under direct vision to ensure proper mesh positioning. Once trocars are removed, the anterior rectus sheath is reclosed with an interrupted suture.

 Mesh placement using the totally extraperitoneal repair.

LAPAROSCOPIC BILATERAL INGUINAL HERNIA REPAIR

In the case of bilateral inguinal hernias approached via TAPP, two separate peritoneal incisions are advised, with a bridge of tissue remaining in the midline, in case of the presence of a patent urachus. In any case, adequate mobilization of tissue must still be performed in the midline, with placement and overlap of the mesh in the midline to prevent a recurrence. Bilateral inguinal hernias approached via TEP are exempt from this consideration, as the entire preperitoneum can more easily be exposed. The authors prefer to

perform the TEP, with a bilateral dissection before placing mesh on either side.

INTRAPERITONEAL ONLAY MESH PROCEDURE

In contrast to TAPP and TEP, the IPOM allows for a laparoscopic approach without dissection of the preperitoneal space. Port placement and identification of the inguinal hernia is identical to TAPP. At this point, the hernia sac is not reduced, and the preperitoneal space is not cleared. Instead, a prosthesis is applied directly over the hernia defect and fixed in place with sutures or spiral tacks. The anchors are placed in much the same manner as in other laparoscopic approaches. Following its introduction in 1991, enthusiasm for the procedure was high, in that the procedure could be performed quickly and across a variety of laparoscopic skill levels. However, enthusiasm waned due to significant drawbacks of the operation. The lack of preperitoneal dissection, which significantly reduces operative time, resulted in increased neuralgias, secondary to nonidentification of the lateral cutaneous nerve of the thigh and genitofemoral nerve. As well, the early recurrence rate was unacceptably high at 11%.³¹ In theory, intra-abdominal pressure would maintain the position of the mesh and prevent hernia recurrence; however, due to the nature of fixation, migration is a significant consideration.

The use of polypropylene mesh as the prosthetic device in IPOM added further postoperative risk such as bowel adherence and possible eventual erosion into contiguous structures. Recent advances in prosthetic material technology have attempted to circumvent this problem. The development of polyester mesh coated with porcine collagen on one surface allows for cellular integration on the polyester surface, while providing a barrier to intestinal contents on the other side until reperitonealization can take place. In a small study of IPOM using this mesh, no postoperative complications were reported in up to 2 years of follow-up. Recurrence rates also were found to be zero.³² Although current evidence clearly favors TAPP and TEP as the preferred laparoscopic approaches to inguinal hernia, there is yet to be defined an important role for IPOM in situations where preperitoneal dissection cannot be safely accomplished. These situations include disruption of the preperitoneal space by previous procedures such as laparoscopic/robotic prostatectomy or laparoscopic inguinal hernia repair. The risks associated with preperitoneal dissection in a previously operated space may outweigh the risks inherent to IPOM, thereby making it an attractive procedure. As well, in the course of a laparoscopic prostatectomy and concurrent inguinal hernia repair, extensive peritoneal dissection may prohibit adequate closure of the peritoneal flap over the mesh prosthesis. In this case, mesh placement is akin to that of IPOM and considerations for mesh choice must take into account possible complications. To this end, an inert prosthesis such as expanded polytetrafluoroethylene may be useful, albeit considering the increased recurrence rates.³³

Conservative Management

The definitive treatment of all hernias is surgical repair. A hernia defect will not decrease in size, but likely increase and possibly progress to incarceration or strangulation of the sac's contents. Surgery can be delayed or avoided in situations where the patient's medical status prohibits operative treatment. Conservative management is aimed at alleviating symptoms related to the inguinal hernia, such as pain, pressure, and protrusion of abdominal contents. Simple maneuvers include assuming a recumbent position, which aids in self-reduction of the hernia. A truss, an elastic belt or brief that aims to keep the hernia reduced, may also be worn; however, its use does not prevent hernia progression or incarceration. A truss may provide relief in up to 65% of patients; however, many will use it only intermittently as it does not provide continuous control of the hernia and may actually lead to an increased rate of hernia incarceration.³⁴

More commonly, conservative management is applied to asymptomatic or minimally symptomatic inguinal hernias. Although surgery is the only definitive therapy for an inguinal hernia, there is debate concerning the need for surgical repair of all inguinal hernias. Of course, the main concern for asymptomatic hernias is their likelihood of incarceration or strangulation. The natural history of an inguinal hernia is not well known and has been minimally studied, thus making it difficult to quantify the number of inguinal hernias that will become emergencies. One study has calculated the cumulative probability of developing a strangulated hernia to be 2.8% at 3 months for an inguinal hernia, and rising to 4.5% after 2 years. The figures were much higher for development of a strangulated femoral hernia at 3 months and 2 years, 22 and 45%, respectively.³⁵ Although the cumulative probability continues to rise, it appears that the risk of incarceration per year decreases in the first year. This is likely due to the presence of a smaller hernia defect initially, which may hinder

reduction of intestinal contents. As the size of the defect enlarges, reduction becomes easier, although incarceration can occur with large amounts of intra-abdominal contents and dense adherence to the hernia sac.

Historical data examining large populations of patients with inguinal hernias have provided limited data as to the risk of incarceration. One of the earliest studies from 1896 involved 8633 patients, of which 242 complications such as incarceration or strangulation were recorded. A number of medical conditions were also assessed within a large population of Colombians, including the risk of hernia complication. In both studies, the yearly risk of incarceration or strangulation was calculated to be approximately 0.3%.³⁶ Perhaps the most compelling data to quantify the risk of hernia complication resulted from a randomized multicenter trial comparing 720 patients with asymptomatic or minimally symptomatic inguinal hernias. These patients were randomized to either receive surgical therapy (Lichtenstein tension-free repair) or undergo watchful waiting. At 2 years follow-up, pain and inability to perform usual activities, the primary outcomes, were found to be equal between both groups. More importantly, the safety of a watchful waiting strategy was confirmed by the incidence of incarceration (0.3%), concluding that conservative management of asymptomatic or mildly symptomatic hernias carried small risk.³⁷ However, the study was limited by relatively short-term follow-up, considering that lifetime risk of incarceration increases with age. Considering that nearly 40% of the study participants did not receive the therapy to which they were randomized, it is appropriate that results were based on an intention to treat analysis. In this manner, the study assesses the therapeutic strategy, rather than comparing two distinct forms of treatment. The study also determined that the risk of complications in the surgical group was similar to the conservatively managed group at 2-year follow-up. Therefore, not only is watchful waiting a safe and acceptable option, but the delay of surgical therapy does not place the patient at a higher risk for complications.

Emergent

The indications for emergent inguinal hernia repair are incarcerated and strangulated inguinal hernias, as well as sliding hernias. By definition, an incarcerated hernia is one that cannot be reduced. Reasons for incarceration include a large amount of intestinal contents within the hernia sac, dense and chronic adhesions of hernia contents to the sac, and a small neck of the hernia defect in relation to the sac contents. The common factor that predisposes these aforementioned hernia syndromes to emergent operation is compromise of intestinal contents.

An incarcerated inguinal hernia without the sequelae of a bowel obstruction is not necessarily a surgical emergency. However, once the patient demonstrates bowel obstruction secondary to incarceration or a sliding inguinal hernia, operative intervention becomes expedited. Patients will often present with vomiting, constipation, obstipation, a distended abdomen, or combination thereof. In a sliding hernia, only one wall of a hollow viscus is present within the hernia sac. Although the lumen of the intestine is initially patent, strangulation of the knuckle of bowel may progress to localized edema and subsequent obstruction of the entire lumen. Less commonly, a sliding hernia will result from a portion of the bladder present within the hernia.

The most common presentation of small-bowel obstruction is usually secondary to previous operation and presence of adhesions. However, in the case of a patient with small-bowel obstruction and virgin abdomen, the diagnosis of carcinoma and inguinal hernia incarceration should be considered first. Physical examination is generally directed to the affected abdomen; however, the inguinal regions must be examined to rule out the presence of an incarcerated hernia. In the case of an ambiguous physical examination, radiologic evaluation such as CT should be considered early to define the source of obstruction. Failing this, diagnostic laparoscopy should be undertaken with the dual aim of diagnosing and alleviating the source of obstruction.

For known incarcerated hernias, reduction should be attempted before definitive surgical intervention. Hernias that are not strangulated and do not reduce with gentle pressure should undergo taxis. The patient is sedated and placed in a Trendelenburg position. The hernia sac is grasped with both hands, elongated, and then milked back through the hernia defect. Pressure applied to the most distal portion of the sac will cause the contents to mushroom and prevent reduction. Before attempting taxis, the patient should be made aware of potential surgery in the case of failure of the maneuver. Laparoscopy can be considered initially in the algorithm of treatment; however, most surgeons would prefer to approach incarcerated hernias with a conventional open approach.

If the blood supply to incarcerated contents becomes compromised, an incarcerated hernia becomes a strangulated hernia. These pose a significant risk to life because the strangulated contents are ischemic and may quickly lose viability. Clinical signs that indicate strangulation include fever, leukocytosis, and hemodynamic instability. The hernia bulge usually is very tender, warm, and may exhibit red discoloration. Taxis should not be applied to strangulated hernias as a potentially gangrenous portion of bowel may be reduced into the abdomen without being addressed. Before proceeding with surgery, the patient should be hemodynamically resuscitated with electrolytes, undergo nasogastric tube placement, and consideration should be given to early prophylactic IV antibiotics. Strangulated inguinal hernias should be approached using a conventional open technique. Once the hernia sac is encountered, efforts must be made to control it and prevent its inadvertent reduction into the abdominal cavity. The sac is opened to assess the viability of its contents. If viable, the contents are reduced intra-abdominally. If viability is in question, the hernia defect is expanded to alleviate the pressure on the intestinal vasculature and allow the intestine to be mobilized into the operative field. The bowel is then wrapped in warm wet towels and reassessed. Bowel viability can be assessed by bowel color, temperature, presence of peristalsis, and the Woods fluorescein test. Entrapped bowel within a femoral hernia may necessitate division of the inguinal ligament to provide for reduction and mobilization of the bowel. If the bowel is clearly ischemic and nonrecoverable, a decision must be made to resect the affected intestinal portion using the groin incision or perform a lower midline incision to increase exposure. Ideally, the ischemic portion is resected and viable portions are anastomosed to restore intestinal continuity. If the procedure becomes clean-contaminated through the resection of bowel, or if the intestine has been significantly compromised, repair of the hernia should proceed without the use of prosthetics, for fear of contamination and infection of the mesh.

Not uncommonly, an incarcerated or strangulated inguinal hernia may reduce with the administration of general anesthesia. A suspected strangulated hernia sac that reduces inadvertently during anesthesia induction, or before visual inspection by the surgeon, usually necessitates the conversion of the procedure to a laparotomy or laparoscopy to fully assess the bowel for viability. The consequences of a retained portion of ischemic bowel may lead to dire consequences for the patient's life.

Rarely, a surgeon will discover that upon entering the inguinal canal during emergent hernia treatment that no inguinal hernia exists. In these situations, strong consideration should be given to the presence of a femoral hernia. The femoral canal, located inferior to the medial inguinal ligament, is assessed for presence of an incarcerated or strangulated hernia.

Elective

The most recent paradigm shift to affect general surgery has been the adoption of laparoscopic surgery. Nearly every abdominal procedure that was commonly performed using a long abdominal incision has been supplanted with a laparoscopic variation. As with the introduction of any new technology, debates have ensued challenging the benefits of laparoscopic surgery vs. open surgery. In regard to laparoscopic inguinal hernia repair, the controversy has endured. Despite numerous data attesting to the success of laparoscopic inguinal hernia repair, general surgeons continue to question the most appropriate approach to primary unilateral inguinal hernias, whether it should be by conventional open or laparoscopic approach. The benefits of laparoscopic inguinal hernia repair for bilateral and recurrent hernias are superior to open approaches. A detailed review of the literature suggests that laparoscopic repair of primary unilateral inguinal hernias can reproduce equivalent recurrence rates demonstrated by open, tension-free repairs, and furthermore, result in less postoperative pain, reduced recovery time, and faster return to normal activities (Table 37-7). The laparoscopic technique relies on advanced instrumentation and expertise, and has the potential for intra-abdominal complications not otherwise seen with the conventional open approach. The selection of the operative approach is therefore predicated on a number of factors.

Table 37-7 Randomized Controlled Trials Comparing Open Tension-Free Hernia Repair to Laparoscopic Hernia Repair												
Study	Intervention	Y	No. of Pts.	No. of Hernias	Follow-Up	Complications	Analgesic Use	Pain Score	Recovery	Return to Work	Quality of Life	Comments
Lau et al ⁴⁶	TEP vs. TFR	2005	200	—	1 wk, 1 y	NS	NE	Yes	Yes	Yes	NE	Decreased chronic pain in the TEP

												group

Payne et al ⁹⁷	TAPP vs. TFR	1994	100	100	1 wk, ?	—	Yes	—	Yes	Yes	NE	

GPRVS = giant prosthetic reinforcement of the visceral sac; MRC = Medical Research Council; NE = not evaluated; NS = no significant difference; P&P = plug and patch; TAPP = transabdominal extraperitoneal repair; TEP = totally extraperitoneal repair; TFR = tension-free repair.

Most surgeons would agree that the laparoscopic approach to bilateral or recurrent inguinal hernias is superior to that of the conventional open approach.³⁸ In regard to the treatment of recurrent hernias, the posterior approach afforded by laparoscopic surgery allows the surgeon to circumvent the previously scarred tissue resulting from the initial open approach. In effect, the surgeon is able to operate in virgin tissue planes, thereby greatly lessening the arduousness of the procedure. Likewise, bilateral inguinal hernias can be treated using the same number of incisions and trocars as a unilateral inguinal hernia, in contrast to the open anterior approach, which requires two separate groin incisions. Lastly, laparoscopic repair can be used concurrently during unrelated abdominal procedures such as laparoscopic prostatectomy.^{39,40}

Nonetheless, there are several contraindications to the laparoscopic technique that must be taken into consideration. Because laparoscopy must be performed using general anesthesia, the patient must be able to hemodynamically tolerate both general anesthesia

and the effects of pneumoperitoneum. As well, previous lower abdominal surgery, such as prostatectomy, or lower midline incisions for other abdominal procedures, are a relative contraindication to a laparoscopic approach secondary to the presence of scarred tissue in the preperitoneal space.

The successful outcomes of a hernia operation must be balanced against the potential adverse events of that procedure when choosing the most appropriate approach. Success can be measured by examining recurrence rates, level of postoperative pain, and return to normal activities. Outcomes of laparoscopic inguinal hernia repair can be compared against conventional open techniques using these outcome measures.

The greatest reduction in hernia recurrence rates has been accomplished through the use of the tension-free repair championed by Lichtenstein.⁴¹ Similarly, when laparoscopic inguinal hernia repair is compared to open tissue repairs, there are significantly improved rates of recurrence, postoperative pain, and return to normal activities.⁴² Detractors of the minimally invasive approach often cite studies that described the early experience of the laparoscopic technique and therefore demonstrated variable outcomes. In one such study, a significantly higher recurrence rate (12.5%) was seen in the TAPP group vs. 1.9% in the giant prosthetic reinforcement of the visceral sac group.⁴³ The authors described concerns about the learning curve associated with mastering the laparoscopic technique, but more importantly, the study was limited by its use of TAPP, which did not allow adequate coverage of mesh medially and therefore may have predisposed the patients to increased recurrence. Secondly, the mesh was not anchored, thereby allowing migration. As the laparoscopic techniques have undergone refinement and experience with them has increased, the multitude of randomized controlled trials comparing laparoscopic hernia repair with tension-free repairs have concluded similar recurrence rates exist between the two procedures. In a study of 168 patients randomized to either TEP or Lichtenstein repair, two recurrences were identified on physical examination at 1 year in the TEP group. Although no recurrences were identified in those treated with the open tension-free repair, the results were not statistically significant. In a later study, the 5-year recurrence rates of the same group of patients was examined. Overall, both the open and laparoscopic group demonstrated good long-term results with a low rate of recurrence (three recurrences in the TEP group and four in the open group).^{44,45} Similarly, a study of 200 male patients randomized to either ambulatory TEP or Lichtenstein repair demonstrated no recurrences in either group at 1-year follow-up.⁴⁶

The controversies associated with laparoscopic inguinal hernia repair were reignited in 2004 with the publication of a randomized controlled trial performed by the VA Cooperative Study. A total of 1983 patients underwent either a laparoscopic (TAPP or TEP) or open (Lichtenstein tension-free) operation. One of the most significant findings was a significantly increased recurrence rate of primary unilateral hernias at 2 years within the laparoscopic group vs. the open group (10.1% vs. 4.9%).⁴⁷ In addition, the overall complication rate was higher in the laparoscopic group vs. open (39% vs. 33.4%). The complications within the laparoscopic group were not subdivided according to whether a TAPP or TEP was performed. A larger proportion of intraoperative complications also were noted within the laparoscopic group, namely those related to general anesthesia and vascular injury. The laparoscopic group was found to have less pain on the operative day and 2 weeks later, as well as an earlier return to normal activities. A post-hoc evaluation of the surgeons' self-reported experience compared to recurrence rates demonstrated a statistically significant reduced recurrence rate for those that had performed >250 laparoscopic procedures. The complication rate was not included in this post-hoc evaluation. A review of the overall literature on the subject of laparoscopic vs. open hernia repair does conclude that both procedures are equivalent in their recurrence rates.⁴⁸ Much of the data, however, originates from highly specialized surgery centers and may not have widespread application to community hospital settings.

One of the greatest benefits of the tension-free repair has been the ease with which optimal outcomes can be reproduced by a wide array of surgeon experience and trainee level. The success of certain tissue repairs such as the Shouldice technique relies on the number of cases the surgeon has performed and the degree of specialization of the surgery center. With increasing experience, the recurrence rate for Shouldice repairs decreased from 9.4% to 2.5% after the performance of six procedures.⁴⁹ The VA cooperative study suggested that proficiency in laparoscopic inguinal hernia repair is achieved following completion of 250 procedures; however, much lower case volumes necessary to master the technique have been reported. One of the main edicts of a successful hernia repair is

proficient knowledge of inguinal anatomy. Lal and colleagues proposed studying the posterior groin anatomy through the performance of open preperitoneal repair (Stoppa technique). After the performance of five cases, the remainder of the 61 patients were approached using a TEP technique. The first five laparoscopic inguinal hernia repairs resulted in a conversion to open Stoppa repair, with an additional conversion later in the study. Of the 50 laparoscopic inguinal hernia repairs that were completed successfully, no recurrences were identified in up to 2-year follow-up.⁵⁰ Retrospective reassessment of one group's 1700 TAPP procedures indicated that following the completion of 100 procedures, the recurrence rate decreased from 9 to 2.9%. Coinciding with this threshold of cases, the surgeons also adopted use of a much larger mesh.⁵¹ Many would agree that routine use of laparoscopy is necessary to achieve and maintain optimal results. The training necessary to reach this level of expertise should be attained through a dedicated fellowship, specialized surgery center, or through repetition of the procedure.

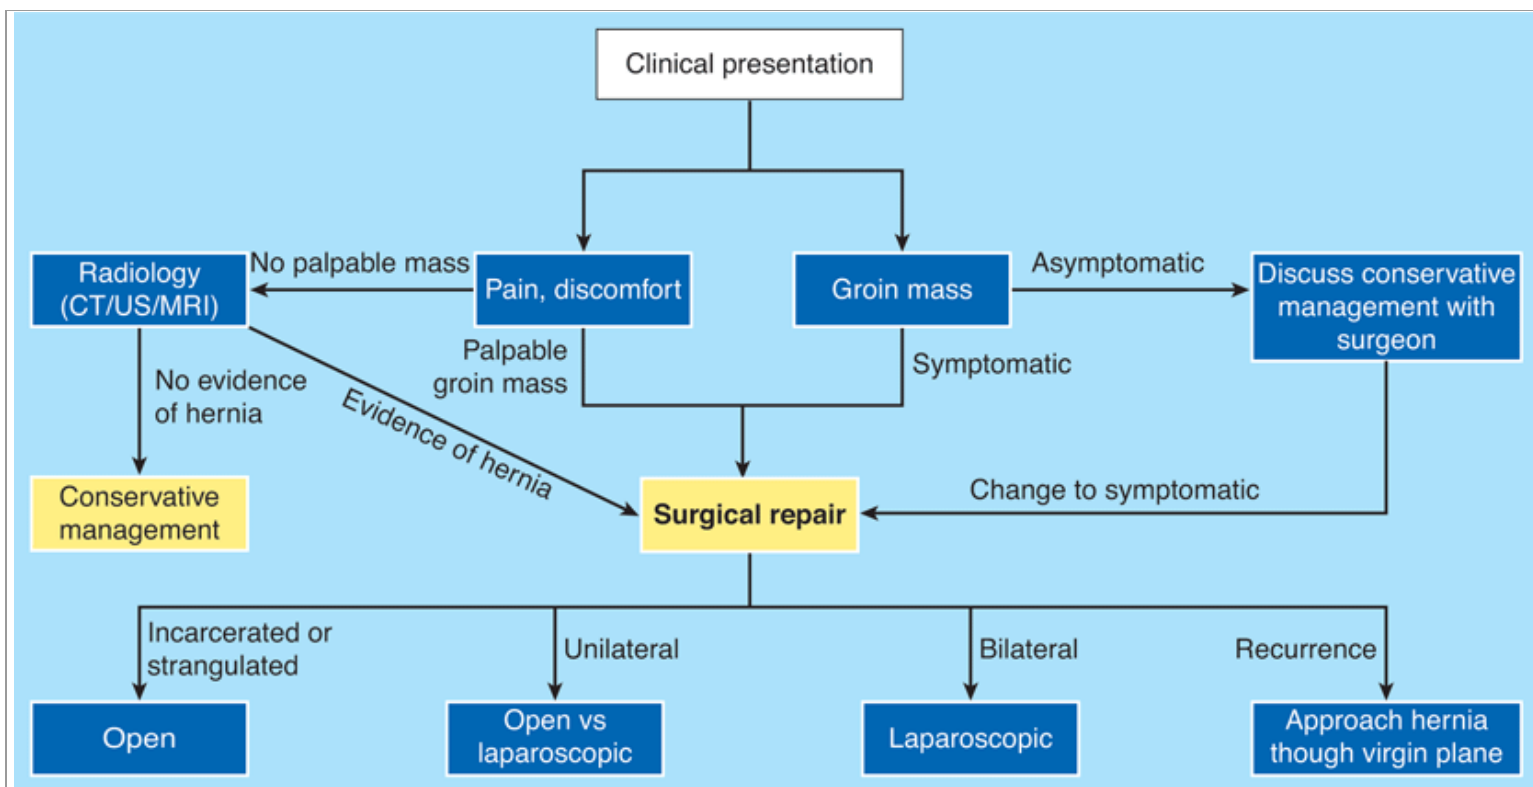

In addition to recurrence rates, success of an inguinal hernia repair can be measured through degree of postoperative pain and return to normal activities. Although the VA Cooperative study described significantly less short-term postoperative pain in the laparoscopic group, the pain scores were equivalent between the open and laparoscopic group at 3 months. Nevertheless, a number of studies have demonstrated a significantly decreased incidence of chronic pain following laparoscopic repair. Overall, the incidence of chronic pain was approximately 11% in a pooled proportion meta-analysis. In randomized controlled trials comparing open to laparoscopic inguinal hernia repair, the presence of chronic pain was increased in the open cohorts.⁵² Possible explanations for the difference may pertain to mode of mesh fixation. In open tension-free repairs, an extensive mesh fixation is necessary, including placement of sutures into the periosteum of the pubic symphysis. The problem of entrapment of the lateral cutaneous nerve of the thigh or the femoral branch of the genitofemoral nerve in laparoscopic procedures can be minimized by placement of sutures or tacks above the iliopectic tract.

Due to various socioeconomic and compensation factors, return to work has been an unreliable variable to assess success of inguinal hernia repair. Convalescence, which examines a patient's return to normal activities, has provided more sound evidence regarding recovery. In a systemic review of randomized controlled trials, the EU Hernia Trialists Collaboration reported a quicker return to various activities in the laparoscopic group in 24 trials and equal to the open group in one trial. Two trials showed a slower return to normal activity.⁵³ In the Cochrane Database of Systemic Reviews, all trials with said data demonstrated a faster return to normal activities in the laparoscopically treated group. This amounted to an absolute difference of 7 days shorter than in the open inguinal hernia repair group and was not limited to whether a TAPP or TEP was performed.⁴² Due to the need for specialized instrumentation and longer operative times, the laparoscopic approach does entail more costs. However, considering the more rapid recovery and reduced postoperative pain, the potential financial benefit to society in the long-term may outweigh these deficiencies.

A number of effective operative therapies exist in the treatment of inguinal hernias. To attain and maintain consistent, successful outcomes, the general surgeon must have a proficient understanding of groin anatomy and be mindful of surgical principles. The application of prosthetics to effect a tension-free repair created an operation that was simple, effective, and reproducible across a range of operative experience, and reduced recurrence rates to a much lower level. Further advances in hernia treatment were part of the laparoscopic revolution, which has improved postoperative pain and shortened recovery time. Although laparoscopic repairs require more extensive training and equipment than open repairs, significant benefits can be imparted to the patient. Despite the controversies associated with laparoscopic inguinal hernia repair for primary unilateral inguinal hernias, the general surgeon must not only be cognizant, but also able to perform a variety of inguinal hernia repairs. By having more than one approach in one's armamentarium, the surgeon has the ability to choose the appropriate procedure for the problem at hand (Fig. 37-33).

RESULTS

Traditionally, the most important measure of success was the recurrence rate of the hernia, although newer measures focus on quality of life and return to normal activities. A repair that results in an asymptomatic recurrence may not be as clinically significant as a repair that imparts a significant amount of chronic pain, yet does not lead to recurrence. Recurrence rates of tissue-based repairs vary according to procedure; however, large-scale analyses continue to confirm the Shouldice repair as the most superior. Surgeons who perform a large volume of the Shouldice repair are able to demonstrate recurrence rates around 1%.⁵⁴ In less experienced hands, such low recurrence rates are not demonstrated, yet overall, recurrence rates for the Shouldice repair are consistently lower than those of the Bassini or McVay repair. Other comparative studies have demonstrated that the Shouldice repair, even with a recurrence rate near 6%, is superior to the Bassini repair (8.6% recurrence rate) and McVay repair (11.2%).⁵⁵ The introduction of the Lichtenstein tension-free repair radically reduced recurrence rates to a consistently low level. In a multi-institutional series, 3019 inguinal hernias were repaired using the Lichtenstein technique, with an overall recurrence rate of 0.2%.⁵⁶ Reports by other surgeons have confirmed the low recurrence rates, namely a 0.5% recurrence rate in 3175 patients with up to 5-year follow-up. Consistently low, easily reproducible recurrence rates eventually led to the widespread acceptance of the tension-free repair as the gold standard for open anterior approaches.⁵⁷ Discussion of recurrence rates for laparoscopic approaches is discussed in the Elective section of this chapter.

Common causes of hernia recurrence postrepair include patient, technical, and tissue factors. Patient factors that affect tissue healing include malnutrition, immunosuppression, diabetes, steroid use, and smoking. Technical factors include mesh size, prosthesis fixation, and technical proficiency of the surgeon. Tissue factors include wound infection, tissue ischemia, and increased tension within the surgical repair. Most recurrences are of the same type as the original hernia. A recurrence generally will present in a similar manner to the primary presentation of the inguinal hernia. The patient may notice the reappearance of a bulge or mass. Differential diagnosis of such a clinical presentation includes an exaggerated cough impulse, strength deficiency of the external oblique aponeurosis, persistent presence of a cord lipoma, or seroma. The lack of a bulge or mass does not exclude the possibility of a recurrence. In these cases,

patients usually present with pain or pressure symptoms. It is important to delineate whether the pain is related to a recurrence or is related to a postherniorrhaphy pain syndrome because the treatment strategy is different. As with primary inguinal hernias, ambiguous physical findings can be further investigated through directed use of radiologic modalities such as ultrasound, CT, or MRI. The development of anterior and preperitoneal approaches to inguinal hernia repair has resulted in more effective treatment of recurrences. Before the introduction of laparoscopic or preperitoneal repairs, recurrence of open anterior approaches were dealt with in the same approach as the original operation. Recurrence rates of the second operation were high because dissection in scarred tissue does not allow for facile identification of the anatomic structures of the inguinal canal or the hernia recurrence.⁵⁸ Current teaching dictates that recurrent inguinal hernias should be approached via a virgin plane. That is, if the primary operation was performed using an anterior open approach, the second operation should be performed using a posterior peritoneal or laparoscopic procedure. Likewise, failed preperitoneal approaches are approached using an open anterior repair.

Difficulty arises when all approaches have been exhausted in successive repairs of the recurrent hernia. Re-entry into either space will be met with significant scarred tissue; therefore, surgeons will often approach these uncommon situations using techniques with which they are most comfortable. An advantage may be gained by using the laparoscopic approach because site of hernia recurrence can be easily visualized from the intra-abdominal perspective.⁵⁹ The hernia defect can be approached by opening peritoneum in a previously unscarred area and progressing the dissection into adhered tissue. A decision must be made whether to attempt to remove the original prosthesis or leave it in place following hernia sac dissection. Extensive dissection of the original prosthesis may result in significant injury to the cord structures, bladder, vessels, and nerves in the vicinity. If the mesh is left in place, a second mesh may be placed as a new layer, ensuring adequate overlap of the pubic tubercle and myopectineal orifice. Oftentimes, creation of the peritoneal flap may cause it to shred and prevent it from adequately separating the new prosthesis from abdominal viscera. These situations may call for the creation of an omental flap. As well, the surgeon may choose to perform an IPOM with appropriate mesh, which effectively covers the defect and does not require peritoneal coverage, although one has to be cognizant of the increased recurrence rates associated with IPOM.

Quality of life is difficult to measure unless the study uses a validated scale. A patient's personal factors, socioeconomic status, occupation, and expectations are just some of the variables that make interpretation of quality of life measures more complicated. Quality of life, however, is invariably linked to the presence of chronic pain. Specific pain syndromes are discussed below under Pain; however, each can impact a patient's life well beyond the local effects of nerve damage. The use of pain scales such as the McGill Pain Questionnaire and University of California and San Francisco Pain Service patient questionnaire can be correlated against the short form 36 questionnaire to identify the impact of pain on functioning. In a study of 226 patients, chronic pain was found to impact social and recreational activities, as well as daily routine activities.⁶⁰ Return to work is more difficult to assess owing to varying patient motivations, occupations, secondary gain, and compensation issues. This is an extremely important issue because patients often will inquire when they can return to work. Advancements in perioperative management in anesthesia and surgical technique have dramatically reduced convalescence. The majority of hernia operations are performed on an outpatient basis, yet the average time to return to work still averages between 1 and 3 weeks.⁶¹ Studies have attempted to compare hernia repair techniques; however, the factors responsible for return to work are multifactorial. Overall, patients with physically demanding occupations generally return to work beyond the average.

COMPLICATIONS

The overall risk of complications of inguinal hernia repair is low. The introduction of laparoscopic surgery to inguinal hernia repair has resulted in approach-specific complications, in addition to the general procedure-specific complications related to the repair itself. Complications common to various approaches include pain, injury to the spermatic cord and testes, wound infection, seroma, hematoma, bladder injury, osteitis pubis, and urinary retention (Table 37-8).

Cardiovascular and respiratory insufficiency

Pain

Postoperative pain is an extremely important consideration in that many primary hernias present without pain as a symptom. Postoperative pain can be subclassified into short term and chronic. Comparisons of short-term postoperative pain between open and laparoscopic procedures are discussed in the Elective section. Historically, either pain was not included in the measure of success of a repair or was difficult to assess. Recent evidence suggests that a majority of patients may indeed experience chronic pain. Chronic postherniorrhaphy pain lasts beyond 3 months and results secondary to nerve entrapment, scar tissue, or mesh adherence (Table 37-9). Identification of a specific nerve that sustained injury may be difficult to determine due to overlapping distributions. Regardless of the etiology or specific nerve, patients will usually present with common symptoms such as sharp localized pains, paresthesias, or numbness over the cutaneous distribution of the affected nerve. The ilioinguinal nerve is at considerable risk to injury during closure of the external oblique aponeurosis. The ilioinguinal, along with the iliohypogastric nerve, may also become entrapped within the mesh in tension-free repairs. Laparoscopically, the lateral femoral cutaneous nerve and the genital and femoral branches of the genitofemoral nerve are at risk when placing lateral fixation tacks below the iliopubic tract, yet the lateral femoral cutaneous nerve may too be affected by mesh entrapment. Such injury to the lateral femoral cutaneous nerve will lead to meralgia paresthetica, a "pins and needles" sensation over the lateral aspect of the thigh. It also may be associated with a specific paresthesia known as *formication*, a sensation of insects crawling on or under the skin. Routine nerve division has been advocated by some, namely within the Shouldice repair, while others continue to stress the need for nerve identification and protection. The sequelae of nerve division, such as numbness of the cutaneous distribution, may be better tolerated than the effects of nerve entrapment, such as sharp chronic pains.

History of a previous herniorrhaphy

A better understanding of postherniorrhaphy pain syndromes can be gained by classifying the pain into one of three syndromes: somatic, visceral, and neuropathic. *Somatic pain* is the most frequently encountered and usually is secondary to damage to ligaments and muscles. Pain that results from these injuries usually is reproduced with exertion or movement of the abdominal wall. Visceral pain refers to pain experienced during a visceral function such as ejaculation and may result from injury to a sympathetic nerve plexus. *Neuropathic pain* is usually a localized sharp pain that may impart a sensation of burning or tearing and indicates direct nerve damage or entrapment. Neuropathic pains may present as early as in the recovery room, where patients may complain of significant sharp pains. Somatic pains are usually treated with rest, NSAIDs, and reassurance. Neuropathic pains also are amenable to NSAIDs, but there is also a role for nerve-directed injections of steroids and anesthetics. Failing conservative management, neurectomy may be undertaken. In a series of 100 patients, of which the majority of patients experienced chronic pain following inguinal hernia repair, neurectomy at the internal ring was undertaken. The nerves were approached using an open anterior approach and then divided proximally as they pierced the internal oblique muscle. Symptoms such as pain radiating into the thigh and genital areas improved in 72%, with only 3% of patients reporting no improvement in symptoms.⁶² More recently, neurectomies of nerves commonly injured in inguinal hernia repairs have been attempted laparoscopically. With the patient in a lateral position, with the affected side up, the quadratus lumborum muscle is traced to the spine, where the junction of L1–L2 is identified with the assistance of fluoroscopy. Superficial dissection of the quadratus lumborum muscle leads to the identification of the proximal portion of the ilioinguinal and iliohypogastric nerves, which are then divided.⁶³

Cord and Testes Injury

Injury to the spermatic cord and subsequently to the testicles is a very serious problem in the male patient. In the female, the round ligament, which occupies the inguinal canal, serves to maintain anteversion of the uterus. Injury to the artery of the round ligament or its division does not impart any clinically significant effects to the patient. The spermatic cord, on the other hand, is well vascularized and is prone to hematoma formation or ischemia with excessive handling. Male patients may experience a significant scrotal hematoma that results in a diffuse blue-black discoloration of the entire scrotum. These hematomas usually result from delayed bleeding from vascular cord structures and are self-limited. Patients should be reassured and counseled to aid resolution using intermittent warm and cold compresses.

More extensive injury to cord structures may result in ischemic orchitis or testicular atrophy. Ischemic orchitis usually presents within the first week following inguinal hernia repair. The patient may present with a low-grade fever, but more commonly with an enlarged,

indurated, and painful testicle. This complication occurs in <1% of all herniorrhaphies, but increases in the reoperations for recurrent inguinal hernias.⁶⁴ Ischemic orchitis is likely caused by injury to the pampiniform plexus, not the testicular artery. Densely adherent or large hernia sacs that require extensive dissection may lead to injury of the pampiniform plexus. Reassurance, NSAIDs, and comfort measures are enacted to allow self-limited resolution of this complication. Long-term effects of ischemic orchitis are rare. Ultrasound will demonstrate the reduction of testicular blood flow to help determine whether it is testicular ischemia or necrosis. Emergent orchiectomy is rarely necessary except in the case of necrosis. Injury to the testicular artery also may lead to testicular atrophy, which is manifest over a protracted period. Again, testicular atrophy is not a surgical emergency; however, the long-term implications to the patient are significant and irreversible. Similar to ischemic orchitis, surgery for hernia recurrence leads to increased rates of testicular atrophy. Injury to cord structures is minimized by using techniques of minimal handling of the spermatic cord and proximal ligation of large hernia sacs. Controversy exists as to whether the open distal hernia sac predisposes the patient to development of a hydrocele. Should a hydrocele result post-inguinal hernia repair, treatment is identical to primary hydroceles. Another less significant testicular complication is ptosis, secondary to the division of cremasteric muscle fibers. This complication is routinely averted in the Shouldice technique, which incorporates routine division of the cremaster muscle, by fixing the medial stump of the cremaster to the pubic tubercle.

In addition to vascular structures of the cord, complications include injury to the vas deferens, which may lead to infertility. Although transection of the vas deferens is rare, crushing or scarring of the vas deferens remains a possibility. In open inguinal hernia repairs, the vas deferens is isolated along with the cord structures using digital manipulation. The vas deferens is more likely grasped with instrumentation in the course of a laparoscopic approach and may result in a crushing injury. Transections of the vas deferens should be addressed with a urologic consult and possible early reanastomosis. Only in the case of a concurrent prostatectomy is injury to the vas deferens a minor consideration because it is otherwise divided in the course of that operation. Chronic scarring may lead to vas deferens obstruction, resulting in decreased fertility rates and a dysejaculation syndrome. The symptoms of pain and burning during ejaculation are usually self-limited and should be differentiated from other causes such as sexually transmitted diseases. Controversy exists as to whether placement of a prosthesis leads to decreased fertility rates because this complication is seen in both tension-free and tissue-based repairs.

Wound Infection

Primary inguinal hernias, which are considered clean cases, are subject to a low wound infection rate, usually 1 to 2%. Arguments have been made for the use of prophylactic antibiotics, especially in the era of the mesh repair. Owing to the large number of inguinal hernia repairs that are performed, some authors suggest that there is a significant lowering of the wound infection rate; however, it is not clinically significant. Large studies have compared wound infection rates with and without prophylactic antibiotics, with no apparent difference identified.^{65,66} The goal of a recent Cochrane Database review of 6705 patients was to demonstrate the effectiveness of antibiotic prophylaxis in reducing postoperative wound infection rates in elective open inguinal hernia repair. The subgroup of patients treated with a mesh prosthesis experienced wound infection rates of 1.4 and 2.9% with and without prophylactic antibiotics, respectively. The authors cautioned that although the systematic review was not able to universally recommend the use of prophylactic antibiotics, they were also not against recommending them in situations where wound infection rates were increased.⁶⁷ Initial management of a wound infection is through use of antibiotics. Failure of medicinal treatment may necessitate incision and drainage of the wound. Polypropylene mesh is rarely removed and usually can be salvaged using conservative treatment.

Seroma

A seroma is a loculated fluid collection more commonly seen following prosthetic repairs, although seromas may result following repair of large hernias. It is perceived that the body attempts to encapsulate the foreign body through a normal reaction. In the case of large hernia sacs, the potential space that remains in the defect may fill with physiologic fluid postoperatively. Seromas will usually develop within the first week and may cause concern for the patient, who may perceive it as an early recurrence. Physical examination of the seroma will demonstrate a compressible bulge in the groin or scrotum. Seromas may be painful but are more likely uncomfortable.

Aspiration of the seroma should be avoided unless it persists over a prolonged period because infection may be secondarily introduced. Warm compression may aid in resolution.

Hematoma

A hematoma may present as a localized collection or diffuse bruising over the operative site. In addition to scrotal hematomas, other sites of hematoma formation include the wound, retroperitoneum, and rectus sheath hematomas. Hematoma at the latter two sites is more commonly seen following laparoscopic repair; however, injury to the corona mortis or iliac vessels regardless of approach may present as a progressively expanding hematoma. Expansion of blood within the peritoneum or preperitoneal space is not tamponaded and may lead to a significant blood loss that is not readily apparent on physical examination. Large hematomas in the abdomen will present with pain and possibly ileus. The management of wound hematomas is expectant, yet they may rarely need to be opened for decompression.

Bladder Injury

Bladder injury may occur in open anterior inguinal hernia repairs but is a more important consideration in laparoscopic surgery. Instances where the bladder may be encountered in open surgery include sliding hernias including the bladder and previous lower abdominal surgeries such as prostate operations. Treatment involves primary closure in multiple layers with Foley catheter decompression of the bladder for 1 to 2 weeks. A confirmatory cystogram may be performed before catheter removal to confirm healing of the injury.

Osteitis Pubis

The placement of sutures or tacks within the periosteum of the pubic bone is generally avoided to prevent osteitis pubis, which is characterized by an inflammation of the pubic symphysis. Currently, the majority of cases of osteitis pubis are seen in athletes that perform repetitive kicking, jumping, or running. Outside the setting of postherniorrhaphy pubic pain, the condition can be categorized into either overload or biomechanical deficiency. Overload situations occur most commonly when an athlete exercises on hard concrete or uneven ground. Biomechanical deficiencies include muscular imbalances or gait deficiencies. The common pathogenesis involves excessive muscular physical strain on the bone that incites a lytic response. Patients usually will present with pain over the medial groin or symphysis, which is reproduced with adduction of the thigh. Diagnosis can be confirmed with a bone scan, but CT scan or MRI is usually used to rule out a possible hernia recurrence. Treatment is conservative and is aimed at symptom control. It consists of rest, ice, NSAIDs, physical therapy, and possibly, local corticosteroid injection. Rarely is surgery necessary to explore the pubic symphysis and remove a suture or tack as a possible cause of inflammation. In these cases, consultation with orthopedic surgery should be enacted for expertise with bone resection and curettage. Conservative management should be exhausted before the suggestion of an exploratory surgery. Regardless of treatment, the condition often takes a protracted course and may require 6 months to resolve.⁶⁸

Urinary Retention

A common short-term complication of routine herniorrhaphy is urinary retention. A number of factors are responsible, the most common being choice of anesthesia. In a group of 880 patients undergoing inguinal hernia repair using only local anesthesia, the rate of urinary retention was 0.2%. In contrast, a similar group of 200 patients undergoing inguinal hernia repair using general or spinal anesthesia were found to have a 13% urinary retention rate.⁶⁹ Whereas open inguinal hernia repairs can be performed using either anesthesia, laparoscopic surgeries are dependent on general anesthesia. Other contributing factors include postoperative pain, narcotic analgesia, and bladder distention. The authors prefer to limit IV hydration, avoid prophylactic catheterization, and administer prophylactic tamsulosin. Initial treatment of urinary retention requires decompression of the bladder with short-term catheterization. Patients will generally require an overnight admission and trial of normal voiding before discharge. Failure to void normally requires reinsertion of the catheter for up to a week. Chronic requirement of a urinary catheter is rare, although prolonged catheterization is seen with advancing age.

Laparoscopic Complications

General complications of laparoscopic surgery include hypercapnia, gas embolism, pneumothorax, and paralytic ileus. In general, postoperative ileus is reduced in laparoscopic vs. open procedures. However, when considering inguinal hernia repair, the incidence of ileus is increased using the laparoscopic approach. The cause is unknown but may be secondary to the temperature of the insufflated gas or abdominal distention. Ileus also can present with complications such as a large rectus sheath hematoma or considerable pain. Treatment may require the use of a nasogastric tube. Unique laparoscopic complications of hernia repair include injuries to intra-abdominal viscera, vascular injuries, and bowel obstruction.

VISCERAL AND VASCULAR INJURY

The risk of visceral injury in inguinal hernia repairs was limited to hernia emergencies and sliding hernias when inguinal hernias were approached with an open anterior approach. The advent of laparoscopic inguinal hernia repair, coupled with a steep learning curve, initially increased the rate of visceral injury significantly. Increased experience and training have decreased the rates. Furthermore, by using the TEP approach, the intra-abdominal environment is avoided, and subsequently, visceral injury is reduced. Viscera at risk include small and large bowel as well as bladder. Previous lower abdominal surgeries may predispose to adhesions and thereby increase the risk of visceral injuries. A past surgical history including these types of procedures is a relative contraindication to laparoscopic inguinal hernia repair. Bowel injuries also result during the course of trocar placement. Strategies to reduce bowel injuries secondary to trocar placement include using an open Hasson technique when placing the umbilical trocar and visualization of trocars as they enter the intra-abdominal space. One of the main arguments against the use of laparoscopy for inguinal hernia repair is the need to cross into the intra-abdominal area, which otherwise would not occur in open repairs. Bowel injury also may occur secondary to arcing of electrocautery and instrument injury outside of the visual field. Because the laparoscopic view is limited, bowel injuries may present as missed injuries, which are associated with an increased mortality. If a bowel injury is suspected, the entire bowel should be inspected, possibly necessitating a conversion to open if repair is required.

Bladder injuries are less common than visceral injuries and are usually associated with a distended bladder or involvement in peritoneal adhesions. Suprapubic trocar placement in a TEP may also lead to bladder injury, but can be avoided using appropriate surgical principles. Rarely, a patent urachus will be divided during the course of peritoneal flap mobilization in a TAPP. Patient presentation is usually delayed with urine extravasation through a trocar site or peritonitis. As with bladder injuries encountered in open surgery, cystotomies must be repaired in several layers with prolonged catheterization. Preoperative prophylactic catheterization or patient-directed bladder emptying may be performed for laparoscopic cases, which decompresses the bladder and therefore places it away from contiguous structures such as Cooper's ligament and the spermatic cord. Controversy exists regarding prophylactic catheterization as the rare case of bladder injury may be outweighed by urinary retention and other urinary tract complications. Incomplete voiding secondary to benign prostatic hypertrophy may, however, necessitate catheterization.

An equally critical complication is vascular injury. Open surgery is not without vascular complications; however, the laparoscopic approach includes additional means for vascular injury such as trocar placement and dissection. Misplaced sutures in a tissue-based or tension-free repair may lead to iliac or femoral vessel injury. Laparoscopically, the most commonly injured vessels include the inferior epigastric and external iliac. Immediately inferior to the spermatic cord, the external iliac vessels can be easily identified with minimal dissection. During mesh fixation, the vessels may be difficult to visualize and become injured through placement of a tack or staple. Less likely, an inadvertent instrument injury during dissection can occur, leading to oozing or frank extravasation of blood. Inferior epigastric vessels may undergo injury during trocar placement in a TAPP. The lateral position of the two accessory trocars may coincide with the course of the inferior epigastrics. Identification of the vessels by direct visualization or transillumination should be performed to minimize the risk. Oftentimes, such an injury may go unnoticed as the trocar will tamponade bleeding. However, once the trocar is removed, a significant amount of blood can be lost. An indication of a significant vessel injury may include dripping of blood along the length of the trocar. Initial management of vascular injuries requires local compression. Definitive treatment may require conversion to open surgery, especially if a major vascular injury has occurred. Otherwise, the injury may be treated by laparoscopic clipping and division, depending

on the skill of the surgeon. Inferior epigastric vessels may also be ligated with use of a percutaneous suture passer. Smaller vessels within the operative field usually respond to direct compression. The surgeon should be wary of the tamponading effects of pneumoperitoneum. If the pressure of the insufflated carbon dioxide is greater than the pressure within the vessel, bleeding will not be manifest until pneumoperitoneum is released. Such a situation is often seen with rectus sheath hematomas, where injury to the inferior epigastric vein results in a delayed presentation. Patients will present with significant diffuse pain and possible hypotension. Less severe vascular complications include trocar site and rectus sheath hematoma. Similar to open repairs, extensive dissection or injury to small vessels within the groin will lead to operative site hematomas that may extend into the scrotum.

BOWEL OBSTRUCTION

Early in the course of development of the laparoscopic technique, an uncommon complication of bowel obstruction was seen, which is otherwise not evidenced in open inguinal hernia repairs. Bowel obstructions more commonly occur with TAPP, following an inadequate peritoneal closure, allowing bowel to herniate through a peritoneal defect. The theoretical advantage to TEP is the avoidance of the peritoneal space, although a missed peritoneal rent may rarely lead to a bowel obstruction. Similar to visceral injuries, bowel obstructions serve as another reason detractors of the laparoscopic approach cite to perform open inguinal hernia repairs. A second cause of bowel obstruction following laparoscopic inguinal hernia repair is umbilical trocar site herniation. The use of only a single 10- to 12-mm trocar has greatly reduced possible trocar site herniation, in addition to increased attention paid to closure of this fascial defect. The possibility of trocar site hernias using 5-mm trocars is greatly reduced. As well, the umbilical trocar in a TEP remains within the rectus sheath, which serves to protect against future herniation. The least common cause of bowel obstruction remains adherence to the implanted prosthesis. Again, incomplete peritoneal closure exposes the highly adherent mesh to intra-abdominal contents, predisposing to adhesions, obstructions, and possibly erosion.

PROSTHESIS CONSIDERATIONS

The purpose of a prosthetic in hernia repairs is to reconstitute strength to the weakened structures. Before the introduction of a mesh prosthesis for clinical use, tissue-based repairs were considered the gold standard. Refinements in mesh technology resulted in widespread application of mesh to tension-free anterior repairs, as well as preperitoneal repairs. Results of mesh-based hernia repairs have consistently been superior to that of tissue-based repairs, leading them to become the gold standard. Concerns related to mesh include rejection, carcinogenesis, and host reaction; however, the widespread implementation of mesh in hernia repairs has demonstrated that prosthesis use is safe, in addition to its effectiveness. Early hernia repairs, both open tension-free and preperitoneal procedures, suffered increased recurrence rates due to too small a prosthesis. Mesh prosthetics produced commercially now account for this by providing a larger size that may be trimmed if necessary. Controversy remains regarding the extent of mesh fixation necessary.

Mesh Choice

One of the most commonly used prosthetics in inguinal hernia repairs is polypropylene, first introduced by Usher in the 1950s. Since that time, numerous advances in mesh technology have led to a variety of prosthetics available for hernia repairs. These can be grouped according to their materials and subsequent bioreactivity, namely nonabsorbable, partially absorbable, and biologic. These factors alone do not account for the behavior of a mesh once it is implanted. Other considerations include its thickness, weight, architecture of fibers, and overall strength of the material. An ideal mesh should be easy to handle, provide adequate strength, be inert, resist contraction, avoid infection, place no restriction on patient function, and be simple and inexpensive to manufacture.⁷⁰ Current meshes have attempted to maximize on these ideals. Polypropylene is a synthetic nonabsorbable mesh that is hydrophobic, electrostatically neutral, and permanent. Common brand names include Marlex (Davol, Cranston, RI), Prolene (Ethicon, Somerville, NJ), and ProLite (Covidien, Norwalk, Conn). Differences between them include the filament size, pore size, and weight. Recent advancements have included change from a heavyweight mesh to a lightweight mesh, with larger pores that promote a host scarring response. The end result is theorized to be better incorporation of the prosthetic into native tissue, without the deleterious effects such as chronic pain or discomfort that may result in the inflammatory response to the mesh. Polyester mesh is available commercially as Parietex (Covidien) and Mersilene (Ethicon). It promotes an inflammatory response similar to polypropylene and exhibits similar contracture rates. Polyester mesh is also

woven and provides for transparency when fixing the mesh. Common to synthetic absorbable meshes is the concept of density, which combines fiber diameter, which relates to strength, and fiber number, which impacts pore size. This subdivides these materials into heavyweight and lightweight, depending on the extent of density. A healthy balance of density must be achieved for optimal results. Too heavy a density may lead to increased chronic pain whereas too lightweight of a mesh may lead to increased recurrences.

Polypropylene and polyester meshes are the most commonly used prosthetics in inguinal hernia repairs, although there is a limited role for expanded polytetrafluoroethylene, which is available as Gore-Tex (W.L. Gore and Associates, Flagstaff, Ariz). The mesh does not promote ingrowth into viscera and therefore makes it useful in IPOM or TAPP repairs where peritoneal closure is difficult. However, the lack of transparency makes fixation difficult. Compatibility of a synthetic nonabsorbable mesh with viscera may also be accomplished through the use of a coating agent. The coating is comprised of an absorbable or nonabsorbable layer that limits the inflammatory response on the side exposed to viscera, while maintaining the handling characteristics of the mesh. Absorbable coatings generally last beyond several months, allowing peritonealization to take place. A similar concept is the partially absorbable mesh, which combines a polypropylene mesh with an absorbable polymer. It is yet unclear whether an advantage is conferred to the patient by use of these materials. Biologic prosthetics do not have a role in routine herniorrhaphy at this time, their use being limited to contaminated fields. Choices include Surgisis (Cook Medical, Bloomington, Ind) and AlloDerm (LifeCell Corporation, Branchburg, NJ). Disadvantages to these materials include a decreased wound strength compared to native connective tissue and subsequently increased recurrence rates.⁷¹

In addition to mesh choice, there is the controversial issue of mesh fixation. Original descriptions of the plug and patch repair described no fixation of mesh in the anterior open approach. Mesh fixation in laparoscopic surgery is intended to prevent mesh migration and subsequent recurrence; however, the use of staples or tacks may also lead to chronic pain and injury to neurovascular structures. In a prospective randomized trial of fixation vs. no fixation in TEP repairs, a new pain was reported in 23% of patients where fixation was used. At the 6-month follow-up, no difference in recurrence was seen.⁷² Studies using preformed mesh have yielded similar results, the theory being that mesh that is already conformed to the preperitoneal space has less tendency to migrate.⁷³ Fixation without tacks or staples has also been attempted with generally positive results. In these studies, mesh fixation has been attempted with fibrin glue. Long-term follow-up (1 to 2 years) has demonstrated that patients in whom fibrin glue is used experience less chronic pain than and equivalent recurrence rates to those in whom tack fixation is used.^{74,75} Despite the encouraging, yet limited data concerning mesh fixation, general practice still involves the use of metal tack fixation of mesh in laparoscopic inguinal hernia repair. Technologic developments such as absorbable tacks may play a significant role in the future of mesh fixation.

SPORTS HERNIA

Groin pain may result from a number of conditions, including injuries to the spine, pelvis, abdomen, and genitourinary system. Despite a classical presentation, the absence of clinical findings makes the diagnosis of a hernia more dubious. Occult hernias such as these may, in fact, be a sports hernia, otherwise known as a *sportsman's hernia* or *athletic pubalgia*. They are commonly seen in athletes that perform repetitive kicking, twisting, or turning, as in hockey, soccer, and football, which results in a weakness or tearing of the posterior inguinal wall. A similar abrupt motion in a nonathlete also may lead to this condition. The hernia often is not identified until the time of surgical exploration, where a number of different anomalies may be visualized. These include tearing of the transversalis fascia or conjoined tendon, tearing of the internal oblique or avulsion of the internal oblique at the pubic tubercle, or tear of the external oblique aponeurosis or widened external ring. The lack of standardization in the literature makes analysis difficult because oftentimes groin pain of other origins is included in the discussion of sports hernias.

The presentation of a sports hernia may be acute, but more often, the deep groin pain presents in an insidious manner, gradually worsening with increasing activity. The pain is aggravated by movements and sudden increases in intra-abdominal pressure from coughing or sneezing. In the athlete, the pain is severe enough to limit optimal functioning during physical exertion. However, the physical examination will fail to identify a noticeable bulge or cough impulse. A dilated external ring may be palpable by a trained investigator, yet most patients will present with tenderness to palpation over the pubic bone and inguinal canal. Imaging generally fails to visualize a hernia or disruption of the inguinal canal but is useful to rule out differential diagnoses. A bone scan may be used to

confirm osteitis pubis but will not be able to confirm the diagnosis of a sports hernia.

Initial treatment of a sports hernia is conservative, which also allows time to rule out other possible conditions such as muscle strain or osteitis pubis. Conservative therapy consists of rest, NSAIDs, deep tissue massage, and physiotherapy. Should the pain return upon gradual return to normal activities after 6 to 8 weeks of conservative management, surgical exploration often is necessary. Groin exploration is performed in the same approach as an open anterior inguinal herniorrhaphy. This allows the surgeon to fully assess the internal and external oblique musculature and aponeuroses, inguinal rings, ligaments and tendons, and pubic tubercle. The most common finding is a deficiency of the floor of the inguinal canal, with a possible occult hernia. Reinforcement of the posterior wall can be performed in a tissue-based repair or using a laparoscopic preperitoneal mesh placement. Both techniques have yielded successful resolution of pain and return to physical activity. A deficiency of the laparoscopic method is the inability to assess the external oblique aponeurosis for any tears or distortions. Disruptions of the adductor tendon may also be considered with a concurrent tenotomy at time of the sports hernia repair.^{76,77} The lack of a classification system makes treatment choices more difficult in this challenging group of patients. Repair of the posterior floor by open or laparoscopic approach is currently an effective strategy, yet improper treatment in professional athletes may impact not only quality of life, but also occupation.

PEDIATRIC HERNIAS

The incidence of inguinal hernias in children is between 0.8 and 44%, with a 10-fold increased incidence in boys vs. girls. The incidence also is significantly increased in low-birth-weight and premature infants, secondary to a patent processus vaginalis (PPV) in the latter. The difference in timing of testicular descent results in closure of the left processus vaginalis before the right. Consequently, right-sided hernias are more common than left-sided hernias, with approximately 10% of hernias presenting as bilateral. Repair of indirect inguinal hernias happens to be one of the most commonly performed procedures in children.^{78,79} Diagnosis of a pediatric hernia is usually obvious to the clinician and supported by the parent's or caregiver's description. Physical examination by inspection alone will usually confirm the diagnosis. A Valsalva's maneuver is difficult to induce in infants, but the intra-abdominal pressure can be increased when crying. Differential diagnosis of a pediatric groin bulge commonly includes undescended testes, testicular mass, varicoceles, or hydroceles. Those hydroceles that present at birth do not necessarily increase the likelihood that a PPV is present and will usually resolve on their own. Conversely, hydroceles that present following birth may be more likely associated with a PPV that will not spontaneously close.⁸⁰

Unlike in adults, pediatric hernias must be treated emergently, even if they are asymptomatic, to prevent the risk of incarceration. The risk of incarceration has been estimated to be up to 20%, with a significantly increased rate of complications when an incarcerated hernia must undergo surgical treatment.⁸¹ Repairs are performed using an open approach using a groin incision over the internal ring. Once the inguinal canal is entered, the indirect hernia sac is identified, dissected, and ligated at the internal ring. A dilated internal ring can be repaired using the Marcy technique. With the cord structures retracted laterally, sutures are placed through the muscular and fascial layers constituting the inguinal ring. Mesh placement or floor reconstruction is unnecessary in uncomplicated indirect inguinal hernias as it may impart inflammatory changes in the vas deferens and testicles.⁸² The classic repair including high ligation of the sac results in recurrence rates of approximately 1.2%, wound infection rates of 1.2%, and testicular atrophy at a rate of 0.3%.⁸³ Classical management of pediatric hernias involved routine exploration of the contralateral side. In up to one third of patients, a contralateral hernia was identified; however, these are usually the processus vaginalis that, if left untreated, is unlikely to lead to a hernia. Routine exploration continued until the last decade when the risks and benefits of contralateral exploration were questioned. Currently, most pediatric surgeons treat only the obvious hernia and avoid routine exploration of the contralateral side. However, the controversy with this treatment strategy continues because the possibility of metachronous hernia formation has been estimated to be 7.2% following a large-scale retrospective review of the literature.⁸⁴ The advent of laparoscopy has provided for a compromise in the debate because routine contralateral exploration can be accomplished with minimal morbidity. Laparoscopy can be performed through the hernia sac or using a separate umbilical incision. A normal internal ring obviates the need for added exploration, whereas an obvious contralateral inguinal hernia requires treatment. The difficulty in choosing management arises when a PPV is demonstrated. The majority of these are

repaired, although only half of these are estimated to become clinically significant. Alternatively, the repair of a PPV reduces the incidence of metachronous hernia incarceration and the need for a second surgery in the future.⁸⁵ Another alternative includes ultrasound evaluation of the hernia and contralateral side, although the success of the imaging modality is heavily operator dependent.⁸⁶

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 38. Thyroid, Parathyroid, and Adrenal >

KEY POINTS

1. There has been a paradigm shift in the surgical management of Graves' disease with increased use of total or near-total thyroidectomy, rather than subtotal thyroidectomy.
2. Familial nonmedullary thyroid cancer is increasingly being recognized as a separate entity. Surgeons must be aware of the potential for false negative fine-needle aspiration biopsy in this setting.
3. Total thyroidectomy is the surgical treatment of choice for most thyroid cancers, provided complication rates are low.
4. The widespread use of positron emission tomography scanning for staging various malignancies and ultrasound for vascular screening is leading to an increased incidence of thyroid incidentalomas. Management should be based on assessment of the individual patient's risk following complete clinical and fine-needle aspiration biopsy evaluation.
5. Focused mini-incision parathyroidectomy, after appropriate localization, has become the procedure of choice for the treatment of sporadic primary hyperparathyroidism.
6. Parathyroidectomy has been shown to improve the classic and so-called *nonspecific symptoms* and metabolic complications of primary hyperparathyroidism.
7. Very high calcium and parathyroid hormone levels in a patient with primary hyperparathyroidism should alert the surgeon to the presence of a possible parathyroid carcinoma.
8. Subclinical Cushing's syndrome is characterized by subtle abnormalities in corticosteroid synthesis, and many of its manifestations appear to be treated by adrenalectomy.
9. Fine-needle aspiration biopsy has a very limited role in the evaluation of adrenal incidentalomas unless the patient has previously had a cancer and should only be performed after appropriate biochemical studies have been performed to rule out pheochromocytoma.
10. Adrenocortical cancer can be difficult to diagnose even on pathology examination so that continued follow-up of patients with resected seemingly benign tumors is advised.

THYROID

Historical Background

Goiters (from the Latin *guttur*, throat), defined as an enlargement of the thyroid, have been recognized since 2700 B.C. even though the thyroid gland was not documented as such until the Renaissance period. In 1619, Hieronymus Fabricius ab Aquapendente recognized that goiters arose from the thyroid gland. The term *thyroid gland* (Greek *thyreoeides*, shield-shaped) is, however, attributed to Thomas Wharton in his *Adenographia* (1656). In 1776, the thyroid was classified as a ductless gland by Albrecht von Haller and was thought to have numerous functions ranging from lubrication of the larynx to acting as a reservoir for blood to provide continuous flow to the brain, to beautifying women's necks. Burnt seaweed was considered to be the most effective treatment for goiters.

The first accounts of thyroid surgery for the treatment of goiters were given by Roger Frugardi in 1170. In response to failure of medical treatment, two setons were inserted at right angles into the goiter and tightened twice daily until the goiter separated. The open wound was treated with caustic powder and left to heal. However, thyroid surgery continued to be hazardous with prohibitive mortality rates (>40%) until the latter half of the nineteenth century, when advances in general anesthesia, antisepsis, and hemostasis enabled surgeons to perform thyroid surgery with significantly reduced mortality and morbidity rates. The most notable thyroid surgeons were Emil Theodor Kocher (1841–1917) and C.A. Theodor Billroth (1829–1894), who performed thousands of operations with increasingly successful results. However, as more patients survived thyroid operations, new problems and issues became apparent. After total thyroidectomy, patients (particularly children) became myxedematous with cretinous features. Myxedema was first effectively treated in 1891 by George Murray using a subcutaneous injection of an extract of sheep's thyroid and later, Edward Fox demonstrated that oral therapy was equally effective. In 1909, Kocher was awarded the Nobel Prize for medicine in recognition "for his works on the physiology, pathology, and surgery of the thyroid gland."

Embryology

The thyroid gland arises as an outpouching of the primitive foregut around the third week of gestation. It originates at the base of the tongue at the foramen cecum. Endoderm cells in the floor of the pharyngeal anlage thicken to form the medial thyroid anlage (Fig. 38-1) that descends in the neck anterior to structures that form the hyoid bone and larynx. During its descent, the anlage remains connected to the foramen cecum via an epithelial-lined tube known as the *thyroglossal duct*. The epithelial cells making up the anlage give rise to the thyroid follicular cells. The paired lateral anlages originate from the fourth branchial pouch and fuse with the median anlage at approximately the fifth week of gestation. The lateral anlages are neuroectodermal in origin (ultimobranchial bodies) and provide the calcitonin producing parafollicular or C cells, which thus come to lie in the superoposterior region of the gland. Thyroid follicles are initially apparent by 8 weeks, and colloid formation begins by the eleventh week of gestation.

Developmental Abnormalities

THYROGLOSSAL DUCT CYST AND SINUS

Thyroglossal duct cysts are the most commonly encountered congenital cervical anomalies. During the fifth week of gestation, the thyroglossal duct lumen starts to obliterate, and the duct disappears by the eighth week of gestation. Rarely, the thyroglossal duct may persist in whole, or in part. Thyroglossal duct cysts may occur anywhere along the migratory path of the thyroid although 80% are found in juxtaposition to the hyoid bone. They are usually asymptomatic but occasionally become infected by oral bacteria, prompting the patient to seek medical advice. Thyroglossal duct sinuses result from infection of the cyst secondary to spontaneous or surgical drainage of the cyst and are accompanied by minor inflammation of the surrounding skin. Histologically, thyroglossal duct cysts are lined by pseudostratified ciliated columnar epithelium and squamous epithelium, with heterotopic thyroid tissue present in 20% of cases.

The diagnosis usually is established by observing a 1- to 2-cm, smooth, well-defined midline neck mass that moves upward with protrusion of the tongue. Routine thyroid imaging is not necessary although thyroid scintigraphy and ultrasound have been performed to document the presence of normal thyroid tissue in the neck. Treatment involves the "Sistrunk operation," which consists of en bloc cystectomy and excision of the central hyoid bone to minimize recurrence. Approximately 1% of thyroglossal duct cysts are found to contain cancer, which is usually papillary (85%). The role of total thyroidectomy in this setting is controversial, but is advised in older patients with large tumors, particularly if there are additional thyroid nodules and evidence of cyst wall invasion or lymph node metastases.¹ Squamous, Hürthle cell, and anaplastic cancers also have been reported but are rare. Medullary thyroid cancers (MTCs) are, however, not found in thyroglossal duct cysts.

LINGUAL THYROID

A lingual thyroid represents a failure of the median thyroid anlage to descend normally and may be the only thyroid tissue present. Intervention becomes necessary for obstructive symptoms such as choking, dysphagia, airway obstruction, or hemorrhage. Many of these patients develop hypothyroidism. Medical treatment options include administration of exogenous thyroid hormone to suppress thyroid-stimulating hormone (TSH) and radioactive iodine (RAI) ablation followed by hormone replacement. Surgical excision is rarely needed but, if required, should be preceded by an evaluation of normal thyroid tissue in the neck to avoid inadvertently rendering the patient hypothyroid.

ECTOPIC THYROID

Normal thyroid tissue may be found anywhere in the central neck compartment, including the esophagus, trachea, and anterior mediastinum. Thyroid tissue has been observed adjacent to the aortic arch, in the aortopulmonary window, within the upper pericardium, or in the interventricular septum. Often, "tongues" of thyroid tissue are seen to extend off the inferior poles of the gland and are particularly apparent in large goiters. Thyroid tissue situated lateral to the carotid sheath and jugular vein, previously termed *lateral aberrant thyroid*, almost always represents metastatic thyroid cancer in lymph nodes, and not remnants of the lateral anlage that had failed to fuse with the main thyroid, as previously suggested by Crile. Even if not readily apparent on physical examination or ultrasound imaging, the ipsilateral thyroid lobe contains a focus of papillary thyroid cancer (PTC), which may be microscopic.

PYRAMIDAL LOBE

Normally the thyroglossal duct atrophies, although it may remain as a fibrous band. In about 50% of individuals, the distal end that connects to the thyroid persists as a pyramidal lobe projecting up from the isthmus, lying just to the left or right of the midline. In the normal individual, the pyramidal lobe is not palpable, but in disorders resulting in thyroid hypertrophy (e.g., Graves' disease,

diffuse nodular goiter, or lymphocytic thyroiditis), the pyramidal lobe usually is enlarged and palpable.

Thyroid Anatomy

The anatomic relations of the thyroid gland and surrounding structures are depicted in Fig. 38-2. The adult thyroid gland is brown in color and firm in consistency, and is located posterior to the strap muscles. The normal thyroid gland weighs approximately 20 g, but gland weight varies with body weight and iodine intake. The thyroid lobes are located adjacent to the thyroid cartilage and connected in the midline by an isthmus that is located just inferior to the cricoid cartilage. A pyramidal lobe is present in about 50% of patients. The thyroid lobes extend to the midthyroid cartilage superiorly and lie adjacent to the carotid sheaths and sternocleidomastoid muscles laterally. The strap muscles (sternohyoid, sternothyroid, and superior belly of the omohyoid) are located anteriorly and are innervated by the ansa cervicalis (ansa hypoglossi). The thyroid gland is enveloped by a loosely connecting fascia that is formed from the partition of the deep cervical fascia into anterior and posterior divisions. The true capsule of the thyroid is a thin, densely adherent fibrous layer that sends out septa that invaginate into the gland, forming pseudolobules. The thyroid capsule is condensed into the posterior suspensory or Berry's ligament near the cricoid cartilage and upper tracheal rings.

Anatomy of the thyroid gland and surrounding structures, viewed anteriorly (A) and in cross-section (B). a. = artery; m. = muscle; n. = nerve; v. = vein.

BLOOD SUPPLY

The superior thyroid arteries arise from the ipsilateral external carotid arteries and divide into anterior and posterior branches at the apices of the thyroid lobes. The inferior thyroid arteries arise from the thyrocervical trunk shortly after their origin from the subclavian arteries. The inferior thyroid arteries travel upward in the neck posterior to the carotid sheath to enter the thyroid lobes at their midpoint. A thyroidea ima artery arises directly from the aorta or innominate in 1 to 4% of individuals to enter the isthmus or replace a missing inferior thyroid artery. The inferior thyroid artery crosses the recurrent laryngeal nerve (RLN), necessitating identification of the RLN before the arterial branches can be ligated. The venous drainage of the thyroid gland occurs via multiple small surface veins, which coalesce to form three sets of veins—the superior, middle, and inferior thyroid veins. The superior thyroid veins run with the superior thyroid arteries bilaterally. The middle vein or veins are the least consistent. The superior and middle veins drain directly into the internal jugular veins. The inferior veins often form a plexus, which drains into the brachiocephalic veins.

NERVES

The left RLN arises from the vagus nerve where it crosses the aortic arch, loops around the ligamentum arteriosum, and ascends medially in the neck within the tracheoesophageal groove. The right RLN arises from the vagus at its crossing with the right subclavian artery. The nerve usually passes posterior to the artery before ascending in the neck, its course being more oblique than the left RLN. Along their course in the neck, the RLNs may branch, and pass anterior, posterior, or interdigitate with branches of the inferior thyroid artery (Fig. 38-3). The right RLN may be nonrecurrent in 0.5 to 1% of individuals and often is associated with a vascular anomaly.² Nonrecurrent left RLNs are rare but have been reported in patients with situs inversus and a right-sided aortic arch. The RLN may branch in its course in the neck and identification of a small nerve should alert the surgeon to this possibility. Identification of the nerves or their branches often necessitates mobilization of the most lateral and posterior extent of the thyroid gland, the tubercle of Zuckerkandl, at the level of the cricoid cartilage. The last segments of the nerves often course below the tubercle and are closely approximated to the ligament of Berry. Branches of the nerve may traverse the ligament in 25% of individuals, and are particularly vulnerable to injury at this junction. The RLNs terminate by entering the larynx posterior to the cricothyroid muscle.

Fig. 38-3.

Relationship of recurrent laryngeal nerve to the inferior thyroid artery—the superior parathyroid is characteristically dorsal to the plane of the nerve, whereas the inferior gland is ventral to the nerve.

The RLNs innervate all the intrinsic muscles of the larynx, except the cricothyroid muscles, which are innervated by the external laryngeal nerves. Injury to one RLN leads to paralysis of the ipsilateral vocal cord, which comes to lie in the paramedian or the abducted position. The paramedian position results in a normal, but weak voice, whereas the abducted position leads to a hoarse voice and an ineffective cough. Bilateral RLN injury may lead to airway obstruction, necessitating emergency tracheostomy, or loss of voice. If both cords come to lie in an abducted position, air movement can occur, but the patient has an ineffective cough and is at increased risk of repeated respiratory tract infections from aspiration.

The superior laryngeal nerves also arise from the vagus nerves. After their origin at the base of the skull, these nerves travel along the internal carotid artery and divide into two branches at the level of the hyoid bone. The internal branch of the superior laryngeal nerve is sensory to the supraglottic larynx. Injury to this nerve is rare in thyroid surgery, but its occurrence may result in aspiration. The external branch of the superior laryngeal nerve lies on the inferior pharyngeal constrictor muscle and descends alongside the superior thyroid vessels before innervating the cricothyroid muscle. Cernea and colleagues³ proposed a classification system to describe the relationship of this nerve to the superior thyroid vessels (Fig. 38-4). The type 2a variant, in which the nerve crosses below the tip of the thyroid superior pole, occurs in up to 20% of individuals and places the nerve at a greater risk of injury. Therefore, the superior pole vessels should not be ligated en masse, but should be individually divided, low on the thyroid gland and dissected lateral to the cricothyroid muscle. Injury to this nerve leads to inability to tense the ipsilateral vocal cord and hence difficulty "hitting high notes," projecting the voice, and voice fatigue during prolonged speech.

Sympathetic innervation of the thyroid gland is provided by fibers from the superior and middle cervical sympathetic ganglia. The fibers enter the gland with the blood vessels and are vasomotor in action. Parasympathetic fibers are derived from the vagus nerve and reach the gland via branches of the laryngeal nerves.

PARATHYROID GLANDS

The embryology and anatomy of the parathyroid glands is discussed in detail in the Parathyroid Gland section of this chapter. About 85% of individuals have four parathyroid glands that can be found within 1 cm of the junction of the inferior thyroid artery and the

RLN. The superior glands are usually located dorsal to the RLN, whereas the inferior glands are usually found ventral to the RLN (Fig. 38-5).

Fig. 38-5.

LYMPHATIC SYSTEM

The thyroid gland is endowed with an extensive network of lymphatics. Intraglandular lymphatic vessels connect both thyroid lobes through the isthmus and also drain to perithyroidal structures and lymph nodes. Regional lymph nodes include pretracheal, paratracheal, perithyroidal, RLN, superior mediastinal, retropharyngeal, esophageal, and upper, middle, and lower jugular chain nodes. These lymph nodes can be classified into seven levels as depicted in Fig. 38-6. The central compartment includes nodes located in the area between the two carotid sheaths, whereas nodes lateral to the vessels are present in the lateral compartment. Thyroid cancers may metastasize to any of these regions, although metastases to submaxillary nodes (level I) are rare (<1%). There also can be "skip" metastases to nodes in the ipsilateral neck.

Fig. 38-6.

A and B. Lymph nodes in the neck can be divided into six regions. Upper mediastinal nodes constitute level VII. m. = muscle; n. = nerve.

Thyroid Histology

Microscopically, the thyroid is divided into lobules that contain 20 to 40 follicles (Fig. 38-7). There are about 3×10^6 follicles in the adult male thyroid gland. The follicles are spherical and average 30 μm in diameter. Each follicle is lined by cuboidal epithelial cells and contains a central store of colloid secreted from the epithelial cells under the influence of the pituitary hormone TSH. The second group of thyroid secretory cells is the C cells or parafollicular cells, which contain and secrete the hormone calcitonin. They are found as individual cells or clumped in small groups in the interfollicular stroma and located in the upper poles of the thyroid lobes.

Fig. 38-7.

Normal thyroid histology—follicular cells surround colloid.

Thyroid Physiology

IODINE METABOLISM

The average daily iodine requirement is 0.1 mg, which can be derived from foods such as fish, milk, and eggs or as additives in bread or salt. In the stomach and jejunum, iodine is rapidly converted to iodide and absorbed into the bloodstream, and from there it is distributed uniformly throughout the extracellular space. Iodide is actively transported into the thyroid follicular cells by an adenosine triphosphate (ATP)–dependent process. The thyroid is the storage site of >90% of the body's iodine content and accounts for one third of the plasma iodine loss. The remaining plasma iodine is cleared via renal excretion.

THYROID HORMONE SYNTHESIS, SECRETION, AND TRANSPORT

The synthesis of thyroid hormone consists of several steps (Fig. 38-8). The first, iodide trapping, involves active (ATP-dependent) transport of iodide across the basement membrane of the thyrocyte via an intrinsic membrane protein, the sodium/iodine (Na^+/I^-) symporter. Thyroglobulin (Tg) is a large (660 kDa) glycoprotein, which is present in thyroid follicles and has four tyrosyl residues. The second step in thyroid hormone synthesis involves oxidation of iodide to iodine and iodination of tyrosine residues on Tg, to form monoiodotyrosines (MIT) and diiodotyrosines (DIT). Both processes are catalyzed by thyroid peroxidase (TPO). A recently

identified protein, pendrin, is thought to mediate iodine efflux at the apical membrane. The third step leads to coupling of two DIT molecules to form tetra-iodothyronine or thyroxine (T_4), and one DIT molecule with one MIT molecule to form 3,5,3'-triiodothyronine (T_3) or 3,3',5'-triiodothyronine reverse (rT_3). When stimulated by TSH, thyrocytes form pseudopodia, which encircle portions of cell membrane containing Tg, which in turn, fuse with enzyme-containing lysosomes. In the fourth step, Tg is hydrolyzed to release free iodothyronines (T_3 and T_4) and mono- and diiodotyrosines. The latter are deiodinated in the fifth step to yield iodide, which is reused in the thyrocyte. In the euthyroid state, T_4 is produced and released entirely by the thyroid gland, whereas only 20% of the total T_3 is produced by the thyroid. Most of the T_3 is produced by peripheral deiodination (removal of 5'-iodine from the outer ring) of T_4 in the liver, muscles, kidney, and anterior pituitary, a reaction that is catalyzed by 5'-mono-deiodinase. Some T_4 is converted to rT_3 , the metabolically inactive compound, by deiodination of the inner ring of T_4 . In conditions such as Graves' disease, toxic multinodular goiter, or a stimulated thyroid gland the proportion of T_3 released from the thyroid may be dramatically elevated. Thyroid hormones are transported in serum bound to carrier proteins such as T_4 -binding globulin, T_4 -binding prealbumin, and albumin. Only a small fraction (0.02%) of thyroid hormone (T_3 and T_4) is free (unbound) and is the physiologically active component. T_3 is the more potent of the two thyroid hormones, although its circulating plasma level is much lower than that of T_4 . T_3 is less tightly bound to protein in the plasma than T_4 , and so it enters tissues more readily. T_3 is three to four times more active than T_4 per unit weight, with a half-life of about 1 day, compared to approximately 7 days for T_4 .

Thyroid follicular cell showing the major signaling pathways involved in thyroid cell growth and function and key steps in thyroid hormone synthesis. The basal membrane of the cell in contact with the circulation and its apical surface contacts the thyroid follicle. Thyroid hormone synthesis is initiated by the binding of thyroid-stimulating hormone (TSH) to the TSH receptor (TSHR), a G-protein coupled transmembrane receptor, on the basal membrane. Activation leads to an increase in cyclic adenosine monophosphate (cAMP), phosphorylation of protein kinase A (PKA), and activation of target cytosolic and nuclear proteins. The protein kinase C (PKC) pathway is stimulated at higher doses of TSH. Iodide is actively transported into the cell via the Na/I symporter (NIS) and flows down an electrical gradient to the apical membrane. There, thyroid peroxidase (TPO) oxidizes iodide and iodinated tyrosyl residues on thyroglobulin (Tg) in the presence of peroxide (H₂O₂). Mono- and diiodotyrosyl (MIT, DIT) residues are also coupled to form T₄ and T₃ by TPO. Thyroglobulin carrying T₄ and T₃ is then internalized by pinocytosis and digested in lysosomes. Thyroid hormone is released into the circulation, while MIT and DIT are deiodinated and recycled. ATP = adenosine triphosphate; CREB = cAMP response element binding protein; CREM = cAMP response element modulator; DAG = diacylglycerol; IGF-1 = insulin-like growth factor; IP₃ = inositol-3-phosphate; NADP⁺ = nicotinamide adenine dinucleotide phosphate, oxidized form; NADPH = nicotinamide adenine dinucleotide phosphate; PIP₂ = phosphatidylinositol; PLC = phospholipase C; T₃ = 3,5',3'-triiodothyronine; T₄ = thyroxine.

(Reproduced with permission from Kopp P: Pendred's syndrome and genetic defects in thyroid hormone synthesis. *Rev Endocr Metab Disord* 1:114, 2000. Kluwer Academic Publishers.)

The secretion of thyroid hormone is controlled by the hypothalamic-pituitary-thyroid axis (Fig. 38-9). The hypothalamus produces a peptide, the thyrotropin-releasing hormone (TRH), which stimulates the pituitary to release TSH or thyrotropin. TRH reaches the pituitary via the portovenous circulation. TSH, a 28-kDa glycopeptide, mediates iodide trapping, secretion, and release of thyroid

hormones, in addition to increasing the cellularity and vascularity of the thyroid gland. The TSH receptor (TSH-R) belongs to a family of G-protein coupled receptors that have seven transmembrane-spanning domains and use cyclic adenosine monophosphate in the signal-transduction pathway. TSH secretion by the anterior pituitary is also regulated via a negative feedback loop by T_4 and T_3 . Because the pituitary has the ability to convert T_4 to T_3 , the latter is thought to be more important in this feedback control. T_3 also inhibits the release of TRH.

Fig. 38-9.

Hypothalamic-pituitary-thyroid hormone axis. In both the hypothalamus and pituitary, 3,5',3-triiodothyronine (T_3) is primarily responsible for inhibition of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) secretion. T_4 = thyroxine.

[Reproduced with permission from Greenspan FS: The thyroid gland, in Greenspan FS, Gardner D (eds): *Basic and Clinical Endocrinology*, 6th ed. New York: McGraw-Hill, 2001, p 217.]

The thyroid gland also is capable of autoregulation, which allows it to modify its function independent of TSH. As an adaptation to low iodide intake, the gland preferentially synthesizes T_3 rather than T_4 , thereby increasing the efficiency of secreted hormone. In situations of iodine excess, iodide transport, peroxide generation, and synthesis and secretion of thyroid hormones is inhibited. Excessively large doses of iodide may lead to initial increased organification, followed by suppression, a phenomenon called the *Wolff-Chaikoff effect*. Epinephrine and human chorionic gonadotrophin hormones stimulate thyroid hormone production. Thus, elevated thyroid hormone levels are found in pregnancy and gynecologic malignancies such as hydatidiform mole. In contrast, glucocorticoids inhibit thyroid hormone production. In severely ill patients, peripheral thyroid hormones may be reduced, without a compensatory increase in TSH levels, giving rise to the euthyroid sick syndrome.

THYROID HORMONE FUNCTION

Free thyroid hormone enters the cell membrane by diffusion or by specific carriers and is carried to the nuclear membrane by binding to specific proteins. T₄ is deiodinated to T₃ and enters the nucleus via active transport, where it binds to the thyroid hormone receptor. The T₃ receptor is similar to the nuclear receptors for glucocorticoids, mineralocorticoids, estrogens, vitamin D, and retinoic acid. In humans, two types of T₃ receptor genes (α and β) are located on chromosomes 3 and 17. Thyroid receptor expression depends upon peripheral concentrations of thyroid hormones and is tissue specific—the α form is abundant in the central nervous system, whereas the β form predominates in the liver. Each gene product has a ligand-independent, amino-terminal domain; a ligand-binding, carboxy-terminal domain; and centrally located DNA-binding regions. Binding of thyroid hormone leads to the transcription and translation of specific hormone responsive genes.

Thyroid hormones affect almost every system in the body. They are important for fetal brain development and skeletal maturation. T₃ increases oxygen consumption, basal metabolic rate, and heat production by stimulation of Na⁺/K⁺ ATPase in various tissues. It also has positive inotropic and chronotropic effects on the heart by increasing transcription of the Ca²⁺ ATPase in the sarcoplasmic reticulum and increasing levels of beta-adrenergic receptors and concentration of G proteins. Myocardial alpha receptors are decreased and actions of catecholamines are amplified. Thyroid hormones are responsible for maintaining the normal hypoxic and hypercapnic drive in the respiratory center of the brain. They also increase GI motility, leading to diarrhea in hyperthyroidism and constipation in hypothyroidism. Thyroid hormones also increase bone and protein turnover and the speed of muscle contraction and relaxation. They also increase glycogenolysis, hepatic gluconeogenesis, intestinal glucose absorption, and cholesterol synthesis and degradation.

Evaluation of Patients with Thyroid Disease

TESTS OF THYROID FUNCTION

A multitude of different tests are available to evaluate thyroid function. No single test is sufficient to assess thyroid function in all situations and the results must be interpreted in the context of the patient's clinical condition.⁴ TSH is the only test necessary in most patients with thyroid nodules that clinically appear to be euthyroid.

Serum Thyroid-Stimulating Hormone (Normal 0.5–5 μ U/mL)

The tests for serum TSH are based on the following principle—monoclonal TSH antibodies are bound to a solid matrix and bind serum TSH. A second monoclonal antibody binds to a separate epitope on TSH and is labeled with radioisotope, enzyme, or fluorescent tag. Therefore, the amount of serum TSH is proportional to the amount of bound secondary antibody (immunometric assay). Serum TSH levels reflect the ability of the anterior pituitary to detect free T₄ levels. There is an inverse relationship between the free T₄ level and the logarithm of the TSH concentration—small changes in free T₄ lead to a large shift in TSH levels. The ultrasensitive TSH assay has become the most sensitive and specific test for the diagnosis of hyper- and hypothyroidism and for optimizing T₄ therapy.

Total T₄ (Reference Range 55–150 nmol/L) and T₃ (Reference Range 1.5–3.5 nmol/L)

Total T₄ and T₃ levels are measured by radioimmunoassay and measure both the free and bound components of the hormones. Total T₄ levels reflect the output from the thyroid gland, whereas T₃ levels in the nonstimulated thyroid gland are more indicative of peripheral thyroid hormone metabolism, and are, therefore, not generally suitable as a general screening test. Total T₄ levels are increased not only in hyperthyroid patients, but also in those with elevated Tg levels secondary to pregnancy, estrogen/progesterone use, or congenital diseases. Similarly, total T₄ levels decrease in hypothyroidism and in patients with decreased Tg levels due to anabolic steroid use and protein-losing disorders like nephrotic syndrome. Individuals with these latter disorders may be euthyroid if their free T₄ levels are normal. Measurement of total T₃ levels is important in clinically hyperthyroid patients with normal T₄ levels,

who may have T₃ thyrotoxicosis. As discussed previously in Thyroid Hormone Synthesis, Secretion, and Transport, total T₃ levels often are increased in early hypothyroidism.

Free T₄ (Reference Range 12–28 pmol/L) and Free T₃ (3–9 pmol/L)

These radioimmunoassay-based tests are a sensitive and accurate measurement of biologically active thyroid hormone. Free T₄ estimates are not performed as a routine screening tool in thyroid disease. Use of this test is confined to cases of early hyperthyroidism in which total T₄ levels may be normal but free T₄ levels are raised. In patients with end-organ resistance to T₄ (Refetoff syndrome), T₄ levels are increased, but TSH levels usually are normal. Free T₃ is most useful in confirming the diagnosis of early hyperthyroidism, in which levels of free T₄ and free T₃ rise before total T₄ and T₃. Free T₄ levels may also be measured indirectly using the T₃ resin-uptake test. If free T₄ levels are increased, fewer hormone binding sites are available for binding radiolabeled T₃ that has been added to the patient's serum. Therefore, more T₃ binds with an ion-exchange resin and the T₃-resin uptake is increased.

Thyrotropin-Releasing Hormone

This test is useful to evaluate pituitary TSH secretory function and is performed by administering 500 µg of TRH intravenously and measuring TSH levels after 30 and 60 minutes. In a normal individual, TSH levels should increase at least 6 µIU/mL from the baseline. This test also was previously used to assess patients with borderline hyperthyroidism, but has largely been replaced by sensitive TSH assays for this purpose.

Thyroid Antibodies

Thyroid antibodies include anti-Tg, antimicrosomal, or anti-TPO and thyroid-stimulating immunoglobulin (TSI). Anti-Tg and anti-TPO antibody levels do not determine thyroid function, but rather indicate the underlying disorder, usually an autoimmune thyroiditis. About 80% of patients with Hashimoto's thyroiditis have elevated thyroid antibody levels; however, levels may also be increased in patients with Graves' disease, multinodular goiter, and occasionally, with thyroid neoplasms.

Serum Thyroglobulin

Tg is only made by normal or abnormal thyroid tissue. It normally is not released into the circulation in large amounts but increases dramatically in destructive processes of the thyroid gland, such as thyroiditis, or overactive states such as Graves' disease and toxic multinodular goiter. The most important use for serum Tg levels is in monitoring patients with differentiated thyroid cancer for recurrence, particularly after total thyroidectomy and RAI ablation. Elevated anti-Tg antibodies can interfere with the accuracy of serum Tg levels and should always be measured when interpreting Tg levels.

Serum Calcitonin (0–4 pg/mL Basal)

This 32-amino-acid polypeptide is secreted by the C cells and functions to lower serum calcium levels, although in humans, it has only minimal physiologic effects. It is also a sensitive marker of MTC.

THYROID IMAGING

Radionuclide Imaging

Both iodine 123 (¹²³I) and iodine 131 (¹³¹I) are used to image the thyroid gland. The former emits low-dose radiation, has a half-life of 12 to 14 hours, and is used to image lingual thyroids or goiters. In contrast, ¹³¹I has a half-life of 8 to 10 days and leads to higher-dose radiation exposure. Therefore, this isotope is used to screen and treat patients with differentiated thyroid cancers for metastatic disease. The images obtained by these studies provide information not only about the size and shape of the gland, but also the distribution of functional activity. Areas that trap less radioactivity than the surrounding gland are termed *cold* (Fig. 38-10),

whereas areas that demonstrate increased activity are termed *hot*. The risk of malignancy is higher in "cold" lesions (20%) compared to "hot" or "warm" lesions (<5%). Technetium Tc 99m pertechnetate (^{99m}Tc) is taken up by the thyroid gland and is increasingly being used for thyroid evaluation. This isotope is taken up by the mitochondria, but is not organified. It also has the advantage of having a shorter half-life and minimizes radiation exposure. It is particularly sensitive for nodal metastases. More recently, ^{18}F -fluorodeoxyglucose positron emission tomography (FDG PET) is being increasingly used to screen for metastases in patients with thyroid cancer in whom other imaging studies are negative.⁵ PET scans are not routinely used in the evaluation of thyroid nodules; however, they may show clinically occult thyroid lesions. There are several recent reports of rates of malignancy in these lesions ranging from 14 to 63%. These incidentally discovered nodules should be worked up by ultrasound and fine-needle aspiration biopsy (FNAB).

Radioactive iodine scan of the thyroid, with the *arrow* showing an area of decreased uptake, a cold nodule.

Ultrasound

Ultrasound is an excellent noninvasive and portable imaging study of the thyroid gland with the added advantage of no radiation exposure. It is helpful in the evaluation of thyroid nodules, distinguishing solid from cystic ones, and providing information about size and multicentricity. Ultrasound also can be used to assess for cervical lymphadenopathy (Fig. 38-11) and to guide FNAB. An experienced ultrasonographer is necessary for the best results.

Thyroid ultrasound showing a lymph node (arrow) along the carotid artery.

Computed Tomography/Magnetic Resonance Imaging Scan

Computed tomography (CT) and magnetic resonance imaging (MRI) studies provide excellent imaging of the thyroid gland and adjacent nodes, and are particularly useful in evaluating the extent of large, fixed, or substernal goiters (which cannot be evaluated by ultrasound) and their relationship to the airway and vascular structures. Noncontrast CT scans should be obtained for patients who are likely to require subsequent RAI therapy. If contrast is necessary, therapy needs to be delayed by several months. Combined PET-CT scans are increasingly being used for Tg-positive, radioactive iodine–negative tumors.

Benign Thyroid Disorders

HYPERTHYROIDISM

The clinical manifestations of hyperthyroidism result from an excess of circulating thyroid hormone. Hyperthyroidism may arise from a number of conditions that are listed in Table 38-1. It is important to distinguish disorders such as Graves' disease and toxic nodular goiters that result from increased production of thyroid hormone from those disorders that lead to a release of stored hormone from injury to the thyroid gland (thyroiditis) or from other nonthyroid gland–related conditions. The former disorders lead to an increase in radioactive iodine uptake (RAIU), whereas the latter group is characterized by low RAIU. Of these disorders, Graves' disease, toxic multinodular goiter, and solitary toxic nodule are most relevant to the surgeon.

Table 38-1 Differential Diagnosis of Hyperthyroidism	
Increased Hormone Synthesis (Increased RAIU)	Release of Preformed Hormone (Decreased RAIU)
Graves' disease (diffuse toxic goiter)	Thyroiditis—acute phase of Hashimoto's thyroiditis, subacute thyroiditis
Toxic multinodular goiter	
Plummer's disease (toxic adenoma)	
Drug induced—amiodarone, iodine	Factitious (iatrogenic) thyrotoxicosis
	"Hamburger thyrotoxicosis"
Thyroid cancer	
Struma ovarii	
Hydatidiform mole	
TSH-secreting pituitary adenoma	

RAIU = radioactive iodine uptake; TSH = thyroid-stimulating hormone.

Diffuse Toxic Goiter (Graves' Disease)

Although originally described by the Welsh physician Caleb Parry in a posthumous article in 1825, this disorder is known as Graves' disease after Robert Graves, an Irish physician who described three patients in 1835. Graves' disease is by far the most common cause of hyperthyroidism in North America, accounting for 60 to 80% of cases. It is an autoimmune disease with a strong familial predisposition, female preponderance (5:1), and peak incidence between the ages of 40 to 60 years. Graves' disease is characterized by thyrotoxicosis, diffuse goiter, and extrathyroidal conditions including ophthalmopathy, dermopathy (pretibial myxedema), thyroid acropachy, gynecomastia, and other manifestations.

Etiology, Pathogenesis, and Pathology

The exact etiology of the initiation of the autoimmune process in Graves' disease is not known. However, conditions such as the postpartum state, iodine excess, lithium therapy, and bacterial and viral infections have been suggested as possible triggers. Genetic factors also play a role, as haplotyping studies indicate that Graves' disease is associated with certain human leukocyte antigen (HLA) haplotypes—HLA-B8 and HLA-DR3 and HLADQA1*0501 in Caucasian patients whereas HLA-DRB1*0701 is protective against it. Polymorphisms of the cytotoxic T-lymphocyte antigen 4 (*CTLA-4*) gene also have been associated with Graves' disease development.⁶ Once initiated, the process causes sensitized T-helper lymphocytes to stimulate B lymphocytes, which produce antibodies directed against the thyroid hormone receptor. TSIs or antibodies that stimulate the TSH-R, as well as TSH-binding inhibiting immunoglobulins or antibodies have been described. The thyroid-stimulating antibodies stimulate the thyrocytes to grow and synthesize excess thyroid hormone, which is a hallmark of Graves' disease. Graves' disease also is associated with other autoimmune conditions such as type I diabetes mellitus, Addison's disease, pernicious anemia, and myasthenia gravis.

Macroscopically, the thyroid gland in patients with Graves' disease is diffusely and smoothly enlarged, with a concomitant increase in vascularity. Microscopically, the gland is hyperplastic, and the epithelium is columnar with minimal colloid present. The nuclei exhibit mitosis, and papillary projections of hyperplastic epithelium are common. There may be aggregates of lymphoid tissue, and vascularity is markedly increased.

Clinical Features

The clinical manifestations of Graves' disease can be divided into those related to hyperthyroidism and those specific to Graves' disease. Hyperthyroid symptoms include heat intolerance, increased sweating and thirst, and weight loss despite adequate caloric intake. Symptoms of increased adrenergic stimulation include palpitations, nervousness, fatigue, emotional lability, hyperkinesis, and tremors. The most common GI symptoms include increased frequency of bowel movements and diarrhea. Female patients often develop amenorrhea, decreased fertility, and an increased incidence of miscarriages. Children experience rapid growth with early bone maturation, whereas older patients may present with cardiovascular complications such as atrial fibrillation and congestive heart failure.

On physical examination, weight loss and facial flushing may be evident. The skin is warm and moist and African American patients often note darkening of their skin. Tachycardia or atrial fibrillation is present with cutaneous vasodilation leading to a widening of the pulse pressure and a rapid falloff in the transmitted pulse wave (collapsing pulse). A fine tremor, muscle wasting, and proximal muscle group weakness with hyperactive tendon reflexes often are present.

Approximately 50% of patients with Graves' disease also develop clinically evident ophthalmopathy, and dermopathy occurs in 1 to 2% of patients. It is characterized by deposition of glycosaminoglycans leading to thickened skin in the pretibial region and dorsum of the foot (Fig. 38-12). Eye symptoms include lid lag (von Graefe's sign), spasm of the upper eyelid revealing the sclera above the corneoscleral limbus (Dalrymple's sign), and a prominent stare, due to catecholamine excess. True infiltrative eye disease results in periorbital edema, conjunctival swelling and congestion (chemosis), proptosis, limitation of upward and lateral gaze (from involvement of the inferior and medial rectus muscles, respectively), keratitis, and even blindness due to optic nerve involvement.

The etiology of Graves' ophthalmopathy is not completely known; however, orbital fibroblasts and muscles are thought to share a common antigen, the TSH-R. Ophthalmopathy is thought to result from inflammation caused by cytokines released from sensitized killer T lymphocytes and cytotoxic antibodies. Gynecomastia is common in young men. Rare bony involvement leads to subperiosteal bone formation and swelling in the metacarpals (thyroid acropachy). Onycholysis, or separation of fingernails from their beds, is a more commonly observed finding. On physical examination, the thyroid usually is diffusely and symmetrically enlarged, as evidenced by an enlarged pyramidal lobe. There may be an overlying bruit or thrill and loud venous hum in the supraclavicular space.

A. Graves' ophthalmopathy and **(B)** pretibial myxedema. This patient demonstrates exophthalmos, proptosis, periorbital swelling, congestion, and edema of the conjunctiva.

Diagnostic Tests

The diagnosis of hyperthyroidism is made by a suppressed TSH with or without an elevated free T₄ or T₃ level. If eye signs are present, other tests are generally not needed. However, in the absence of eye findings, an ¹²³I uptake and scan should be performed. An elevated uptake, with a diffusely enlarged gland, confirms the diagnosis of Graves' disease and helps to differentiate it from other causes of hyperthyroidism. If free T₄ levels are normal, free T₃ levels should be determined, as they often are elevated in early Graves' or Plummer's disease (T₃ toxicosis). Anti-Tg and anti-TPO antibodies are elevated in up to 75% of patients, but are not specific. Elevated TSH-R or thyroid-stimulating antibodies (TSAb) are diagnostic of Graves' disease and are increased in about 90% of patients. MRI scans of the orbits are useful in evaluating Graves' ophthalmopathy.

Treatment

Graves' disease may be treated by any of three treatment modalities—antithyroid drugs, thyroid ablation with radioactive ¹³¹I, and thyroidectomy.⁷ The choice of treatment depends upon several factors, as discussed in the following sections.

Antithyroid Drugs

Antithyroid medications generally are administered in preparation for RAI ablation or surgery. The drugs commonly used are propylthiouracil (PTU, 100 to 300 mg three times daily) and methimazole (10 to 30 mg three times daily, then once daily). Methimazole has a longer half-life and can be dosed once daily. Both drugs reduce thyroid hormone production by inhibiting the organic binding of iodine and the coupling of iodotyrosines (mediated by TPO). In addition, PTU also inhibits the peripheral conversion of T₄ to T₃, making it useful for the treatment of thyroid storm. Both drugs can cross the placenta, inhibiting fetal thyroid function, and are excreted in breast milk, although PTU has a lower risk of transplacental transfer. Methimazole also has

been associated with congenital aplasia; therefore, PTU is preferred in pregnant and breastfeeding women. Side effects of treatment include reversible granulocytopenia, skin rashes, fever, peripheral neuritis, polyarteritis, vasculitis, and, rarely, agranulocytosis and aplastic anemia. Patients should be monitored for these possible complications and should always be warned to stop PTU or methimazole immediately and seek medical advice should they develop a sore throat or fever. Treatment of agranulocytosis involves admission to the hospital, discontinuation of the drug, and broad-spectrum antibiotic therapy. Surgery should be postponed until the granulocyte count reaches 1000 cells/m³.

The dose of antithyroid medication is titrated as needed in accordance with TSH and T₄ levels. Most patients have improved symptoms in 2 weeks and become euthyroid in about 6 weeks. Some physicians use the block-replace regimen, by adding T₄ (0.05 to 0.10 mg) to prevent hypothyroidism and suppress TSH secretion, because some, but not all, studies suggest that this reduces recurrence rates. The length of therapy is debated. Treatment with antithyroid medications is associated with a high relapse rate when these drugs are discontinued, with 40 to 80% of patients developing recurrent disease after a 1- to 2-year course. Patients with small glands are less likely to recur so that treatment for curative intent is reserved for patients with (a) small, nontoxic goiters less than 40 g, (b) mildly elevated thyroid hormone levels, and (c) rapid decrease in gland size with antithyroid medications. The catecholamine response of thyrotoxicosis can be alleviated by administering beta-blocking agents. These drugs have the added effect of decreasing the peripheral conversion of T₄ to T₃. Propranolol is the most commonly prescribed medication in doses of about 20 to 40 mg four times daily. Higher doses are sometimes required due to increased clearance of the medication.

Radioactive Iodine Therapy (¹³¹I)

RAI forms the mainstay of Graves' disease treatment in North America. The major advantages of this treatment are the avoidance of a surgical procedure and its concomitant risks, reduced overall treatment costs, and ease of treatment. Antithyroid drugs are given until the patient is euthyroid and then discontinued to maximize drug uptake. The ¹³¹I dose is calculated after a preliminary scan, and usually consists of 8 to 12 mCi administered orally. After standard treatment with RAI, most patients become euthyroid within 2 months. However, only about 50% of patients treated with RAI are euthyroid 6 months after treatment, and the remaining are still hyperthyroid or already hypothyroid.⁸ After 1 year, about 2.5% of patients develop hypothyroidism each year. RAI also has been documented to lead to progression of Graves' ophthalmopathy (33% after RAI compared to 16% after surgery), and ophthalmopathy is more common in smokers. Although there is no evidence of long-term problems with infertility, and overall cancer incidence rates are unchanged, there is a small increased risk of nodular goiter, thyroid cancer⁹ and hyperparathyroidism (HPT)¹⁰ in patients who have been treated with RAI. Patients treated with RAI have an unexplained increase in their overall and cardiovascular mortality rates when compared to the general population.

RAI therapy is therefore most often used in older patients with small or moderate-sized goiters, those who have relapsed after medical or surgical therapy, and those in whom antithyroid drugs or surgery are contraindicated. Absolute contraindications to RAI include women who are pregnant or breastfeeding. Relative contraindications include young patients (i.e., especially children and adolescents), those with thyroid nodules, and those with ophthalmopathy. The higher the initial dose of ¹³¹I, the earlier the onset and the higher the incidence of hypothyroidism.

Surgical Treatment

In North America, surgery is recommended when RAI is contraindicated as in patients who (a) have confirmed cancer or suspicious thyroid nodules, (b) are young, (c) are pregnant or desire to conceive soon after treatment, (d) have had severe reactions to antithyroid medications, (e) have large goiters causing compressive symptoms, and (f) are reluctant to undergo RAI therapy. Relative indications for thyroidectomy include patients, particularly smokers, with moderate to severe Graves' ophthalmopathy, those desiring rapid control of hyperthyroidism with a chance of being euthyroid, and those demonstrating poor compliance to antithyroid medications. The goal of thyroidectomy for Graves' disease should be the complete and permanent control of the disease

with minimal morbidity. Patients should be rendered euthyroid before operation with antithyroid drugs that should be continued up to the day of surgery. Lugol's iodide solution or saturated potassium iodide generally is administered beginning 7 to 10 days preoperatively (three drops twice daily) to reduce vascularity of the gland and decrease the risk of precipitating thyroid storm. The major action of iodine in this situation is to inhibit release of thyroid hormone.

The extent of thyroidectomy to be performed is controversial and is determined by the desired outcome (risk of recurrence vs. euthyroidism) and surgeon experience. Patients with coexistent thyroid cancer, and those who refuse RAI therapy or have severe ophthalmopathy or have life-threatening reactions to antithyroid medications (vasculitis, agranulocytosis, or liver failure) should undergo total or near-total thyroidectomy. Ophthalmopathy has been demonstrated to stabilize or improve in most patients after total thyroidectomy, presumably from removal of the antigenic stimulus. A subtotal thyroidectomy, leaving a 4- to 7-g remnant, is recommended for all remaining patients. Remnants <3 g are recommended for children. Remnants <4 g are associated with a 2 to 10% recurrence rate but a high (>40%) rate of hypothyroidism. During subtotal thyroidectomy, remnant tissue may be left on each side (bilateral subtotal thyroidectomy), or a total lobectomy can be performed on one side with a subtotal thyroidectomy on the other side (Hartley-Dunhill procedure). Results are similar with either procedure,¹¹ but the latter procedure is theoretically associated with fewer complications and requires re-entering only one side of the neck should recurrence require reoperation. Most studies, however, show no difference in the rates of complications with either approach. Recurrent thyrotoxicosis usually is managed by radioiodine treatment. Long-term follow-up should be maintained for all patients undergoing subtotal procedures, with clinical review and yearly TSH measurement to detect the possible late onset of hypothyroidism or recurrent hyperthyroidism.

Toxic Multinodular Goiter

Toxic multinodular goiters usually occur in older individuals, who often have a prior history of a nontoxic multinodular goiter. Over several years, enough thyroid nodules become autonomous to cause hyperthyroidism. The presentation often is insidious in that hyperthyroidism may only become apparent when patients are placed on low doses of thyroid hormone suppression for the goiter. Some patients have T₃ toxicosis, whereas others may present only with atrial fibrillation or congestive heart failure. Hyperthyroidism also can be precipitated by iodide-containing drugs such as contrast media and the antiarrhythmic agent amiodarone (iodine-based hyperthyroidism). Symptoms and signs of hyperthyroidism are similar to Graves' disease, but extrathyroidal manifestations are absent.

Diagnostic Studies

Blood tests are similar to Graves' disease with a suppressed TSH level and elevated free T₄ or T₃ levels. RAI uptake also is increased, showing multiple nodules with increased uptake and suppression of the remaining gland.

Treatment

Hyperthyroidism must be adequately controlled. Surgical resection is the preferred treatment of patients with toxic multinodular goiter with subtotal thyroidectomy being the standard procedure. Remnant size is not as crucial a concern because these patients require thyroid hormone suppression to prevent recurrence of the goiter. The Hartley-Dunhill procedure is preferred over a bilateral subtotal thyroidectomy for the reasons outlined earlier in Surgical Treatment. Care must be taken in identifying the RLN, which may be found laterally on the thyroid (rather than posterior) or stretched anteriorly over a nodule. Total thyroidectomy may sometimes be necessary if no normal thyroid tissue is present. RAI therapy is reserved for elderly patients who represent very poor operative risks, provided there is no airway compression from the goiter, and thyroid cancer is not a concern. However, because uptake is less than in Graves' disease, larger doses of RAI often are needed to treat the hyperthyroidism. Furthermore, RAI-induced thyroiditis has the potential to cause swelling and acute airway compromise, and leaves the goiter intact, with the possibility of recurrent hyperthyroidism.

Toxic Adenoma (Plummer's Disease)

Hyperthyroidism from a single hyperfunctioning nodule typically occurs in younger patients who note recent growth of a long-standing nodule along with the symptoms of hyperthyroidism. Toxic adenomas are characterized by somatic mutations in the TSH-R gene, although G-protein stimulating gene (*gsp*) mutations may occur also.¹² Most hyperfunctioning or autonomous thyroid nodules have attained a size of at least 3 cm before hyperthyroidism occurs. Physical examination usually reveals a solitary thyroid nodule without palpable thyroid tissue on the contralateral side. RAI scanning shows a "hot" nodule with suppression the rest of the thyroid gland. These nodules are rarely malignant. Smaller nodules may be managed with antithyroid medications and RAI. Surgery (lobectomy and isthmusectomy) is preferred to treat young patients and those with larger nodules.

Thyroid Storm

Thyroid storm is a condition of hyperthyroidism accompanied by fever, central nervous system agitation or depression, cardiovascular dysfunction that may be precipitated by infection, surgery, or trauma. Occasionally, thyroid storm may result from amiodarone administration. This condition was previously associated with high mortality rates but can be appropriately managed in an intensive care unit setting. Beta blockers are given to reduce peripheral T4 to T₃ conversion and decrease the hyperthyroid symptoms. Oxygen supplementation and hemodynamic support should be instituted. Non-aspirin compounds can be used to treat pyrexia and Lugol's iodine or sodium ipodate (intravenously) should be administered to decrease iodine uptake and thyroid hormone secretion. PTU therapy blocks the formation of new thyroid hormone and reduces peripheral conversion of T₄ to T₃. Corticosteroids often are helpful to prevent adrenal exhaustion and block hepatic thyroid hormone conversion.

HYPOTHYROIDISM

Deficiency in circulating levels of thyroid hormone leads to hypothyroidism and, in neonates, to cretinism, which is characterized by neurologic impairment and mental retardation. Hypothyroidism also may occur in Pendred's syndrome (associated with deafness) and Turner's syndrome. Conditions that cause hypothyroidism are listed in Table 38-2.

Table 38-2 Causes of Hypothyroidism		
Primary (Increased TSH Levels)	Secondary (Decreased TSH Levels)	Tertiary
Hashimoto's thyroiditis	Pituitary tumor	Hypothalamic insufficiency
RAI therapy for Graves' disease	Pituitary resection or ablation	Resistance to thyroid hormone
Postthyroidectomy		
Excessive iodine intake		
Subacute thyroiditis		
Medications: antithyroid drugs, lithium		
Rare: iodine deficiency, dyshormogenesis		

RAI = radioactive iodine; TSH = thyroid-stimulating hormone.

Clinical Features

Failure of thyroid gland development or function in utero leads to cretinism and characteristic facies similar to those of children with Down syndrome and dwarfism. Failure to thrive and severe mental retardation often are present. Immediate testing and treatment with thyroid hormone at birth can lessen the neurologic and intellectual deficits. Hypothyroidism developing in childhood or adolescence results in delayed development and may also lead to abdominal distention, umbilical hernia, and rectal prolapse. In adults, symptoms in general are nonspecific, including tiredness, weight gain, cold intolerance, constipation, and menorrhagia. Patients with severe hypothyroidism or myxedema develop characteristic facial features due to the deposition of glycosaminoglycans in the subcutaneous tissues, leading to facial and periorbital puffiness. The skin becomes rough and dry and often develops a

yellowish hue from reduced conversion of carotene to vitamin A. Hair becomes dry and brittle, and severe hair loss may occur. There is also a characteristic loss of the outer two thirds of the eyebrows. An enlarged tongue may impair speech, which is already slowed, in keeping with the impairment of mental processes. Patients may also have nonspecific abdominal pain accompanied by distention and constipation. Libido and fertility are impaired in both sexes. Cardiovascular changes in hypothyroidism include bradycardia, cardiomegaly, pericardial effusion, reduced cardiac output, and pulmonary effusions. When hypothyroidism occurs as a result of pituitary failure, other features of hypopituitarism, such as pale, waxy skin; loss of body hair; and atrophic genitalia, may be present.

Laboratory Findings

Hypothyroidism is characterized by low circulating levels of T_4 and T_3 . Raised TSH levels are found in primary thyroid failure, whereas secondary hypothyroidism is characterized by low TSH levels that do not increase following TRH stimulation. Thyroid autoantibodies are highest in patients with autoimmune disease (Hashimoto's thyroiditis, Graves' disease) and may also be elevated in patients with nodular goiter and thyroid neoplasms. An electrocardiogram demonstrates decreased voltage with flattening or inversion of T waves.

Treatment

T_4 is the treatment of choice and is administered in dosages varying from 50 to 200 μg per day, depending upon the patient's size and condition. Starting doses of 100 μg of T_4 daily are well tolerated; however, elderly patients and those with coexisting heart disease and profound hypothyroidism should be started on a considerably lower dose such as 25 to 50 μg daily because of associated hypercholesterolemia and atherosclerosis. The dose can be slowly increased over weeks to months to attain a euthyroid state. A baseline electrocardiogram should always be obtained in patients with severe hypothyroidism before treatment. T_4 dosage is titrated against clinical response and TSH levels, which should return to normal. The management of patients with subclinical hypothyroidism (normal T_4 , slightly raised TSH) is controversial. Some evidence suggests that patients with subclinical hypothyroidism and increased antithyroid antibody levels should be treated, because they will subsequently develop hypothyroidism. Patients who present with myxedema coma may require initial emergency treatment with large doses of IV T_4 (300 to 400 μg), with careful monitoring in an intensive care unit setting.

THYROIDITIS

Thyroiditis usually is classified into acute, subacute, and chronic forms, each associated with a distinct clinical presentation and histology.

Acute (Suppurative) Thyroiditis

The thyroid gland is inherently resistant to infection due to its extensive blood and lymphatic supply, high iodide content, and fibrous capsule. However, infectious agents can seed it (a) via the hematogenous or lymphatic route, (b) via direct spread from persistent pyriform sinus fistulae or thyroglossal duct cysts, (c) as a result of penetrating trauma to the thyroid gland, or (d) due to immunosuppression. *Streptococcus* and anaerobes account for about 70% of cases; however, other species also have been cultured.¹³ Acute suppurative thyroiditis is more common in children and often is preceded by an upper respiratory tract infection or otitis media. It is characterized by severe neck pain radiating to the jaws or ear, fever, chills,odynophagia, and dysphonia. Complications such as systemic sepsis, tracheal or esophageal rupture, jugular vein thrombosis, laryngeal chondritis, and perichondritis or sympathetic trunk paralysis may also occur.

The diagnosis is established by leukocytosis on blood tests and FNAB for Gram's stain, culture, and cytology. CT scans may help to delineate the extent of infection. A persistent pyriform sinus fistula should always be suspected in children with recurrent acute thyroiditis. A barium swallow demonstrates the anomalous tract with 80% sensitivity. Treatment consists of parenteral antibiotics

and drainage of abscesses. Patients with pyriform sinus fistulae require complete resection of the sinus tract, including the area of the thyroid where the tract terminates, to prevent recurrence.

Subacute Thyroiditis

Subacute thyroiditis can occur in the painful or painless forms. Although the exact etiology is not known, painful thyroiditis is thought to be viral in origin or result from a postviral inflammatory response. Genetic predisposition may also play a role, as manifested by its strong association with the HLA-B35 haplotype. One model of pathogenesis suggests that viral or thyroid antigens, when presented by macrophages in the context of HLA-B35, stimulate cytotoxic T lymphocytes and damage thyroid follicular cells.

Painful thyroiditis most commonly occurs in 30- to 40-year-old women and is characterized by the sudden or gradual onset of neck pain, which may radiate toward the mandible or ear. History of a preceding upper respiratory tract infection often can be elicited. The gland is enlarged, exquisitely tender, and firm. The disorder classically progresses through four stages. An initial hyperthyroid phase, due to release of thyroid hormone, is followed by a second, euthyroid phase. The third phase, hypothyroidism, occurs in about 20 to 30% of patients and is followed by resolution and return to the euthyroid state in >90% of patients. A few patients develop recurrent disease.

In the early stages of the disease, TSH is decreased, and Tg, T₄, and T₃ levels are elevated due to the release of preformed thyroid hormone from destroyed follicles. The erythrocyte sedimentation rate is typically >100 mm/h. RAIU also is decreased (<2% at 24 hours), even in euthyroid patients, due to the release of thyroid hormones from destruction of the thyroid parenchyma. Painful thyroiditis is self-limited, and therefore, treatment is primarily symptomatic. Aspirin and other NSAIDs are used for pain relief, but steroids may be indicated in more severe cases. Short-term thyroid replacement may be needed and may shorten the duration of symptoms. Thyroidectomy is reserved for the rare patient who has a prolonged course not responsive to medical measures or for recurrent disease.

Painless thyroiditis is considered to be autoimmune in origin and may occur sporadically or in the postpartum period; the latter typically occurs at about 6 weeks after delivery in women with high TPO antibody titers in early pregnancy. This timing is thought to coincide with a decrease in the normal immune tolerance of pregnancy and consequent rebound elevation of antibody titers.

Painless thyroiditis also is more common in women and usually occurs between 30 to 60 years of age. Physical examination demonstrates a normal sized or minimally enlarged, slightly firm, nontender gland. Laboratory tests and RAIU are similar to those in painful thyroiditis, except for a normal erythrocyte sedimentation rate. The clinical course also parallels painful thyroiditis. Patients with symptoms may require beta blockers and thyroid hormone replacement. Thyroidectomy or RAI ablation is only indicated for the rare patient with recurrent, disabling episodes of thyroiditis.

Chronic Thyroiditis

Lymphocytic (Hashimoto's) Thyroiditis

Lymphocytic thyroiditis was first described by Hashimoto in 1912 as *struma lymphomatosa*—a transformation of thyroid tissue to lymphoid tissue. It is the most common inflammatory disorder of the thyroid and the leading cause of hypothyroidism.

Etiology, Pathogenesis, and Pathology

Hashimoto's thyroiditis is an autoimmune process that is thought to be initiated by the activation of CD4⁺ T (helper) lymphocytes with specificity for thyroid antigens. Once activated, T cells can recruit cytotoxic CD8⁺ T cells to the thyroid. Hypothyroidism results not only from the destruction of thyrocytes by cytotoxic T cells but by autoantibodies, which lead to complement fixation and killing by natural killer cells or block the TSH-R. Antibodies directed against three main antigens—Tg (60%), TPO (95%), the TSH-R (60%), and, less commonly, to the sodium/iodine symporter (25%). Apoptosis (programmed cell death) also has been implicated in the pathogenesis of Hashimoto's thyroiditis. Chronic thyroiditis also has been associated with increased intake of iodine and

administration of medications such as interferon- α , lithium, and amiodarone. Support for an inherited predisposition includes an increased incidence of thyroid autoantibodies in first-degree relatives of patients with Hashimoto's thyroiditis compared to controls and the occurrence of the autoantibodies and hypothyroidism in patients with specific chromosomal abnormalities such as Turner's syndrome and Down syndrome. Associations with HLA-B8, DR3, and DR5 haplotypes of the major histocompatibility complex also have been described.

On gross examination, the thyroid gland is usually mildly enlarged throughout and has a pale, gray-tan cut surface that is granular, nodular, and firm. On microscopic examination, the gland is diffusely infiltrated by small lymphocytes and plasma cells and occasionally shows well-developed germinal centers. Thyroid follicles are smaller than normal with reduced amounts of colloid and increased interstitial connective tissue. The follicles are lined by Hürthle or Askanazy cells, which are characterized by abundant eosinophilic, granular cytoplasm.

Clinical Presentation

Hashimoto's thyroiditis is also more common in women (male:female ratio 1:10 to 20) between the ages of 30 and 50 years old. The most common presentation is that of a minimally or moderately enlarged firm granular gland discovered on routine physical examination or the awareness of a painless anterior neck mass, although 20% of patients present with hypothyroidism, and 5% present with hyperthyroidism (Hashitoxicosis). In classic goitrous Hashimoto's thyroiditis, physical examination reveals a diffusely enlarged, firm gland, which also is lobulated. An enlarged pyramidal lobe often is palpable.

Diagnostic Studies

When Hashimoto's thyroiditis is suspected clinically, an elevated TSH and the presence of thyroid autoantibodies usually confirm the diagnosis. FNAB is indicated in patients who present with a solitary suspicious nodule or a rapidly enlarging goiter. Thyroid lymphoma is a rare but well-recognized, ominous complication of chronic autoimmune thyroiditis and has a prevalence 80 times higher than expected frequency in this population than in a control population without thyroiditis. Recent studies of clonal similarity indicate that lymphoma may, in fact, evolve from Hashimoto's thyroiditis.¹⁴

Treatment

Thyroid hormone replacement therapy is indicated in overtly hypothyroid patients, with a goal of maintaining normal TSH levels. The management of patients with subclinical hypothyroidism (normal T4 and elevated TSH) is controversial. Treatment is advised especially for middle-aged patients with cardiovascular risk factors such as hyperlipidemia or hypertension and in pregnant patients.¹⁵ Treatment also is indicated in euthyroid patients to shrink large goiters. Surgery may occasionally be indicated for suspicion of malignancy or for goiters causing compressive symptoms or cosmetic deformity.

Riedel's Thyroiditis

Riedel's thyroiditis is a rare variant of thyroiditis also known as *Riedel's struma* or *invasive fibrous thyroiditis* that is characterized by the replacement of all or part of the thyroid parenchyma by fibrous tissue, which also invades into adjacent tissues. The etiology of this disorder is controversial, and it has been reported to occur in patients with other autoimmune diseases. This association, coupled with the presence of lymphoid infiltration and response to steroid therapy, suggests a primary autoimmune etiology. Riedel's thyroiditis also is associated with other focal sclerosing syndromes including mediastinal, retroperitoneal, periorbital, and retro-orbital fibrosis and sclerosing cholangitis, suggesting that it may, in fact, be a primary fibrotic disorder. The disease occurs predominantly in women between the ages of 30 to 60 years old. It typically presents as a painless, hard anterior neck mass, which progresses over weeks to years to produce symptoms of compression, including dysphagia, dyspnea, choking, and hoarseness. Patients may present with symptoms of hypothyroidism and hypoparathyroidism as the gland is replaced by fibrous tissue. Physical examination reveals a hard, "woody" thyroid gland with fixation to surrounding tissues. The diagnosis needs to be confirmed by open thyroid biopsy, because the firm and fibrous nature of the gland renders FNAB inadequate.

Surgery is the mainstay of the treatment. The chief goal of operation is to decompress the trachea by wedge excision of the thyroid isthmus and to make a tissue diagnosis. More extensive resections are not advised due to the infiltrative nature of the fibrotic process that obscures usual landmarks and structures. Hypothyroid patients are treated with thyroid hormone replacement. Some patients who remain symptomatic have been reported to experience dramatic improvement after treatment with corticosteroids and tamoxifen.¹⁶

GOITER

Any enlargement of the thyroid gland is referred to as a goiter. The causes of nontoxic goiters are listed in Table 38-3. Goiters may be diffuse, uninodular, or multinodular. Most nontoxic goiters are thought to result from TSH stimulation secondary to inadequate thyroid hormone synthesis and other paracrine growth factors.¹⁷ Elevated TSH levels induce diffuse thyroid hyperplasia, followed by focal hyperplasia, resulting in nodules that may or may not concentrate iodine, colloid nodules, or microfollicular nodules. The TSH-dependent nodules progress to become autonomous. Familial goiters resulting from inherited deficiencies in enzymes necessary for thyroid hormone synthesis may be complete or partial. The term *endemic goiter* refers to the occurrence of a goiter in a significant proportion of individuals in a particular geographic region. In the past, dietary iodine deficiency was the most common cause of endemic goiter. This condition has largely disappeared in North America due to routine use of iodized salt and iodination of fertilizers, animal feeds, and preservatives. However, in areas of iodine deficiency, such as Central Asia, South America, and Indonesia, up to 90% of the population have goiters. Other dietary goitrogens that may participate in endemic goiter formation include kelp, cassava, and cabbage. In many sporadic goiters, no obvious cause can be identified.

Table 38-3 Etiology of Nontoxic Goiter	
Classification	Specific Etiology
Endemic	Iodine deficiency, dietary goitrogens (cassava, cabbage)
Medications	Iodide, amiodarone, lithium
Thyroiditis	Subacute, chronic (Hashimoto's)
Familial	Impaired hormone synthesis from enzyme defects
Neoplasm	Adenoma, carcinoma
Resistance to thyroid hormone	—

Clinical Features

Most patients with nontoxic goiters are asymptomatic, although patients often complain of a pressure sensation in the neck. As the goiters become very large, compressive symptoms such as dyspnea and dysphagia ensue. Patients also describe having to clear their throats frequently (catarrh). Dysphonia from RLN injury is rare, except when malignancy is present. Obstruction of venous return at the thoracic inlet from a substernal goiter results in a positive Pemberton's sign—facial flushing and dilatation of cervical veins upon raising the arms above the head (Fig. 38-13A). Sudden enlargement of nodules or cysts due to hemorrhage may cause acute pain. Physical examination may reveal a soft, diffusely enlarged gland (simple goiter) or nodules of various size and consistency in case of a multinodular goiter. Deviation or compression of the trachea may be apparent.

A. Retrosternal extension of a large goiter may result in impeded flow in the superior vena cava, leading to dilated veins over the chest wall. This may become more prominent when patients raise their arms above the head—Pemberton's sign. **B.** Computed tomography scan demonstrating retrosternal extension and consequent tracheal deviation and compression from a large goiter.

Diagnostic Tests

Patients usually are euthyroid with normal TSH and low-normal or normal-free T₄ levels. If some nodules develop autonomy, patients have suppressed TSH levels or become hyperthyroid. RAI uptake often shows patchy uptake with areas of hot and cold nodules. FNAB is recommended in patients who have a dominant nodule or one that is painful or enlarging, as carcinomas have been reported in 5 to 10% of multinodular goiters. CT scans are helpful to evaluate the extent of retrosternal extension and airway compression (Fig. 38-13B).

Treatment

Most euthyroid patients with small, diffuse goiters do not require treatment. Some physicians give patients with large goiters exogenous thyroid hormone to reduce the TSH stimulation of gland growth; this treatment may result in decrease and/or stabilization of goiter size and is most effective for small diffuse goiters. Endemic goiters are treated by iodine administration. Surgical resection is reserved for goiters that (a) continue to increase despite T₄ suppression, (b) cause obstructive symptoms, (c) have substernal extension, (d) have malignancy suspected or proven by FNAB, and (e) are cosmetically unacceptable. Subtotal thyroidectomy is the treatment of choice and patients require lifelong T₄ therapy to prevent recurrence.

Solitary Thyroid Nodule

Solitary thyroid nodules are present in approximately 4% of individuals in the United States, whereas thyroid cancer has a much

lower incidence of 40 new cases per 1 million. Therefore, it is of utmost importance to determine which patients with solitary thyroid nodule would benefit from surgery.

HISTORY

Details regarding the nodule, such as time of onset, change in size, and associated symptoms such as pain, dysphagia, dyspnea, or choking, should be elicited. Pain is an unusual symptom and, when present, should raise suspicion for intrathyroidal hemorrhage in a benign nodule, thyroiditis, or malignancy. Patients with MTC may complain of a dull, aching sensation. A history of hoarseness is worrisome, as it may be secondary to malignant involvement of the RLNs. Most importantly, patients should be questioned regarding risk factors for malignancy, such as exposure to ionizing radiation and family history of thyroid and other malignancies associated with thyroid cancer.

External Beam Radiation

Low-dose therapeutic radiation has been used to treat conditions such as tinea capitis (6.5 cGy), thymic enlargement (100 to 400 cGy), enlarged tonsils and adenoids (750 cGy), acne vulgaris (200 to 1500 cGy), and other conditions such as hemangioma and scrofula. Radiation (approximately 4000 cGy) is also an integral part of the management of patients with Hodgkin's disease. It is now known that a history of exposure to low-dose ionizing radiation to the thyroid gland places the patient at increased risk for developing thyroid cancer. The risk increases linearly from 6.5 to 2000 cGy, beyond which the incidence declines as the radiation causes destruction of the thyroid tissue. The risk is maximum 20 to 30 years after exposure, but these patients require lifelong monitoring. During the nuclear fallout from Chernobyl in 1986, ¹³¹I release was accompanied by a marked increase in the incidence of both benign and malignant thyroid lesions noted within 4 years of exposure, particularly in children.¹⁸ Most thyroid carcinomas following radiation exposure are papillary, and some of these cancers with a solid type of histology and presence of *RET*/*PTC* translocations appear to be more aggressive. There is a 40% chance that patients presenting with a thyroid nodule and a history of radiation have thyroid cancer. Of those patients who have thyroid cancer, the cancer is located in the dominant nodule in 60% of patients, but in the remaining 40% of patients, the cancer is in another nodule in the thyroid gland.

Family History

A family history of thyroid cancer is a risk factor for the development of both medullary and nonmedullary thyroid cancer. Familial MTCs occur in isolation or in association with other tumors as part of multiple endocrine neoplasia type 2 (MEN2) syndromes. Nonmedullary thyroid cancers can occur in association with other known familial cancer syndromes such as Cowden's syndrome, Werner's (adult progeroid syndrome), and familial adenomatous polyposis (Table 38-4). Nonmedullary thyroid cancers can also occur independently of these syndromes. Several candidate loci that predispose to these tumors have been identified, but they account for only a small proportion of families.¹⁹

Table 38-4 Familial Cancer Syndromes Involving Nonmedullary Thyroid Cancer			
Syndrome	Gene	Manifestation	Thyroid Tumor
Cowden's syndrome	<i>PTEN</i>	Intestinal hamartomas, benign and malignant breast tumors	FTC, rarely PTC and Hürthle cell tumors
FAP	<i>APC</i>	Colon polyps and cancer, duodenal neoplasms, desmoids	PTC cribriform growth pattern
Werner's syndrome	<i>WRN</i>	Adult progeroid syndrome	PTC, FTC, anaplastic cancer
Carney complex type 1	<i>PRKAR1</i> α	Cutaneous and cardiac myxomas, breast and adrenal tumors	PTC, FTC
McCune-Albright syndrome	<i>GNAS1</i>	Polyostotic fibrous dysplasia, endocrine abnormalities, café-au-lait spots	PTC clear cell

FAP = familial adenomatous polyposis; FTC = follicular thyroid cancer; PTC = papillary thyroid cancer.

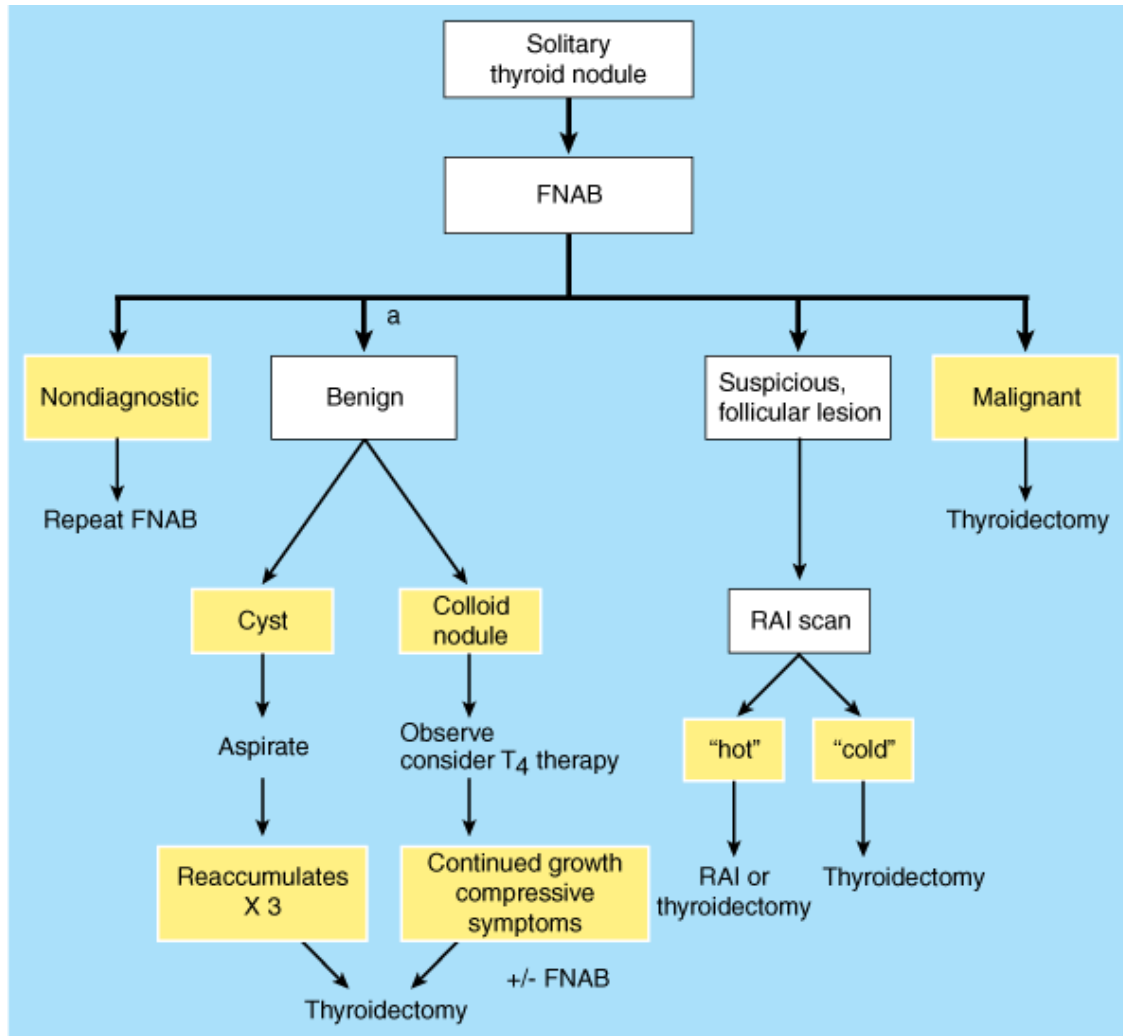

PHYSICAL EXAMINATION

The thyroid gland is best palpated from behind the patient and with the neck in mild extension. The cricoid cartilage is an important landmark, as the isthmus is situated just below it. Nodules that are hard, gritty, or fixed to surrounding structures such as the trachea or strap muscles are more likely to be malignant. The cervical chain of lymph nodes should be assessed as well as the nodes in the posterior triangle.

DIAGNOSTIC INVESTIGATIONS

An algorithm for the work-up of a solitary thyroid nodule is shown in Fig. 38-14.

Fig. 38-14.

Management of a solitary thyroid nodule. a = except in patients with a history of external radiation exposure or a family history of thyroid cancer; FNAB = fine-needle aspiration biopsy; RAI = radioactive iodine; T4 = thyroxine.

Fine-Needle Aspiration Biopsy

FNAB has become the single most important test in the evaluation of thyroid masses and can be performed with or without ultrasound guidance.²⁰ Ultrasound guidance is recommended for nodules that are difficult to palpate and for cystic or solid-cystic nodules that recur after the initial aspiration. A 23-gauge needle is inserted into the thyroid mass, and several passes are made

while aspirating the syringe. After releasing the suction on the syringe, the needle is withdrawn and the cells are immediately placed on prelabeled dry glass slides; some are immersed in a 70% alcohol solution while others are air dried. A sample of the aspirate is also placed in a 90% alcohol solution for cytospin or cell pellet. The slides are stained by Papanicolaou's or Wright's stains and examined under the microscope. If a bloody aspirate is obtained, the patient should be repositioned in a more upright position and the biopsy repeated with a finer (25- to 30-gauge) needle.

After FNAB, the majority of nodules can be categorized into the following groups: benign (65%), suspicious (20%), malignant (5%), and nondiagnostic (10%). The incidence of false-positive results is about 1% and false-negative results occur in approximately 3% of patients. If a biopsy is reported as nondiagnostic, it generally should be repeated. Benign lesions include cysts and colloid nodules. The risk of malignancy in this setting is <3%. The risk of malignancy in the setting of a suspicious cytology is about 20%. Most of these lesions are follicular or Hürthle cell neoplasms. In this situation, diagnosis of malignancy relies on demonstrating capsular or vascular invasion, features that cannot be determined via FNAB. FNAB also is less reliable in patients who have a history of head and neck irradiation or a family history of thyroid cancer, due to higher likelihood of multifocal lesions and occult cancer.

Laboratory Studies

Most patients with thyroid nodules are euthyroid. Determining the blood TSH level is helpful. If a patient with a nodule is found to be hyperthyroid, the risk of malignancy is approximately 1%. Serum Tg levels cannot differentiate benign from malignant thyroid nodules unless the levels are extremely high, in which case metastatic thyroid cancer should be suspected. Tg levels are, however, useful in following patients who have undergone total thyroidectomy for thyroid cancer and also for serial evaluation of patients undergoing nonoperative management of thyroid nodules. Serum calcitonin levels should be obtained in patients with MTC or a family history of MTC or MEN2. All patients with MTC should be tested for *RET* oncogene mutations and have a 24-hour urine collection with measurement of levels of vanillylmandelic acid (VMA), metanephrine, and catecholamine to rule out a coexisting pheochromocytoma. About 10% of patients with familial MTC and MEN2A have de novo *RET* mutations, so that their children are at risk for thyroid cancer.

Imaging

Ultrasound is helpful for detecting nonpalpable thyroid nodules, differentiating solid from cystic nodules, and identifying adjacent lymphadenopathy. Ultrasound evaluation can identify features of a nodule that increase the a priori risk of malignancy, such as fine stippled calcification and enlarged regional nodes; however, a tissue diagnosis is strongly recommended before thyroidectomy.²¹ Ultrasound also provides a noninvasive and inexpensive method of following the size of suspected benign nodules diagnosed by FNAB and for identifying enlarged lymph nodes. CT and MRI are unnecessary in the routine evaluation of thyroid tumors except for large, fixed, or substernal lesions. Scanning the thyroid with ¹²³I or ^{99m}Tc is rarely necessary, and thyroid scanning currently is recommended in the assessment of thyroid nodules only in patients who have follicular thyroid nodules on FNAB and a suppressed TSH. As previously indicated in Thyroid Imaging, PET scanning does not play a major role in the primary evaluation of thyroid nodules.

MANAGEMENT

Malignant tumors are treated by thyroidectomy, as discussed later in this chapter in Surgical Treatment under Malignant Thyroid Disease. Simple thyroid cysts resolve with aspiration in about 75% of cases, although some require a second or third aspiration. If the cyst persists after three attempts at aspiration, unilateral thyroid lobectomy is recommended. Lobectomy also is recommended for cysts >4 cm in diameter or complex cysts with solid and cystic components, as the latter have a higher incidence of malignancy (15%). When FNAB is used in complex nodules, the solid portion should be sampled. If a colloid nodule is diagnosed by FNAB, patients should still be observed with serial ultrasound and Tg measurements. If the nodule enlarges, repeat FNAB often is indicated. Although controversial, L-thyroxine in doses sufficient to maintain a serum TSH level between 0.1 and 1.0 μ U/mL may also be

administered. Approximately 50% of these nodules decrease in size in response to the TSH suppression of this regimen, and others may not continue to grow, but it is most effective for nodules <3 cm. Thyroidectomy should be performed if a nodule enlarges on TSH suppression, causes compressive symptoms, or for cosmetic reasons. An exception to this general rule is the patient who has had previous irradiation of the thyroid gland or has a family history of thyroid cancer. In these patients, total or near-total thyroidectomy is recommended because of the high incidence of thyroid cancer and decreased reliability of FNAB in this setting.

Malignant Thyroid Disease

In the United States, thyroid cancer accounts for <1% of all malignancies (2% of women and 0.5% of men) and is the most rapidly increasing cancer in women. Thyroid cancer is responsible for six deaths per million persons annually. Most patients present with a palpable swelling in the neck, which initiates assessment through a combination of history, physical examination, and FNAB.

MOLECULAR GENETICS OF THYROID TUMORIGENESIS

Several oncogenes and tumor suppressor genes are involved in thyroid tumorigenesis,²² as depicted in Table 38-5. The *RET* proto-oncogene (Fig. 38-15) plays a significant role in the pathogenesis of thyroid cancers. It is located on chromosome 10 and encodes a receptor tyrosine kinase, which binds several growth factors such as glial-derived neurotrophic factor and neurturin. The *RET* protein is expressed in tissues derived from the embryonic nervous and excretory systems. Therefore, *RET* disruption can lead to developmental abnormalities in organs derived from these systems, such as the enteric nervous system (Hirschsprung's disease) and kidney. Germline mutations in the *RET* proto-oncogene are known to predispose to MEN2A, MEN2B, and familial MTCs, and somatic mutations have been demonstrated in tumors derived from the neural crest, such as MTCs (30%) and pheochromocytomas. The tyrosine kinase domain of *RET* can fuse with other genes by rearrangement. These fusion products also function as oncogenes and have been implicated in the pathogenesis of PTCs. At least 15 *RET*/PTC rearrangements have been described and appear to be early events in tumorigenesis. Young age and radiation exposure seem to be independent risk factors for the development of *RET*/PTC rearrangements. Up to 70% of papillary cancers in children exposed to the radiation fallout from the 1986 Chernobyl disaster carry *RET*/PTC rearrangements, the most common being *RET*/PTC1 and *RET*/PTC3. These rearrangements confer constitutive activation of the receptor tyrosine kinases. *RET*/PTC3 is associated with a solid type of PTC that appears to present at a higher stage and to be more aggressive.²³ It has now been established that *RET*/PTC signaling involves the mitogen-activated protein kinase (MAPK) pathway via other signaling molecules such as *Ras*, Raf, and MEK. In normal cells, physiologic activation of Raf kinases occurs via direct interaction with guanosine triphosphate (GTP)-bound Ras, a membrane bound small G-protein. Activated Raf, a serine-threonine kinase, in turn phosphorylates MEK, another serine-threonine kinase. This leads to phosphorylation of ERK/MAPK, which phosphorylates regulatory molecules in the nucleus, thereby altering gene expression. Aberrant activation of the MAPK pathway leads to tumorigenesis. Aside from *RET*/PTC alterations, mutations in the *Ras* genes can also activate the MAPK pathway. Mutated *ras* oncogenes have been identified in up to 20 to 40% of thyroid follicular adenomas and carcinomas, multinodular goiters, and papillary and anaplastic carcinomas. There are three Raf kinases, A-Raf, B-Raf (*BRAF*), and C-Raf. Mutations in *BRAF* also have been implicated in aberrant MAPK pathway activation and tumorigenesis. Of the various identified *BRAF* mutations, T1799A (V600E amino acid substitution) is the most common and occurs frequently in thyroid cancers. Interestingly, *BRAF* mutations occur in papillary and anaplastic tumors (average prevalence of 44% and 22% respectively),²⁴ but not in follicular thyroid cancers, suggesting a role in the pathogenesis of these malignancies. Studies also show that *BRAF* mutations are associated with more aggressive clinicopathologic features, including larger tumor size, invasion, and lymphadenopathy, and may have a role as prognostic markers.

Table 38-5 Oncogenes and Tumor-Suppressor Genes Implicated in Thyroid Tumorigenesis		
Gene	Function	Tumor
Oncogenes		

<i>RET</i>	Membrane receptor with tyrosine kinase activity	Sporadic and familial MTC, PTC (RET/PTC rearrangements)
<i>MET</i>	Same	Overexpressed in PTC
<i>TRK1</i>	Same	Activated in some PTC
<i>TSH-R</i>	Linked to heterotrimeric G protein	Hyperfunctioning adenoma
<i>Gsα (gsp)</i>	Signal transduction molecule (GTP binding)	Hyperfunctioning adenoma, follicular adenoma
<i>Ras</i>	Signal transduction protein	Follicular adenoma and carcinoma, PTC
<i>PAX8/PPARγ1</i>	Oncoprotein	Follicular adenoma, follicular carcinoma
<i>B-Raf (BRAF)</i>	Signal transduction	PTC, tall cell and poorly differentiated, anaplastic
Tumor suppressors		
<i>p53</i>	Cell cycle regulator, arrests cells in G ₁ , induces apoptosis	De-differentiated PTC, FTC, anaplastic cancers
<i>p16</i>	Cell cycle regulator, inhibits cyclin dependent kinase	Thyroid cancer cell lines
<i>PTEN</i>	Protein tyrosine phosphatase	Follicular adenoma and carcinoma

FTC = follicular thyroid cancer; GTP = guanosine triphosphate; MTC = medullary thyroid cancer; PTC = papillary thyroid cancer.

Structure of the RET tyrosine kinase receptor. MEN2A, MEN2B, familial medullary thyroid cancer (FMTC), and Hirschsprung's disease result from germline mutations in the RET proto-oncogene. The extracellular domain binds the ligand glial-derived neurotrophic factor (GDNF) and contains 28 cysteine residues. Mutations in cysteine residues at codons 609, 611, 618, 620, and 634, which are in the juxtamembrane region of the receptor, are associated with MEN2A and FMTC. The ATP-binding site is located

intracellularly near the site, which binds the substrate for the tyrosine kinase catalytic domain. Mutations at codon 918 (Met to Thr) alter the substrate binding pocket located in the intracellular region and cause MEN2B. FMTC is associated with mutations at codons 768 and 804. ATP = adenosine triphosphate.

The *p53* gene is a tumor suppressor gene encoding a transcriptional regulator, which causes cell cycle arrest allowing repair of damaged DNA, thus helping to maintain genomic integrity. Mutations of *p53* are rare in PTCs, but are common in undifferentiated thyroid cancers and thyroid cancer cell lines. Other cell cycle regulators and tumor suppressors such as *p15* and *p16* are mutated more commonly in thyroid cancer cell lines than in primary tumors. An oncogene resulting from the fusion of the DNA binding domain of the thyroid-transcription factor *PAX8* gene to the peroxisome proliferator-activated receptor gamma 1 (PPAR γ 1) has been noted to play an important role in the development of follicular neoplasms, including follicular cancers.²⁵

SPECIFIC TUMOR TYPES

Papillary Carcinoma

Papillary carcinoma accounts for 80% of all thyroid malignancies in iodine-sufficient areas and is the predominant thyroid cancer in children and individuals exposed to external radiation. Papillary carcinoma occurs more often in women, with a 2:1 female-to-male ratio, and the mean age at presentation is 30 to 40 years. Most patients are euthyroid and present with a slow-growing painless mass in the neck. Dysphagia, dyspnea, and dysphonia usually are associated with locally advanced invasive disease. Lymph node metastases are common, especially in children and young adults, and may be the presenting complaint. "Lateral aberrant thyroid" almost always denotes a cervical lymph node that has been invaded by metastatic cancer. Suspicion of thyroid cancer often originates through physical examination of patients and a review of their history. Diagnosis is established by FNAB of the thyroid mass or lymph node. Once thyroid cancer is diagnosed on FNAB, a complete neck ultrasound is strongly recommended to evaluate the contralateral lobe and for lymph node metastases in the central and lateral neck compartments. Distant metastases are uncommon at initial presentation, but may ultimately develop in up to 20% of patients. The most common sites are lungs, followed by bone, liver, and brain.

Pathology

On gross examination, PTCs generally are hard and whitish and remain flat on sectioning with a blade, in contrast to normal tissue or benign nodular lesions that tend to bulge. Macroscopic calcification, necrosis, or cystic change may be apparent. Histologically, papillary carcinomas may exhibit papillary projections (Fig. 38-16A), a mixed pattern of papillary and follicular structures, or a pure follicular pattern (follicular variant). The diagnosis is established by characteristic nuclear cellular features. Cells are cuboidal with pale, abundant cytoplasm, crowded nuclei that may demonstrate "grooving," and intranuclear cytoplasmic inclusions [leading to the designation of *Orphan Annie* nuclei (Fig. 38-16B)], which allow diagnosis by FNAB. Psammoma bodies, which are microscopic, calcified deposits representing clumps of sloughed cells, also may be present. Mixed papillary-follicular tumors and follicular variants of papillary carcinoma are classified as papillary carcinomas because they behave biologically as papillary carcinomas. Multifocality is common in papillary carcinoma and may be present in up to 85% of cases on microscopic examination. Multifocality is associated with an increased risk of cervical nodal metastases, and these tumors may rarely invade adjacent structures such as the trachea, esophagus, and RLNs. Other variants of papillary carcinoma include tall cell, insular, columnar, diffuse sclerosing, clear cell, trabecular, and poorly differentiated types. These variants account for about 1% of all papillary carcinomas and are generally associated with a worse prognosis.

A. Histomicrograph of a papillary thyroid cancer (hematoxylin-eosin stain). **B.** Fine-needle aspiration biopsy specimen from a papillary thyroid cancer showing typical intranuclear cytoplasmic inclusions in the center of the slide.

Minimal or occult/microcarcinoma refers to tumors of 1 cm or less in size with no evidence of local invasiveness through the thyroid capsule or angioinvasion, and that are not associated with lymph node metastases. They are nonpalpable and usually are incidental findings at operative, histologic, or autopsy examination. Studies have demonstrated occult PTC to be present in 2 to 36% of thyroid glands removed at autopsy. These tumors are also being identified more frequently due to the widespread use of ultrasound. These

occult tumors are generally associated with a better prognosis than larger tumors, but they may be more aggressive than previously appreciated.²⁶

Prognostic Indicators

In general, patients with PTC have an excellent prognosis with a >95% 10-year survival rate. Several prognostic indicators have been incorporated into various staging systems, which enable patients to be stratified into low-risk and high-risk groups. Unfortunately, all of these classification systems rely on data that are not available preoperatively.

In 1987, Hay and colleagues²⁷ at the Mayo Clinic proposed the *AGES* scoring system, which incorporates Age, histologic Grade, Extrathyroidal invasion, and metastases and tumor Size to predict the risk of dying from papillary cancer. Low-risk patients are young, with well-differentiated tumors, no metastases, and small primary lesions, whereas high-risk patients are older, with poorly differentiated tumors, local invasion, distant metastases, and large primary lesions. The *MACIS* scale is a postoperative system modified from the AGES scale. This scale incorporates distant Metastases, Age at presentation (<40 or >40 years old), Completeness of original surgical resection, extrathyroidal Invasion, and Size of original lesion (in cm) and classifies patients into four risk groups based on their scores. Cady proposed the *AMES* system²⁸ to classify differentiated thyroid tumors into low- and high-risk groups using Age (men <40 years old, women <50 years old), Metastases, Extrathyroidal spread, and Size of tumors (less than or >5 cm). Another classification systems is the *TNM* system, (Tumor, Nodal status, Metastases, Table 38-6), used by most medical centers in North America.²⁹ A simplified system by DeGroot and associates³⁰ uses four groups—class I (intrathyroidal), class II (cervical nodal metastases), class III (extrathyroidal invasion), and class IV (distant metastases) to determine prognosis.

Table 38-6 TNM Classification of Thyroid Tumors ²⁹	
Papillary or Follicular Tumors	
Stage	TNM
<45 y	
I	Any T, any N, M0
II	Any T, any N, M1

IVB	T4b, Any N, M0
IVC	Any T, Any M, M1

Definitions:

Primary tumor (T)

TX = Primary tumor cannot be assessed

T0 = No evidence of primary tumor

T1 = Tumor ≤ 2 cm in diameter, limited to thyroid

T2 = Tumor > 2 cm but < 4 cm in diameter, limited to thyroid

T3 = Tumor > 4 cm in diameter, limited to thyroid, or any tumor with minimal extrathyroidal invasion

T4a = Any size tumor extending beyond capsule to invade subcutaneous soft tissue, larynx, trachea, esophagus, or recurrent laryngeal nerve, or intrathyroidal anaplastic cancer

T4b = Tumor invading prevertebral fascia, or encasing carotid artery or mediastinal vessels; or extrathyroidal anaplastic cancer

Regional lymph nodes (N)—include central, lateral cervical, and upper mediastinal nodes

NX = Regional lymph nodes cannot be assessed

N0 = No regional lymph node metastasis

N1 = Regional lymph node metastasis

N1a = Metastases to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)

N1b = Metastases to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes

Distant metastasis (M)

MX = Distant metastases cannot be assessed

M1 = No distant metastasis

Several molecular and genetic markers such as tumor DNA aneuploidy, decreased cyclic adenosine monophosphate response to TSH, increased epidermal growth factor binding, presence of *N-ras* and *gsp* mutations, overexpression of *c-myc*, and presence of *p53* mutations also have been associated with a worse prognosis. The presence of *BRAF* mutations also has been demonstrated to be associated with lymph node metastasis and higher stage (III and IV) papillary tumors.³¹

Surgical Treatment

Most authors agree that patients with high-risk tumors (judged by any of the classification systems discussed above in Prognostic Indicators) or bilateral tumors should undergo total or near-total thyroidectomy. When patients are found to have a minimal papillary thyroid carcinoma in a thyroid specimen removed for other reasons, unilateral thyroid lobectomy and isthmusectomy is usually considered to be adequate treatment, unless the tumor has evidence of angioinvasion, multifocality, or positive margins. The optimal surgical strategy in the majority of patients with low-risk (small, unilateral) cancers remains controversial. The focus of the debate centers around outcome data and risks associated with extent of thyroidectomy in this group of patients.

Proponents of total thyroidectomy argue that the procedure (a) enables the use of RAI to effectively detect and treat residual thyroid tissue or metastatic disease, (b) makes serum Tg level a more sensitive marker of recurrent or persistent disease, (c) eliminates contralateral occult cancers as sites of recurrence (because up to 85% of tumors are bilateral), (d) reduces the risk of recurrence and improves survival, (e) decreases the 1% risk of progression to undifferentiated or anaplastic thyroid cancer, and (f) reduces the

need for reoperative surgery with its attendant risk of increased complication rates.

Investigators that favor lobectomy argue that (a) total thyroidectomy is associated with a higher complication rate than lobectomy, (b) recurrence in the remaining thyroid tissue is unusual (5%) and most are curable by surgery, (c) tumor multicentricity seems to have little prognostic significance, and (d) patients who have undergone lesser procedures such as lobectomy still have an excellent prognosis.

However, it is known that a significant proportion (33 to 50%) of patients who develop a recurrence die from their disease³² and even though the data are retrospective, long-term, follow-up studies suggest that recurrence rates are lowered and that survival is improved in patients undergoing near-total or total thyroidectomy³⁰⁻³⁶ (Fig. 38-17). In addition, diminished survival is noted in patients with low-risk disease (mortality rates of 5% at 10 to 20 years), and it is not possible to accurately risk stratify patients preoperatively. Given the above, it is recommended that even patients with low-risk tumors undergo total or near-total thyroidectomy, provided complication rates are low (<2%).³⁷

Improved survival in patients with papillary or follicular thyroid cancer following total or near-total thyroidectomy compared to those who underwent less than near-total thyroidectomy.

(Reproduced with permission from Mazzaferri E, Jhiang S: Long-term impact of initial surgical and medical therapy on papillary and follicular thyroid cancer. *Am J Med* 97:424, 1994. Copyright Elsevier.)

Thus, when PTC is diagnosed by FNAB, the definitive operation can be done without confirming the diagnosis by frozen section during the operation. Patients with a nodule that may be papillary cancer should be treated by thyroid lobectomy, isthmusectomy, and removal of any pyramidal lobe or adjacent lymph nodes. If intraoperative frozen-section examination of a lymph node or primary tumor confirms carcinoma, completion total or near-total thyroidectomy is performed. If a definitive diagnosis cannot be

made or the surgeon is concerned about the viability of the parathyroid glands or the status of the RLN, the operation is terminated. When final histology confirms carcinoma, completion thyroidectomy usually is performed. For patients who have minimal PTCs (<1 cm) confined to the thyroid gland without angioinvasion, no further operative treatment is recommended.

During thyroidectomy, enlarged central neck nodes should be removed. Some investigators recommend routine bilateral central neck dissection due to the high incidence of microscopic metastases and data showing improved rates of recurrence and survival (compared to historic controls). However, these risks need to be balanced with the increased risk of hypoparathyroidism with routine central neck dissection. Biopsy-proven lymph node metastases detected clinically or by imaging in the lateral neck in patients with papillary carcinoma are managed with modified radical or functional neck dissection³⁷ as described later in this chapter in Thyroid Surgery. Dissection of the posterior triangle and suprahyoid dissection usually are not necessary unless there is extensive metastatic disease in levels 2, 3, and 4, but should be performed when appropriate.³⁸ Prophylactic lateral neck node dissection is not necessary in patients with PTC, because these cancers do not appear to metastasize systemically from lymph nodes, and micrometastases often can be ablated with RAI therapy.

Follicular Carcinoma

Follicular carcinomas account for 10% of thyroid cancers and occur more commonly in iodine-deficient areas. The overall incidence of this tumor is declining in the United States, probably due to iodine supplementation and improved histologic classification. Women have a higher incidence of follicular cancer, with a female-to-male ratio of 3:1, and a mean age at presentation of 50 years old. Follicular cancers usually present as solitary thyroid nodules, occasionally with a history of rapid size increase, and long-standing goiter. Pain is uncommon, unless hemorrhage into the nodule has occurred. Unlike papillary cancers, cervical lymphadenopathy is uncommon at initial presentation (about 5%), although distant metastases may be present. In <1% of cases, follicular cancers may be hyperfunctioning, leading patients to present with signs and symptoms of thyrotoxicosis. FNAB is unable to distinguish benign follicular lesions from follicular carcinomas. Therefore, preoperative clinical diagnosis of cancer is difficult unless distant metastases are present. Large follicular tumors (>4 cm) in older men are more likely to be malignant.

Due to the limitations inherent in the FNAB diagnosis, a number of studies have focused on identifying molecular markers to distinguish benign from malignant follicular lesions. Loss of heterozygosity (LOH) analysis compares normal and tumor tissue DNA at specific chromosomal loci for loss of one copy of a gene pair. LOH near the von Hippel-Lindau (VHL) locus of chromosome 3p25-26 has been reported to be a strong discriminant of benign from malignant follicular lesions.³⁹ Other studies have used complementary DNA microarrays to compare tumor tissue for differences in the expression of thousands of genes and have shown very promising results for the correct subsequent diagnosis of unknowns. These studies have identified combinations of three to six genes that appear to be useful in distinguishing benign from malignant follicular lesions.⁴⁰ Expression arrays also have been used to investigate the role of microRNAs, which are a new class of small, noncoding RNA that have been implicated in carcinogenesis. The specific microRNAs miR-197 and miR-364 are upregulated in follicular thyroid cancers.⁴¹ Many of these genetic changes can be identified using tissue obtained during FNAB and have the potential to be used as diagnostic and possibly prognostic markers.

Pathology

Follicular carcinomas usually are solitary lesions, and the majority are surrounded by a capsule. Histologically, follicles are present, but the lumen may be devoid of colloid. Architectural patterns depend on the degree of differentiation demonstrated by the tumor. Malignancy is defined by the presence of capsular and vascular invasion (Fig. 38-18). In general, minimally invasive tumors appear grossly encapsulated and have microscopic invasion through the tumor capsule without extension into the parenchyma and/or invasion into small- to medium-sized vessels (venous caliber) in or immediately outside the capsule, but not within the tumor.⁴² On the other hand, widely invasive tumors demonstrate evidence of large vessel invasion and/or broad areas of tumor invasion through the capsule. They may, in fact, be unencapsulated. It is important to note that there is a wide variation of opinion among clinicians and pathologists with respect to the above definitions. Tumor infiltration and invasion, as well as tumor thrombus within the middle

thyroid or jugular veins, may be apparent at operation.

Hematoxylin-eosin–stained section from follicular thyroid carcinoma showing capsular invasion.

Surgical Treatment and Prognosis

Patients diagnosed by FNAB as having a follicular lesion should undergo thyroid lobectomy because at least 80% of these patients will have benign adenomas. Some surgeons recommend total thyroidectomy in older patients with follicular lesions >4 cm because of the higher risk of cancer in this setting (50%). Intraoperative frozen-section examination usually is not helpful, but should be performed when there is evidence of capsular or vascular invasion, or when adjacent lymphadenopathy is present. Total thyroidectomy should be performed when thyroid cancer is diagnosed. There is debate among experts about whether patients with minimally invasive follicular cancers should undergo completion thyroidectomy because the prognosis is so good in these patients. A diagnosis of frankly invasive carcinoma or follicular carcinoma with angioinvasion, with or without capsular invasion, necessitates completion of total thyroidectomy primarily so that ^{131}I can be used to detect and ablate metastatic disease. Prophylactic nodal dissection is unwarranted because nodal involvement is infrequent, but in the unusual patient with nodal metastases, therapeutic neck dissection is recommended. The cumulative mortality from follicular thyroid cancer is approximately 15% at 10 years and 30% at 20 years. Poor long-term prognosis is predicted by age over 50 years old at presentation, tumor size >4 cm, higher tumor grade, marked vascular invasion, extrathyroidal invasion, and distant metastases at the time of diagnosis.

Hürthle Cell Carcinoma

Hürthle cell carcinomas account for approximately 3% of all thyroid malignancies and, under the World Health Organization classification, are considered to be a subtype of follicular thyroid cancer. Hürthle cell cancers also are characterized by vascular or capsular invasion and can, therefore, not be diagnosed by FNAB. Tumors contain sheets of eosinophilic cells packed with mitochondria, which are derived from the oxyphilic cells of the thyroid gland. Hürthle cell tumors differ from follicular carcinomas in that they are more often multifocal and bilateral (about 30%), usually do not take up RAI (about 5%), are more likely to metastasize to local nodes (25%) and distant sites, and are associated with a higher mortality rate (about 20% at 10 years). Hence,

they are considered to be a separate class of tumors by some groups.

Management is similar to that of follicular neoplasms, with lobectomy and isthmusectomy being sufficient surgical treatment for unilateral Hürthle cell adenomas. When Hürthle cell neoplasms are found to be invasive on definitive paraffin-section histology, then total thyroidectomy should be performed. These patients should also undergo routine central neck node removal, similar to patients with MTC, and modified radical neck dissection when lateral neck nodes are palpable. Although RAI scanning and ablation usually are ineffective, they probably should be considered to ablate any residual normal thyroid tissue and occasionally ablate tumors because there is no other good therapy. Redifferentiating therapies such as retinoic acid, PPAR γ agonists have shown some utility in treating these tumors in vitro; however, the results of phase II clinical trials have been mixed.⁴³ Further research is needed to clarify the role of these treatments.

POSTOPERATIVE MANAGEMENT OF DIFFERENTIATED THYROID CANCER

Radioiodine Therapy

The issue of whether RAI therapy offers any benefit to patients with differentiated thyroid cancer remains controversial in the absence of prospective, randomized controlled trials. Long-term cohort studies by Mazzaferri and associates and DeGroot and colleagues demonstrate that postoperative RAI therapy reduces recurrence (Fig. 38-19) and provides a small improvement in survival, even in low-risk patients.^{30,33} Screening with RAI is more sensitive than chest x-ray or CT scanning for detecting metastases; however, it is less sensitive than Tg measurements for detecting metastatic disease in most differentiated thyroid cancers except Hürthle cell tumors. Screening and treatment are facilitated by the removal of all normal thyroid tissue, which effectively competes for iodine uptake. Metastatic differentiated thyroid carcinoma can be detected and treated by ¹³¹I in about 75% of patients. Multiple studies show that RAI effectively treats >70% of lung micrometastases that are detected by RAI scan in the presence of a normal chest x-ray, whereas the success rates drop to <10% with pulmonary macrometastases. Early detection therefore appears to be very important to improve prognosis. RAI ablation currently is recommended for all patients with stage III or IV disease, all patients with stage II disease younger than 45 years old, most patients 45 years or older with stage II disease, and patients with stage I disease who have aggressive histologies, nodal metastases, multifocal disease, and extrathyroid or vascular invasion.³⁷

Tumor recurrence at a median of 16.7 years after thyroid surgery. The numerator is the number of patients with recurrence, and the denominator is the number of patients in each time interval. The P values are derived from log-rank statistical analysis of 40-year life-table data. Figure shows that all recurrences (**A**) and distant metastases (**B**) were reduced in patients who received radioactive iodine (RAI) in addition to thyroxine (T4) therapy.

(Reproduced with permission from Mazzaferri E, Kloos R: Current approaches to primary therapy for papillary and follicular thyroid cancer. *J Clin Endocrinol Metab* 86: 1453, 2001, Copyright by The Endocrine Society.)

Generally, T4 therapy should be discontinued for approximately 6 weeks before scanning with ^{131}I . Patients should receive T_3 during this time period to decrease the period of hypothyroidism. T_3 has a shorter half-life than T_4 (1 day vs. 1 week) and needs to be discontinued for 2 weeks to allow TSH levels to rise before treatment. Levels >30 mU/L are considered optimal, based on noncontrolled studies.³⁷ A low-iodine diet also is recommended during this 2-week period. The usual protocol involves administering a screening dose of 1 to 3 mCi of ^{123}I and measuring uptake 24 hours later. After a total thyroidectomy, this value should be $<1\%$. A "hot" spot in the neck after initial screening usually represents residual normal tissue in the thyroid bed. Some investigators recommend omitting the scanning dose altogether to minimize thyrocyte "stunning" and subsequent requirement for higher treatment doses. Others recommend scanning only if the size of the remnant cannot be determined by the operative report or ultrasound, or if the results would alter the decision to treat or the dose to be administered. If there is significant uptake, then a therapeutic dose of ^{131}I , 30 to 100 mCi should be administered to low-risk patients and 100 to 200 mCi in high-risk patients. If patients have an elevated Tg level, but negative RAI scan, some physicians recommend treating once with 100 mCi of ^{131}I and repeating the imaging 1 to 2 weeks later. Approximately one third of these patients demonstrate uptake on posttreatment imaging, and Tg levels usually decrease in these patients, documenting therapeutic benefit. Patients with previously positive scans and patients with serum Tg levels >2 ng/mL usually need another ^{131}I treatment after 6 to 12 months until one or two negative scans

are obtained. The follow-up scan can be done after hormone withdrawal or after recombinant TSH. The latter is more expensive but is preferred by patients. The maximum dose of radioiodine that can be administered at one time without performing dosimetry is approximately 200 mCi with a cumulative dose of 1000 to 1500 mCi. Up to 500 mCi can be given with proper pretreatment dosimetry. The early and delayed complications of RAI therapy are listed in Table 38-7.

Table 38-7 Complications of Radioactive Iodine Therapy (¹³¹ I) and Doses at Which They Are Observed	
Acute	Long-Term
Neck pain, swelling, and tenderness	Hematologic
Thyroiditis (if remnant present)	Bone marrow suppression (>500 mCi)
Sialadenitis (50–450 mCi), taste dysfunction	Leukemia (>1000 mCi)
Hemorrhage (brain metastases)	Fertility
Cerebral edema (brain metastases, 200 mCi)	Ovarian/testicular damage, infertility
Vocal cord paralysis	Increased spontaneous abortion rate
Nausea and vomiting (50–450 mCi)	
Bone marrow suppression (200 mCi)	Pulmonary fibrosis
	Chronic sialadenitis, nodules, taste dysfunction
	Increased risk of cancer
	Anaplastic thyroid cancer
	Gastric cancer
	Hepatocellular cancer
	Lung cancer
	Breast cancer (>1000 mCi)
	Bladder cancer
	Hypoparathyroidism

External Beam Radiotherapy and Chemotherapy

External beam radiotherapy is occasionally required to control unresectable, locally invasive or recurrent disease⁴⁴ and to treat metastases in support bones to decrease the risk of fractures. It also is of value for the treatment and control of pain from bony metastases when there is minimal or no RAIU. Single and multidrug chemotherapy has been used with little success in disseminated thyroid cancer, and there is no role for routine chemotherapy.³⁷ Doxorubicin (Adriamycin) and paclitaxel (Taxol) are the most frequently used agents. The former acts as a radiation sensitizer and should be considered in patients undergoing external beam radiation.

Thyroid Hormone

T4 is necessary not only as replacement therapy in patients after total or near-total thyroidectomy, but has the additional effect of suppressing TSH and reducing the growth stimulus for any possible residual thyroid cancer cells. TSH suppression reduces tumor recurrence rates. T₄ should be administered to ensure that the patient remains euthyroid, with circulating TSH levels at about 0.1 μU/L in low-risk patients, or <0.1 μU/mL in high-risk patients.³⁷ The risk of tumor recurrence must be balanced with the side effects associated with prolonged TSH suppression, including osteopenia and cardiac problems, particularly in older patients.

FOLLOW-UP OF PATIENTS WITH DIFFERENTIATED THYROID CANCER

Thyroglobulin Measurement

Tg levels in patients who have undergone total thyroidectomy should be <2 ng/mL when the patient is taking T4 , and <5 ng/mL when the patient is hypothyroid. A Tg level >2 ng/mL is highly suggestive of metastatic disease or persistent normal thyroid tissue, especially if it increases when TSH levels increase when hypothyroid during preparation for RAI scanning or after recombinant TSH. Approximately 95% of patients with persistent or recurrent thyroid cancer of follicular cell origin will have Tg levels >2 ng/mL. Tg and anti-Tg antibody levels should be measured initially at 6-month intervals and then annually if the patient is clinically disease free.³⁷ More recently, Tg measurements in FNAB aspirates have been shown to be useful in the detection of nodal metastatic disease.⁴⁵

Imaging

After the first posttreatment scan, low-risk patients with negative TSH-stimulated Tg and cervical ultrasound do not require routine diagnostic whole body radioiodine scans. However, diagnostic whole body scans 6 to 12 months after remnant ablation may be of value in the follow-up of patients with high or intermediate risk of persistent disease. It also is recommended that cervical ultrasound to evaluate the thyroid bed and central and lateral cervical nodal compartments should be performed at 6 and 12 months postthyroidectomy and then annually for at least 3 to 5 years, depending on the patients' risk for recurrent disease and Tg status. If RAI and ultrasound scans are negative but Tg levels remain elevated, FDG PET scans can help to localize the disease.³⁷

Medullary Carcinoma

MTC accounts for about 5% of thyroid malignancies and arises from the parafollicular or C cells of the thyroid, which, in turn, are derived from the ultimobranchial bodies. These cells are concentrated superolaterally in the thyroid lobes, and this is where MTC usually develops. C cells secrete calcitonin, a 32-amino-acid polypeptide that functions to lower serum calcium levels, although its effects in humans are minimal. Most MTCs occur sporadically. However, approximately 25% occur within the spectrum of several inherited syndromes such as familial MTC, MEN2A, and MEN2B. All these variants are known to result secondary to germline mutations in the *RET* proto-oncogene. The syndromes also are characterized by genotype-phenotype correlations, with specific mutations leading to particular clinical manifestations. The salient clinical and genetic features of these syndromes are outlined in Table 38-8. Some clinical features of MEN2B patients are shown in Fig. 38-20.

Table 38-8 Clinical and Genetic Features of Medullary Thyroid Cancer Syndromes		
Syndrome	Manifestations	Ret Mutations
MEN2A	MTC, pheochromocytoma, primary hyperparathyroidism, lichen planus amyloidosis	Exon 10—codons 609, 611, 618, 620
		Exon 11—codon 634 (more commonly associated with pheochromocytoma and primary hyperparathyroidism)
MEN2B	MTC, pheochromocytoma, Marfanoid habitus, mucocutaneous ganglioneuromatosis	Exon 16—codon 918
Familial MTC	MTC	Codons 609, 611, 618, 620, and 634
		Codons 768, 790, 791, or 804 (rare)
MEN2A and Hirschsprung's disease	MTC, pheochromocytoma, primary hyperparathyroidism, Hirschsprung's disease	Codons 609, 618, 620

MTC = medullary thyroid cancer.

Features of MEN2B: thickened lips (**A**) and mucosal neuromas (**A** and **B**).

Patients with MTC often present with a neck mass that may be associated with palpable cervical lymphadenopathy (15 to 20%). Pain or aching is more common in patients with these tumors, and local invasion may produce symptoms of dysphagia, dyspnea, or dysphonia. Distant blood-borne metastases to the liver, bone (frequently osteoblastic), and lung occur later in the disease. The female-to-male ratio is 1.5:1. Most patients present between 50 and 60 years old, although patients with familial disease present at a younger age. Medullary thyroid tumors secrete not only calcitonin and carcinoembryonic antigen (CEA), but also other peptides such as calcitonin gene-related peptide, histaminases, prostaglandins E_2 and $F_{2\alpha}$, and serotonin. Patients with extensive

metastatic disease frequently develop diarrhea, which may result from increased intestinal motility and impaired intestinal water and electrolyte flux. About 2 to 4% of patients develop Cushing's syndrome as a result of ectopic production of adrenocorticotrophic hormone (ACTH).

Pathology

MTCs typically are unilateral (80%) in patients with sporadic disease and multicentric in familial cases, with bilateral tumors occurring in up to 90% of familial patients. Familial cases also are associated with C-cell hyperplasia, which is considered a premalignant lesion. Microscopically, tumors are composed of sheets of infiltrating neoplastic cells separated by collagen and amyloid. Marked heterogeneity is present; cells may be polygonal or spindle shaped. The presence of amyloid is a diagnostic finding, but immunohistochemistry for calcitonin is more commonly used as a diagnostic tumor marker. These tumors also stain positively for CEA and calcitonin gene-related peptide.

Diagnosis

The diagnosis of MTC is established by history, physical examination, raised serum calcitonin, or CEA levels, and FNAB cytology of the thyroid mass. Attention to family history is important because about 25% of patients with MTC have familial disease. Because it is not possible to distinguish sporadic from familial disease at initial presentation, all new patients with MTC should be screened for *RET* point mutations, pheochromocytoma, and HPT. Screening of patients with familial MTC for *RET* point mutations has largely replaced using provocation testing with pentagastrin or calcium-stimulated calcitonin levels to make the diagnosis. Calcitonin and CEA are used to identify patients with persistent or recurrent MTC. Calcitonin is a more sensitive tumor marker, but CEA is a better predictor of prognosis.

Treatment

If patients are found to have a pheochromocytoma, this must be operated on first. These tumors are generally (>50%) bilateral. Total thyroidectomy is the treatment of choice for patients with MTC because of the high incidence of multicentricity, the more aggressive course, and the fact that ^{131}I therapy usually is not effective. Central compartment nodes frequently are involved early in the disease process, so that a bilateral central neck node dissection should be routinely performed. In patients with palpable cervical nodes or involved central neck nodes, ipsilateral or bilateral, modified radical neck dissection is recommended. The role of prophylactic lateral neck dissection is controversial. However, in patients with tumors >1 cm, ipsilateral prophylactic modified radical neck dissection is recommended because >60% of these patients have nodal metastases. If ipsilateral nodes are positive, a contralateral node dissection should be performed. In the case of locally recurrent or metastatic disease, tumor debulking is advised not only to ameliorate symptoms of flushing and diarrhea, but also to decrease risk of death from recurrent central neck or mediastinal disease. External beam radiotherapy is controversial, but is recommended for patients with unresectable residual or recurrent tumor. There is no effective chemotherapy regimen. Various targeted therapies are being investigated for the treatment of MTC. A tyrosine kinase inhibitor STI571 (imatinib) had shown promise in in vitro studies, but phase II clinical trials have been less encouraging.^{46,47} Another tyrosine kinase inhibitor with activity against the vascular endothelial growth factor receptor 2, ZD6474 (Zactima) was more effective in that phase II studies have shown partial responses in 27% of patients, with reduction in both calcitonin and CEA levels. An anti-CEA monoclonal antibody (labetuzumab) also has shown antitumor response in a small group of patients.⁴⁸ Radiofrequency ablation done laparoscopically appears promising in the palliative treatment of liver metastases >1.5 cm.

In patients who have hypercalcemia at the time of thyroidectomy, only obviously enlarged parathyroid glands should be removed. The other parathyroid glands should be preserved and marked in patients with normocalcemia, as only about 20% of patients with MEN2A develop HPT. When a normal parathyroid cannot be maintained on a vascular pedicle, it should be removed, biopsied to confirm that it is a parathyroid, and then autotransplanted to the forearm of the nondominant arm. Total thyroidectomy is indicated in *RET* mutation carriers once the mutation is confirmed. The procedure should be performed before age 6 in MEN2A patients and

before age 1 year old in MEN2B patients. Central neck dissection can be avoided in children who are *RET* -positive and calcitonin-negative with a normal ultrasound examination. When the calcitonin is increased or the ultrasound suggests a thyroid cancer, a prophylactic central neck dissection is indicated.

Postoperative Follow-Up and Prognosis

Patients are followed by annual measurements of calcitonin and CEA levels, in addition to history and physical examination. Other modalities used to localize recurrent disease include ultrasound, CT, MRI, and more recently, FDG PET scans. The latter have been reported to be superior to other radionuclide-based and routine morphologic imaging by some investigators.⁵¹ Prognosis is related to disease stage. The 10-year survival rate is approximately 80% but decreases to 45% in patients with lymph node involvement. Survival also is significantly influenced by disease type. It is best in patients with non-MEN familial MTC, followed by those with MEN2A, and then those with sporadic disease. Prognosis is the worst (survival 35% at 10 years) in patients with MEN2B. Performing prophylactic surgery in *RET* oncogene mutation carriers not only improves survival rates but also renders most patients calcitonin free.

Anaplastic Carcinoma

Anaplastic carcinoma accounts for approximately 1% of all thyroid malignancies in the United States and is declining in incidence. Women are more commonly affected, and the majority of tumors present in the seventh and eighth decade of life. The typical patient has a long-standing neck mass, which rapidly enlarges and may be painful. Associated symptoms such as dysphonia, dysphagia, and dyspnea are common. The tumor is large and may be fixed to surrounding structures or may be ulcerated with areas of necrosis (Fig. 38-21). Lymph nodes usually are palpable at presentation. Evidence of metastatic spread also may be present. Diagnosis is confirmed by FNAB revealing characteristic giant and multinucleated cells. Incisional biopsy occasionally is needed to confirm the diagnosis, and isthmusectomy with or without a tracheostomy may be needed to alleviate tracheal obstruction.

Magnetic resonance imaging scan of a patient with anaplastic thyroid cancer. Note heterogeneity consistent with necrosis.

Pathology

On gross inspection, anaplastic tumors are firm and whitish in appearance. Microscopically, sheets of cells with marked heterogeneity are seen. Cells may be spindle shaped, polygonal, or large, multinucleated cells. Foci of more differentiated thyroid tumors, either follicular or papillary, may be seen, suggesting that anaplastic tumors arise from more well-differentiated tumors. One should confirm that the tumor is not a MTC or a small cell lymphoma because the prognosis varies considerably.

Treatment and Prognosis

This tumor is one of the most aggressive thyroid malignancies, with few patients surviving 6 months beyond diagnosis. All forms of treatment have been disappointing. If anaplastic carcinoma presents as a resectable mass, thyroidectomy may lead to a small improvement in survival, especially in younger individuals. Combined radiation and chemotherapy in an adjuvant setting in patients with resectable disease has been associated with prolonged survival,⁵² although these agents are also being used in a neoadjuvant fashion. Tracheostomy may be needed to alleviate airway obstruction.

Lymphoma

Lymphomas account for <1% of thyroid malignancies and most are of the non-Hodgkin's B-cell type. Although the disease can arise as part of a generalized lymphomatous condition, most thyroid lymphomas develop in patients with chronic lymphocytic thyroiditis. Chronic antigenic lymphocyte stimulation has been suggested to result in lymphocyte transformation. Patients usually present with symptoms similar to those of patients with anaplastic carcinoma, although the rapidly enlarging neck mass often is painless. Patients may present with acute respiratory distress. The diagnosis usually is suggested by FNAB, although needle-core or open biopsy may be necessary for definitive diagnosis. Staging studies should be obtained expeditiously to assess the extent of extrathyroidal spread.

Treatment and Prognosis

Patients with thyroid lymphoma respond rapidly to chemotherapy (CHOP—cyclophosphamide, doxorubicin, vincristine, and prednisone), which also has been associated with improved survival. Combined treatment with radiotherapy and chemotherapy often is recommended. Thyroidectomy and nodal resection are used to alleviate symptoms of airway obstruction in patients who do not respond quickly to the above regimens or who have completed the regimen before diagnosis. Prognosis depends on the histologic grade of the tumor and whether the lymphoma is confined to the thyroid gland or is disseminated. The overall 5-year survival rate is about 50%; patients with extrathyroidal disease have markedly lower survival rates.

Metastatic Carcinoma

The thyroid gland is a rare site of metastases from other cancers, including kidney, breast, lung, and melanoma. Clinical examination and a review of the patient's history often suggest the source of the metastatic disease, and FNAB usually provides definitive diagnosis. Resection of the thyroid, usually lobectomy, may be helpful in many patients, depending on the status of their primary tumor.

THYROID SURGERY

Conduct of Thyroidectomy

Patients with any recent or remote history of altered phonation or prior neck surgery should undergo vocal cord assessment by direct or indirect laryngoscopy before thyroidectomy. The patient is positioned supine, with a sandbag between the scapulae. The head is placed on a donut cushion and the neck is extended to provide maximal exposure. A Kocher transverse collar incision, typically 4 to 5 cm in length, is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage (Fig. 38-22A), although longer incisions may be needed. The subcutaneous tissues and platysma are incised sharply and subplatysmal flaps are raised superiorly to the level of the thyroid cartilage and inferiorly to the suprasternal notch (Fig. 38-22B). The strap muscles are divided in the midline along the entire length of the mobilized flaps, and the thyroid gland is exposed. On the side to be approached first, the sternohyoid muscles are separated from the underlying sternothyroid muscle by blunt dissection until the internal jugular vein and ansa cervicalis nerve are identified. The strap muscles rarely need to be divided to gain exposure to the thyroid gland. If this maneuver is necessary, the muscles should be divided high to preserve their innervation by branches of the ansa cervicalis. If there is evidence of direct tumor invasion into the strap muscles, the portion of involved muscle should be resected en bloc with the thyroid gland. The sternothyroid muscle is then dissected off the underlying thyroid by a combination of sharp and blunt dissection, thus exposing the middle thyroid veins. The thyroid lobe is retracted medially and anteriorly and the lateral tissues are swept posterolaterally using a peanut sponge. The middle thyroid veins are ligated and divided (Fig. 38-22C). Attention is then turned to the midline where Delphian nodes and the pyramidal lobe are identified. The fascia just cephalad and caudad to the isthmus is divided. The superior thyroid pole is identified by retracting the thyroid first inferiorly and medially and then the upper pole of the thyroid is mobilized caudally and laterally. The dissection plane is kept as close to the thyroid as possible and the superior pole vessels are individually identified, skeletonized, ligated, and divided low on the thyroid gland to avoid injury to the external branch of the superior laryngeal nerve (Fig. 38-22D). Once these vessels are divided, the tissues posterior and lateral to the superior pole can be swept from the gland in a posteromedial direction, to reduce the risk of damaging vessels supplying the upper parathyroid.

Conduct of thyroidectomy. **A.** Correct placement of thyroidectomy incision. **B.** Raising subplatysmal flaps. **C.** Dissection of middle thyroid vein. **D.** Dissection of the superior pole vessels, which should be individually ligated. **E.** Dissection at the ligament of Berry. Note small artery and vein within the ligament and the recurrent laryngeal nerve coursing laterally. **F.** Endoscopic thyroidectomy via axillary incisions. m. = muscle; n. = nerve; v. = vein.

The RLNs should then be identified. The course of the right RLN is more oblique than the left RLN. The nerves can be most consistently identified at the level of the cricoid cartilage. The parathyroids usually can be identified within 1 cm of the crossing of

the inferior thyroid artery and the RLN, although they also may be ectopic in location. The lower pole of the thyroid gland should be mobilized by gently sweeping all tissues dorsally. The inferior thyroid vessels are dissected, skeletonized, ligated, and divided as close to the surface of the thyroid gland as possible to minimize devascularization of the parathyroids (extracapsular dissection) or injury to the RLN. The RLN is most vulnerable to injury in the vicinity of the ligament of Berry. The nerve often passes through this structure along with small crossing arterial and venous branches (Fig. 38-22E). Any bleeding in this area should be controlled with gentle pressure before carefully identifying the vessel and ligating it. Use of the electrocautery should be avoided in proximity to the RLN. Once the ligament is divided, the thyroid can be separated from the underlying trachea by sharp dissection. The pyramidal lobe, if present, must be dissected in a cephalad direction to above the level of the notch in the thyroid cartilage or higher in continuity with the thyroid gland. If a lobectomy is to be performed, the isthmus is divided flush with the trachea on the contralateral side and suture ligated. The procedure is repeated on the opposite side for a total thyroidectomy.

Parathyroid glands that are located anteriorly on the surface of the thyroid cannot be dissected from the thyroid with a good blood supply or that have been inadvertently removed during the thyroidectomy should be resected, confirmed as parathyroid tissue by frozen section, divided into 1-mm fragments, and reimplanted into individual pockets in the sternocleidomastoid muscle. The sites should be marked with silk sutures and a clip. If a subtotal thyroidectomy is to be performed, once the superior pole vessels are divided and the thyroid lobe mobilized anteriorly, the thyroid lobe is cross-clamped with a Mayo clamp, leaving approximately 4 g of the posterior portion of the thyroid. The thyroid remnant is suture ligated, taking care to avoid injury to the RLN. Routine drain placement rarely is necessary. After adequate hemostasis is obtained, the strap muscles are reapproximated in the midline. The platysma is approximated in a similar fashion. The skin can be closed with subcuticular sutures or clips.

Minimally Invasive Approaches

Several approaches to minimally invasive thyroidectomy have been described. Mini-incision procedures use a small, 3-cm incision with no flap creation and minimal dissection to deliver the thyroid into the wound and then perform the pretracheal and paratracheal dissection. Video assistance can be used to improve the visualization via the small incision. Totally endoscopic approaches also have been described, via the supraclavicular, anterior chest, axillary, and breast approach. The axillary, anterior chest, and breast approaches eliminate the skin incision in the neck but are more invasive. All endoscopic thyroidectomies are performed under general anesthesia. For the axillary approach, a 30-mm skin incision is made in the axilla, and 12-mm and 5-mm trocars are inserted through this incision (Figure 38-22F). An additional 5-mm trocar is inserted adjacent to the incision. For the anterior chest approach, a 12-mm skin incision is made in the skin of the anterior chest approximately 3 to 5 cm below the border of the ipsilateral clavicle. Two additional 5-mm trocars are inserted by endoscopic guidance below the ipsilateral clavicle, and carbon dioxide (CO₂) is then insufflated up to a pressure of 4 mmHg to facilitate creation of a working space. The anterior border of the sternocleidomastoid muscle is then separated from the sternohyoid muscle to expose the sternothyroid muscle. The thyroid gland is exposed by splitting the sternothyroid muscle. The lower pole is retracted upward and dissected from the adipose tissue to identify the RLN. As the RLN is exposed, Berry's ligament is exposed and incised with a 5-mm clip or laparoscopic coagulating shears. The upper pole of the thyroid gland is separated from the cricothyroid muscle, and the external branch of the superior laryngeal nerve can be identified during this maneuver. The upper pole of the thyroid gland then is dissected free.

These methods are feasible, but clear benefits over the "traditional" open approach have not been established.

Surgical Removal of Intrathoracic Goiter

A goiter is considered mediastinal if at least 50% of the thyroid tissue is located intrathoracically. Mediastinal goiters can be primary or secondary. Primary mediastinal goiters constitute approximately 1% of all mediastinal goiters and arise from accessory (ectopic) thyroid tissue located in the chest. These goiters are supplied by intrathoracic blood vessels and do not have any connection to thyroid tissue in the neck. The vast majority of mediastinal goiters are, however, secondary mediastinal goiters that arise from downward extension of cervical thyroid tissue along the fascial planes of the neck and derive their blood supply from the superior

and inferior thyroid arteries. Virtually all intrathoracic goiters can be removed via a cervical incision. Patients who have (a) invasive thyroid cancers, (b) had previous thyroid operations and may have developed parasitic mediastinal vessels, or (c) primary mediastinal goiters with no thyroid tissue in the neck may require a median sternotomy for removal.⁵³ The chest, however, should be prepared in most cases in the event it is necessary to perform a median sternotomy to control mediastinal bleeding or completely remove an unsuspected invasive cancer. The goiter is approached via a neck incision. The superior pole vessels and the middle thyroid veins are identified and ligated first. Early division of the isthmus helps with subsequent mobilization of the substernal goiter from beneath the sternum. Placement of large 1-0 or 2-0 sutures deep into the goiter, when necessary, helps deliver it. For patients in whom thyroid cancer is suspected or demonstrated in an intrathoracic gland, attempts should be made to avoid rupture of the thyroid capsule. When sternotomy is indicated, the sternum usually should be divided to the level of the third intercostal space and then laterally on one side at the space between the third and fourth ribs (Fig. 38-23).

Central and Lateral Neck Dissection for Nodal Metastases

Central compartment (medial to the carotid sheath) lymph nodes frequently are involved in patients with papillary, medullary, and Hürthle cell carcinomas and should be removed at the time of thyroidectomy, preserving the RLNs and parathyroid glands. Central neck dissection is particularly important in patients with medullary and Hürthle cell carcinoma because of the high frequency of microscopic tumor spread and because these tumors cannot be ablated with ¹³¹I. An ipsilateral modified radical neck dissection is indicated in the presence of palpable cervical lymph nodes or prophylactically in patients with medullary carcinoma when the thyroid lesion is >1 cm.

A modified radical (functional) neck dissection can be performed via the cervical incision used for thyroidectomy, which can be extended laterally (Fig. 38-24A) to the anterior margin of the trapezius muscle (MacFee extension). The procedure involves removal of all fibro-fatty tissue along the internal jugular vein (levels II, III, and IV) and the posterior triangle (level V). In contrast to a radical neck dissection, the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle are preserved unless they are adherent to or invaded by tumor. The procedure begins by opening the

plane between the strap muscles medially and the sternocleidomastoid muscle laterally. The anterior belly of the omohyoid muscle is retracted laterally, and the dissection is carried posteriorly until the carotid sheath is reached. The internal jugular vein is retracted medially with a vein retractor and the fibro-fatty tissue and lymph nodes are dissected away from it by a combination of sharp and blunt dissection. The lateral dissection is carried along the posterior border of the sternocleidomastoid muscle, removing the tissue from the posterior triangle. The deep dissection plane is the anterior scalenus muscle, the phrenic nerve, the brachial plexus, and the medial scalenus muscle. The phrenic nerve is preserved on the scalenus anterior muscle, as are the cervical sensory nerves in most patients (Fig. 38-24B). Dissection along the spinal accessory nerve superiorly is most important because this is a frequent site of metastatic disease.

Complications of Thyroid Surgery

Nerves, parathyroids, and surrounding structures are all at risk of injury during thyroidectomy. Injury to the RLN may occur by severance, ligation, or traction, but should occur in <1% of patients undergoing thyroidectomy by experienced surgeons. The RLN is most vulnerable to injury during the last 2 to 3 cm of its course, but also can be damaged if the surgeon is not alert to the possibility of nerve branches and the presence of a nonrecurrent nerve, particularly on the right side. If the injury is recognized intraoperatively, most surgeons advocate primary reapproximation of the perineurium using nonabsorbable sutures. Approximately 20% of patients are at risk of injury to the external branches of the superior laryngeal nerve, especially if superior pole vessels are ligated en masse. Intraoperative RLN and external laryngeal nerve monitoring techniques are being increasingly used during thyroid and parathyroid surgery. Both continuous monitoring using endotracheal tube electrodes and intermittent monitoring by periodic stimulation and laryngeal palpation are used. No large scale studies have shown that nerve monitoring equivocally reduces nerve injury, particularly by experienced surgeons.⁵⁴ The cervical sympathetic trunk is at risk of injury in invasive thyroid cancers and retroesophageal goiters and may result in Horner's syndrome. Transient hypocalcemia (from surgical injury or inadvertent removal of parathyroid tissue) has been reported in up to 50% of cases, but permanent hypoparathyroidism occurs <2% of the time. Postoperative hypocalcemia is more likely in patients who undergo concomitant thyroidectomy, central and lateral neck dissection. Postoperative hematomas or bleeding may also complicate thyroidectomies and rarely necessitate emergency reoperation to evacuate the hematoma. Bilateral vocal cord dysfunction with airway compromises requires immediate reintubation and tracheostomy. Seromas may need aspiration to relieve patient discomfort. Wound cellulitis and infection, and injury to surrounding

structures such as the carotid artery, jugular vein, and esophagus are infrequent.

PARATHYROID

Historical Background

In 1849, the curator of the London Zoological Gardens, Sir Richard Owen, provided the first accurate description of the normal parathyroid gland after autopsy examination of an Indian rhinoceros. However, human parathyroids were not grossly and microscopically described until 1879 by Ivar Sandström, a medical student in Uppsala, Sweden. He suggested that these glands be named the *glandulae parathyroideae*, although their function was not known.

The association of HPT and the bone disease osteitis fibrosa cystica (described by von Recklinghausen) was recognized in 1903. Calcium measurement became possible in 1909, and the association between serum calcium levels and the parathyroid glands was established. The first successful parathyroidectomy was performed in 1925 by Felix Mandl on a 38-year-old man who had severe bone pain secondary to advanced osteitis fibrosa cystica. The patient's condition dramatically improved after the operation, and he lived for another 7 years before dying of recurrent HPT or renal failure. In 1926, the first parathyroid operation was performed at Massachusetts General Hospital. Edward Churchill, assisted by an intern named Oliver Cope, operated on the famous sea captain Charles Martell for severe PHPT. It was not until his seventh operation, which included total thyroidectomy, that an ectopic adenoma was found substernally. Unfortunately, Captain Martell died 6 weeks later, likely due to laryngeal spasm and complications of renal stones and ureteral obstruction. The first successful parathyroidectomy for HPT in the United States was performed on a 56-year-old woman in 1928 by Isaac Y. Olch at the Barnes Hospital in St. Louis, Missouri. At operation, a parathyroid adenoma was found attached to the left lower lobe of the thyroid gland. Postoperatively, the patient developed tetany, requiring lifelong supplemental calcium.

Embryology

In humans, the superior parathyroid glands are derived from the fourth branchial pouch, which also gives rise to the thyroid gland. The third branchial pouches give rise to the inferior parathyroid glands and the thymus (Fig. 38-25). The parathyroids remain closely associated with their respective branchial pouch derivatives. The position of normal superior parathyroid glands is more consistent, with 80% of these glands being found near the posterior aspect of the upper and middle thyroid lobes, at the level of the cricoid cartilage.⁵⁵ Approximately 1% of normal upper glands may be found in the paraesophageal or retroesophageal space. Enlarged superior glands may descend in the tracheoesophageal groove and come to lie caudal to the inferior glands. Truly ectopic superior parathyroid glands are rare, but may be found in the middle or posterior mediastinum, or in the aortopulmonary window.⁵⁵ As the embryo matures, the thymus and inferior parathyroids migrate together caudally in the neck. The most common location for inferior glands is within a distance of 1 cm from a point centered where the inferior thyroid artery and RLN cross. Approximately 15% of inferior glands are found in the thymus. The position of the inferior glands, however, tends to be more variable due to their longer migratory path. Undescended inferior glands may be found near the skull base, angle of the mandible, or superior to the upper parathyroid glands along with an undescended thymus. The frequency of intrathyroidal glands is about 2%.

Parathyroid embryology. Figure demonstrates a schematic view of the pharynx of an 8- to 10-mm embryo (**A**) and locations of the thyroid, parathyroid, and thymic tissues in a 13- to 14-mm embryo (**B**). The lower parathyroids are derived from the third branchial pouch and migrate with the thymus, whereas the upper parathyroids are derived from the fourth branchial pouch and lie in close proximity to the ultimobranchial bodies.

Anatomy and Histology

Most patients have four parathyroid glands. The superior glands usually are dorsal to the RLN at the level of the cricoid cartilage, whereas the inferior parathyroid glands are located ventral to the nerve. Normal parathyroid glands are gray and semitransparent in newborns but appear golden yellow to light brown in adults. Parathyroid color depends on cellularity, fat content, and vascularity. Moreover, they often are embedded in and sometimes difficult to discern from surrounding fat. Normal parathyroid glands are located in loose tissue or fat and are ovoid. They measure up to 7 mm in size and weigh approximately 40 to 50 mg each.

Parathyroid glands usually derive their blood supply from branches of the inferior thyroid artery, although branches from the superior thyroid artery supply at least 20% of upper glands. Branches from the thyroidea ima, and vessels to the trachea, esophagus, larynx, and mediastinum may also be found. The parathyroid glands drain ipsilaterally by the superior, middle, and inferior thyroid veins.

Akerström and colleagues,⁵⁵ in an autopsy series of 503 cadavers, found four parathyroid glands in 84% of cases. Supernumerary glands were present in 13% of patients, most commonly in the thymus. Only 3% of patients had less than four glands. Similar results were obtained in other dissection studies of 428 human subjects by Gilmour who reported a 6.7% incidence of supernumerary glands.⁵⁶

Histologically, parathyroid glands are composed of chief cells and oxyphil cells arranged in trabeculae, within a stroma composed primarily of adipose cells (Fig. 38-26). The parathyroid glands of infants and children are composed mainly of chief cells, which produce parathyroid hormone (PTH). Acidophilic, mitochondria-rich oxyphil cells are derived from chief cells, can be seen around puberty, and increase in numbers in adulthood. A third group of cells, known as *water-clear cells*, also are derived from chief cells, are present in small numbers, and are rich in glycogen. Although most oxyphil and water-clear cells retain the ability to secrete PTH, their functional significance is not known.

Parathyroid Physiology and Calcium Homeostasis

Calcium is the most abundant cation in human beings, and has several crucial functions. Extracellular calcium levels are 10,000-fold higher than intracellular levels, and both are tightly controlled. Extracellular calcium is important for excitation-contraction coupling in muscle tissues, synaptic transmission in the nervous system, coagulation, and secretion of other hormones. Intracellular calcium is an important second messenger regulating cell division, motility, membrane trafficking, and secretion. Calcium is absorbed from the small intestine in its inorganic form. Calcium fluxes in the steady state are depicted in Fig. 38-27.

Fig. 38-27.

Calcium balance and fluxes in a normal human. *Solid arrows* depict a direct effect, whereas *dashed arrows* depict an indirect effect. The thickness of the arrows is representative of the magnitude of the flux. ECF = extracellular fluid; PTH = parathyroid hormone; VIT. = vitamin.

[Reproduced with permission from Bruder J, et al: Mineral metabolism, in Felig P, Frohman L (eds): *Endocrinology and Metabolism*. New York: McGraw-Hill Publishers, Inc., 2001, p 1081.]

Extracellular calcium (900 mg) accounts for only 1% of the body's calcium stores, the majority of which is sequestered in the skeletal system. Approximately 50% of the serum calcium is in the ionized form, which is the active component. The remainder is bound to albumin (40%) and organic anions such as phosphate and citrate (10%). The total serum calcium levels range from 8.5 to 10.5 mg/dL (2.1 to 2.6 mmol/L) and ionized calcium levels range from 4.4 to 5.2 mg/dL (1.1 to 1.3 mmol/L). Both concentrations are tightly regulated. The total serum calcium level must always be considered in its relationship to plasma protein levels, especially serum albumin. For each gram per deciliter of alteration of serum albumin above or below 4.0 mg/dL, there is a 0.8 mg/dL increase or decrease in protein-bound calcium, and thus, in total serum calcium levels. Total and, particularly, ionized calcium levels are influenced by various hormone systems.

PARATHYROID HORMONE

The parathyroid cells rely on a G-protein coupled membrane receptor, designated the calcium-sensing receptor (CASR), to regulate PTH secretion by sensing extracellular calcium levels⁵⁷ (Fig. 38-28). PTH secretion also is stimulated by low levels of 1,25-dihydroxy vitamin D, catecholamines, and hypomagnesemia. The PTH gene is located on chromosome 11. PTH is synthesized in the parathyroid gland as a precursor hormone preproPTH, which is cleaved first to pro-PTH and then to the final 84-amino-acid PTH. Secreted PTH has a half-life of 2 to 4 minutes. In the liver, PTH is metabolized into the active N-terminal component and the relatively inactive C-terminal fraction. The C-terminal component is excreted by the kidneys and accumulates in chronic renal failure.

Fig. 38-28.

Regulation of calcium homeostasis. The calcium-sensing receptor (CASR) is expressed on the surface of the parathyroid cell and senses fluctuations in the concentration of extracellular calcium. Activation of the receptor is thought to increase intracellular calcium levels, which, in turn, inhibit parathyroid hormone (PTH) secretion via posttranslational mechanisms. Increased PTH secretion leads to an increase in serum calcium levels by increasing bone resorption and enhancing renal calcium reabsorption. PTH also stimulates renal 1- α -hydroxylase activity, leading to an increase in 1,25-dihydroxy vitamin D, which also exerts a negative feedback on PTH secretion. PKC = protein kinase C; PLC = phospholipase C.

(Reproduced with permission from Carling T: Molecular pathology of parathyroid tumors. *Trends Endocrinol Metab* 12:54, 2001. Copyright Elsevier.)

PTH functions to regulate calcium levels via its actions on three target organs, the bone, kidney, and gut. PTH increases the resorption of bone by stimulating osteoclasts and promotes the release of calcium and phosphate into the circulation. At the kidney, calcium is primarily absorbed in concert with sodium in the proximal convoluted tubule, but fine adjustments occur more distally. PTH acts to limit calcium excretion at the distal convoluted tubule via an active transport mechanism. PTH also inhibits phosphate reabsorption (at the proximal convoluted tubule) and bicarbonate reabsorption. It also inhibits the Na^+/H^+ antiporter, which results

in a mild metabolic acidosis in hyperparathyroid states. PTH and hypophosphatemia also enhance 1-hydroxylation of 25-hydroxyvitamin D, which is responsible for its indirect effect of increasing intestinal calcium absorption.

CALCITONIN

Calcitonin is produced by thyroid C cells and functions as an antihypercalcemic hormone by inhibiting osteoclast-mediated bone resorption. Calcitonin production is stimulated by calcium and pentagastrin and also by catecholamines, cholecystokinin, and glucagon. When administered intravenously to experimental animals, it produces hypocalcemia. At the kidney, calcitonin increases phosphate excretion by inhibiting its reabsorption. Calcitonin plays a minimal, if any, role in the regulation of calcium levels in humans. However, it is very useful as a marker of MTC and in treating acute hypercalcemic crisis.

VITAMIN D

Vitamin D refers to vitamin D₂ and vitamin D₃, both of which are produced by photolysis of naturally occurring sterol precursors. Vitamin D₂ is available commercially in pharmaceutical preparations, whereas vitamin D₃ is the most important physiologic compound and is produced from 7-dehydrocholesterol, which is found in the skin. Vitamin D is metabolized in the liver to its primary circulating form, 25-hydroxyvitamin D. Further hydroxylation in the kidney results in 1,25-dihydroxy vitamin D, which is the most metabolically active form of vitamin D. Vitamin D stimulates the absorption of calcium and phosphate from the gut and the resorption of calcium from the bone.

Hyperparathyroidism

Hyperfunction of the parathyroid glands may be classified as primary, secondary, or tertiary. PHPT arises from increased PTH production from abnormal parathyroid glands and results from a disturbance of normal feedback control exerted by serum calcium. Elevated PTH levels may also occur as a compensatory response to hypocalcemic states resulting from chronic renal failure or GI malabsorption of calcium. This secondary HPT can be reversed by correction of the underlying problem (e.g., kidney transplantation for chronic renal failure). However, chronically stimulated glands may occasionally become autonomous, resulting in persistence or recurrence of hypercalcemia after successful renal transplantation, resulting in tertiary HPT.

PRIMARY HYPERPARATHYROIDISM

PHPT is a common disorder, affecting 100,000 individuals annually in the United States. PHPT occurs in 0.1 to 0.3% of the general population and is more common in women (1:500) than in men (1:2000). Increased PTH production leads to hypercalcemia via increased GI absorption of calcium, increased production of vitamin D₃, and reduced renal calcium clearance. PHPT is characterized by increased parathyroid cell proliferation and PTH secretion that is independent of calcium levels.

Etiology

The exact cause of PHPT is unknown, although exposure to low-dose therapeutic ionizing radiation and familial predisposition account for some cases. Various diets and intermittent exposure to sunshine may also be related. Other causes include renal leak of calcium and declining renal function with age as well as alteration in the sensitivity of parathyroid glands to suppression by calcium. The latency period for development of PHPT after radiation exposure is longer than that for the development of thyroid tumors, with most cases occurring 30 to 40 years after exposure. Patients who have been exposed to radiation have similar clinical presentations and calcium levels when compared to patients without a history of radiation exposure. However, the former tend to have higher PTH levels and a higher incidence of concomitant thyroid neoplasms. Lithium therapy has been known to shift the set point for PTH secretion in parathyroid cells, thereby resulting in elevated PTH levels and mild hypercalcemia. Lithium stimulates the growth of abnormal parathyroid glands in vitro and also in susceptible patients in vivo.⁵⁸ PHPT results from the enlargement of a single gland or parathyroid adenoma in approximately 80% of cases, multiple adenomas or hyperplasia in 15 to 20% of patients, and parathyroid carcinoma in 1% of patients. Existence of two enlarged glands or double adenomas is supported by biochemical (calcium and PTH),

intraoperative PTH (IOPTH), molecular, and histologic data. This entity is less common in younger patients but accounts for up to 10% of older patients with PHPT. It should be emphasized that when more than one abnormal parathyroid gland is identified preoperatively or intraoperatively, the patient has hyperplasia (all glands abnormal) until proven otherwise.

GENETICS

Most cases of PHPT are sporadic. However, PHPT also occurs within the spectrum of a number of inherited disorders such as MEN1, MEN2A, isolated familial HPT, and familial HPT with jaw-tumor syndrome. All of these syndromes are inherited in an autosomal dominant fashion. PHPT is the earliest and most common manifestation of MEN1⁵⁹ and develops in 80 to 100% of patients by age 40 years old. These patients also are prone to pancreatic neuroendocrine tumors and pituitary adenomas and, less commonly, to adrenocortical tumors, lipomas, skin angiomas, and carcinoid tumors of the bronchus, thymus, or stomach. About 50% of patients develop gastrinomas, which often are multiple and metastatic at diagnosis. Insulinomas develop in 10 to 15% of cases, whereas many patients have nonfunctional pancreatic endocrine tumors. Prolactinomas occur in 10 to 50% of MEN1 patients and constitute the most common pituitary lesion. MEN1 has been shown to result from germline mutations in the *MEN1* gene, a tumor-suppressor gene located on chromosome 11q12-13 which encodes menin, a protein that is postulated to interact with the transcription factors JunD and nuclear factor κ B in the nucleus, in addition to replication protein A and other proteins.⁶⁰ Most *MEN1* mutations result in a nonfunctional protein and are scattered throughout the translated nine exons of the gene. This makes presymptomatic screening for mutation carriers difficult. *MEN1* mutations also have been found in kindreds initially suspected to represent isolated familial HPT. HPT develops in about 20% of patients with MEN2A and generally is less severe. MEN2A is caused by germline mutations of the *RET* proto-oncogene located on chromosome 10. In contrast to MEN1, genotype-phenotype correlations have been noted in this syndrome in that individuals with mutations at codon 634 are more likely to develop HPT. Patients with the familial HPT with jaw-tumor syndrome have an increased predisposition to parathyroid carcinoma. This syndrome maps to a tumor-suppressor locus *HRPT2*, on chromosome 1. Patients belonging to isolated HPT kindreds also appear to demonstrate linkage to *HRPT2*.

Approximately 25 to 40% of sporadic parathyroid adenomas and some hyperplastic parathyroid glands have LOH at 11q 13, the site of the *MEN1* gene. The parathyroid adenoma 1 oncogene (*PRAD1*), which encodes cyclin D1, a cell cycle control protein, is overexpressed in about 18% of parathyroid adenomas. This was demonstrated to result from a rearrangement on chromosome 11 that places the *PRAD1* gene under the control of the PTH promoter. Other chromosomal regions deleted in parathyroid adenomas and possibly reflecting loss of tumor-suppressor genes include 1p, 6q, and 15q, whereas amplified regions suggesting oncogenes have been identified at 16p and 19p. Sporadic parathyroid cancers are characterized by uniform loss of the tumor-suppressor gene *RB*, which is involved in cell cycle regulation, and 60% have *HRPT2* mutations. These alterations are rare in benign parathyroid tumors and may have implications for diagnosis. The *p53* tumor-suppressor gene is also inactivated in a subset (30%) of parathyroid carcinomas. Germline *HRPT2* mutations also have been detected in cases of apparently sporadic parathyroid carcinomas.⁶¹

Clinical Manifestations

Patients with PHPT formerly presented with the "classic" pentad of symptoms (i.e., kidney stones, painful bones, abdominal groans, psychic moans, and fatigue overtones). With the advent and widespread use of automated blood analyzers in the early 1970s, there has been an alteration in the "typical" patient with PHPT. They are more likely to be minimally symptomatic or asymptomatic. Currently, most patients present with weakness, fatigue, polydipsia, polyuria, nocturia, bone and joint pain, constipation, decreased appetite, nausea, heartburn, pruritus, depression, and memory loss. Patients with PHPT also tend to score lower than healthy controls when assessed by general multidimensional health assessment tools such as the Medical Outcomes Study Short-Form Health Survey (SF-36)⁶² and other specific questionnaires designed by Pasioka and associates, the Parathyroid Assessment of Symptoms (PAS score).⁶³ Furthermore, these symptoms and signs improve in most, but certainly not all, patients after parathyroidectomy. Truly "asymptomatic" PHPT appears to be rare, occurring in <5% of patients, as determined by prospectively administered

questionnaires. Complications of PHPT are described below.

Renal Disease
