Two perfusion strategies have been developed to reduce the risks that circulatory arrest entails: retrograde cerebral perfusion and selective antegrade cerebral perfusion. Retrograde cerebral perfusion delivers cold, oxygenated blood from the pump into a cannula placed in the superior vena cava (Fig. 22-7A). This technique was introduced in the hope that the retrograde delivery of blood would provide oxygen to the brain; however, accumulating evidence suggests that it does not.^{59–62} The apparent benefits of this technique are more likely due to maintenance of cerebral hypothermia and retrograde flushing of air and debris.

Illustration of perfusion strategies used during aortic arch aneurysm repair performed under hypothermic circulatory arrest. **A.** Retrograde cerebral perfusion. Oxygenated blood is delivered through a cannula placed in the superior vena cava. **B.** Antegrade cerebral perfusion. Oxygenated blood is delivered through balloon perfusion catheters inserted into the innominate and left common carotid arteries.

[Images adapted from Gravlee GP, Davis RF, Kurusz M, et al (eds): *Cardiopulmonary Bypass: Principles and Practice*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2000, Chap. 34, Fig. 34.3B.]

Selective antegrade cerebral perfusion delivers blood directly into the brachiocephalic arteries while circulatory arrest is maintained in the rest of the body.⁶³ This technique originally required cumbersome bypass grafts and cannulas and consequently fell out of favor. However, recent technologic improvements and new strategies for delivery have resulted in a resurgence of interest in this technique, which should now be considered a standard adjunct for cerebral protection during hypothermic circulatory arrest. One common way of delivering antegrade cerebral perfusion involves the insertion of small, flexible balloon perfusion catheters into one or more of the branch arteries (Fig. 22-7B). Another method, which is rapidly gaining popularity because of its relative simplicity, involves cannulating the right axillary artery (Fig. 22-8).⁶⁴ After circulatory arrest is induced and the proximal innominate artery is occluded, the axillary artery cannula delivers blood into the cerebral circulation via the right common carotid artery. Note that, with this technique, blood flow to the left side of the brain requires an intact circle of Willis. Antegrade cerebral perfusion via the right axillary artery has become our standard adjunct for cerebral perfusion during circulatory arrest.

Illustration of an alternative technique for delivering antegrade cerebral perfusion during aortic arch repairs. **A.** A graft sewn to the right axillary artery is used to return oxygenated blood from the cardiopulmonary bypass circuit. **B.** After adequate hypothermia is

established, the innominate artery is occluded with a tourniquet (*inset*) so that flow is diverted to the right common carotid artery, which maintains cerebral circulation.

[Images adapted from Gravlee GP, Davis RF, Stammers AH, et al (eds): *Cardiopulmonary Bypass: Principles and Practice*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2008, Chap. 32, Fig. 1A and 1B.]

Several reports have noted the safety of using only deep to moderate hypothermia [25° to 30°C (77° to 86°F)] when antegrade cerebral perfusion is used during circulatory arrest.^{65,66} The advantages of moderate hypothermia relate mainly to avoiding the severe coagulopathy that develops with deep hypothermia. Some authors have raised concerns that reducing the degree of hypothermia narrows the safety margin that profound hypothermia provides, because it increases the risk of ischemic complications involving the spinal cord, kidneys, and other organs that are left unprotected while the brain receives antegrade cerebral perfusion.⁶⁷ To address this issue, some groups have devised perfusion strategies that provide flow to the descending aorta during arch repair.^{68,69}

Endovascular Repair

Experience with purely endovascular treatment of proximal aortic disease remains limited and only investigational. The unique anatomy of the aortic arch and the need for uninterrupted cerebral perfusion pose difficult challenges. There are reports of the use of "homemade" grafts to exclude arch aneurysms; however, these grafts are highly experimental at this time. For example, in 1999, Inoue and colleagues⁷⁰ reported placing a triple-branched stent graft in a patient with an aneurysm of the aortic arch. The three brachiocephalic branches were positioned by placing percutaneous wires in the right brachial, left carotid, and left brachial arteries. The patient underwent two subsequent procedures: surgical repair of a right brachial pseudoaneurysm and placement of a distal stent graft extension to control a major perigraft leak. Since then, efforts to employ endovascular techniques in the treatment of the proximal aorta have been essentially limited to the use of approved devices for off-label indications, such as the exclusion of pseudoaneurysms in the ascending aorta.

Hybrid Repair

Unlike purely endovascular approaches, hybrid repairs of the aortic arch have entered the mainstream clinical arena, although they remain controversial. Hybrid arch repairs involve some form of "debranching" of the brachiocephalic vessels, followed by endovascular exclusion of some or all of the aortic arch (Fig. 22-9). Although this technique has many variants, they often involve sewing a branched graft to the proximal ascending aorta with the use of a partial aortic clamp. The branches of the graft are then sewn to the arch vessels. Once the arch is "debranched," the arch aneurysm can be excluded with an endograft. The arguments for using a hybrid approach to treat aortic arch aneurysms include the elimination of cardiopulmonary bypass, circulatory arrest, and cardiac ischemia.

Illustration of a hybrid approach—which combines open and endovascular techniques—for repair of an extensive aortic aneurysm. **A.** Preoperative computed tomographic images detail an enormous aneurysm involving the aortic arch and entire thoracoabdominal aorta. **B.** Debranching the arch and thoracoabdominal segments allows the use of a series of endovascular stent grafts to exclude the entire aneurysm.

It is not yet clear whether hybrid repairs are as durable as traditional ones.⁷¹ Also, there is a risk of embolization and stroke due to

wire and device manipulation within the aortic arch. There are no large-scale studies comparing hybrid and traditional repairs. In a recent expert consensus document, the recommendation was to limit direct stenting of the aortic arch to patients who fall into the high surgical risk category. These are patients with significant comorbidities such as chronic pulmonary disease.⁷²

Distal Thoracic Aortic Aneurysms

Open Repair

In patients with descending thoracic or thoracoabdominal aortic aneurysms, several aspects of treatment—including preoperative risk assessment, anesthetic management, choice of incision, and use of protective adjuncts—are dictated by the overall extent of aortic involvement. By definition, descending thoracic aortic aneurysms involve the portion of the aorta between the left subclavian artery and the diaphragm. Thoracoabdominal aneurysms can involve the entire thoracoabdominal aorta, from the origin of the left subclavian artery to the aortic bifurcation, and are categorized according to the Crawford classification scheme (Fig. 22-10). Extent I thoracoabdominal aortic aneurysms involve most of the descending thoracic aorta, usually beginning near the left subclavian artery, and extend down to encompass the aorta at the origins of the celiac axis and superior mesenteric arteries. The renal arteries also may be involved. Extent II aneurysms also arise near the left subclavian artery but extend distally into the infrarenal abdominal aorta, and they often reach the aortic bifurcation. Extent III aneurysms originate in the lower descending thoracic aorta (below the sixth rib) and extend into the abdomen. Extent IV aneurysms begin within the diaphragmatic hiatus and often involve the entire abdominal aorta.

Illustration of the Crawford classification of thoracoabdominal aortic aneurysms based on the extent of aortic involvement.

[Reproduced with permission from Coselli JS, LeMaire SA: Descending and Thoracoabdominal Aortic Aneurysms, in Cohn LH (ed): *Cardiac Surgery in the Adult*, 3rd ed. New York: McGraw-Hill, Inc., 2008, Chap. 54, Fig. 54-5.]

Descending thoracic aortic aneurysms are repaired through a left thoracotomy. In patients with thoracoabdominal aortic aneurysms, the thoracotomy is extended across the costal margin and into the abdomen. Use of a double-lumen endobronchial tube allows selective ventilation of the right lung and deflation of the left lung. Transperitoneal exposure of the thoracoabdominal aorta is achieved by performing medial visceral rotation and circumferential division of the diaphragm. During a period of aortic clamping, the diseased segment is replaced with a polyester tube graft. Important branch arteries—including intercostal arteries and the celiac, superior mesenteric, and renal arteries—are reattached to openings made in the side of the graft. Visceral and renal artery occlusive disease is commonly encountered during aneurysm repair; options for correcting branch vessel stenosis include endarterectomy, direct arterial stenting, and bypass grafting.

Clamping the descending thoracic aorta causes ischemia of the spinal cord and abdominal viscera. Clinically significant manifestations of hepatic, pancreatic, and bowel ischemia are relatively uncommon. However, both acute renal failure and spinal cord injury resulting in paraplegia or paraparesis remain major causes of morbidity and mortality after these operations. Therefore, several aspects of the operation are devoted to minimizing spinal and renal ischemia (Table 22-3). Our multimodal approach to spinal cord protection includes expeditious repair to minimize aortic clamping time, moderate systemic heparinization (1.0 mg/kg) to prevent small-vessel thrombosis, mild permissive hypothermia [32° to 34°C (89.6° to 93.2°F)] [nasopharyngeal temperature], and reattachment of segmental intercostal and lumbar arteries. As the aorta is replaced from proximal to distal, the aortic clamp is moved sequentially to lower positions along the graft to restore perfusion to newly reattached branch vessels. During extensive thoracoabdominal aortic repairs (i.e., Crawford extent I and II aneurysms), cerebrospinal fluid drainage is used. The benefits of this adjunct, which improves spinal perfusion by reducing cerebrospinal fluid pressure, have been confirmed in a prospective, randomized trial performed by our group.⁷³ Motor evoked potentials often are used to monitor the spinal cord throughout the operation.^{74,75} Left heart bypass, which provides perfusion of the distal aorta and its branches during the clamping period, is also used during extensive thoracoabdominal aortic repairs.^{76–78} Because left heart bypass unloads the heart, it is also useful in patients with poor cardiac reserve. Balloon perfusion cannulas connected to the left heart bypass circuit can be used to deliver blood directly to the celiac axis and superior mesenteric artery during their reattachment. The potential benefits of reducing hepatic and bowel ischemia include reduced risks of postoperative coagulopathy and bacterial translocation, respectively. Whenever possible, renal protection is achieved by perfusing the kidneys with cold [4°C (39.2°F)] crystalloid. In a randomized clinical trial, reduced kidney temperature was found to be associated with renal protection, and the use of cold crystalloid independently predicted preserved renal function.⁷⁹

Table 22-3 Current Strategy for Spinal Cord and Visceral Protection during Repair of Distal Thoracic Aortic Aneurysms
<i>All extents</i>
• Permissive mild hypothermia [32–34°C (89.6–93.2°F), nasopharyngeal]
• Moderate heparinization (1 mg/kg)
• Aggressive reattachment of segmental arteries, especially between T8 and L1
• Sequential aortic clamping when possible
• Perfusion of renal arteries with 4°C (39.2°F) crystalloid solution when possible
<i>Crawford extent I and II thoracoabdominal repairs</i>
• Cerebrospinal fluid drainage
• Left heart bypass during proximal anastomosis
• Selective perfusion of celiac axis and superior mesenteric artery during intercostal and visceral anastomoses

In certain cases, hypothermic circulatory arrest is required for descending thoracic or thoracoabdominal aortic repairs.⁸⁰ The primary indication for this approach is the inability to clamp the aorta because of rupture, extremely large aneurysm size, or extension of the aneurysm into the distal transverse aortic arch.

As discussed earlier, complete repair of extensive aneurysms involving the ascending aorta, transverse arch, and descending thoracic aorta generally requires staged operations. In such procedures, when the descending or thoracoabdominal component is symptomatic (e.g., causes back pain or has ruptured) or is disproportionately large (compared with the ascending aorta), the distal segment is treated during the initial operation, and repair of the ascending aorta and transverse aortic arch is performed as a second procedure. A reversed elephant trunk repair, in which a portion of the proximal end of the aortic graft is inverted down into the lumen, can be performed during the first operation; this technique facilitates the second-stage repair of the ascending aorta and transverse aortic arch (Fig. 22-11).⁸¹

Fig. 22-11.

Illustration of the reversed elephant trunk technique. **A.** Stage 1: The distal aorta is repaired through a left thoracoabdominal approach. The aneurysm is opened after the aorta is clamped between the left common carotid artery and the left subclavian artery, which is also clamped. Before the proximal anastomosis is performed, the end of the graft is partly invaginated to leave a "trunk" for the subsequent repair. Proximal intercostal arteries are oversewn. **B.** After the proximal suture line is completed, the clamps are repositioned to restore blood flow to the left subclavian artery. The repair is completed by reattaching patent intercostal arteries to an opening in the side of the graft and creating a beveled distal anastomosis at the level of the visceral branches. **C.** Stage 2: The

proximal aorta is repaired through a median sternotomy. The aortic arch is opened under hypothermic circulatory arrest. The "trunk" is pulled out and used to replace the aortic arch and ascending aorta. This eliminates the need for a new distal anastomosis and simplifies the procedure. Circulatory arrest and operative time, along with their attendant risks, are reduced. **D.** The completed two-stage repair of the entire thoracic aorta.

Although spinal cord ischemia and renal failure receive the most attention, several other complications warrant consideration. The most common complication of extensive repairs is pulmonary dysfunction. With aneurysms adjacent to the left subclavian artery, the vagus and left recurrent laryngeal nerves are often adherent to the aortic wall and thus are susceptible to injury. Vocal cord paralysis should be suspected in patients who have postoperative hoarseness, and the presence of nerve damage should be confirmed by endoscopic examination. Vocal cord paralysis can be treated effectively by direct cord medialization (type 1 thyroplasty). Injury to the esophagus during the proximal anastomosis can have catastrophic consequences. Carefully separating the proximal descending thoracic aorta from the underlying esophagus before performing the proximal anastomosis minimizes the risk of a secondary aorto-esophageal fistula. In patients who have previously undergone coronary artery bypass with a left internal thoracic artery graft, clamping proximal to the left subclavian artery can precipitate severe myocardial ischemia and cardiac arrest. When the need to clamp at this location is anticipated in these patients, a left common carotid to subclavian bypass is performed to prevent cardiac complications.

Endovascular Repair

Descending Thoracic Aortic Aneurysms

Stent graft repair of descending thoracic aortic aneurysms has become an accepted treatment option for selected patients.⁷² In 1991, Parodi and associates⁸² reported using endovascular stent grafting to repair abdominal aortic aneurysms. Only 3 years after this seminal report was published, Dake and colleagues⁸³ reported performing endovascular descending thoracic aortic repair with "homemade" stent grafts in 13 patients.

At this time, endografting is primarily used to treat degenerative descending thoracic aortic aneurysms. However, many authors have reported using this new, less invasive option in patients with aortic dissection or with traumatic, mycotic, or ruptured aneurysms of the descending thoracic aorta.

In elderly patients with severe comorbidity and patients who have undergone previous complex thoracic aortic procedures, endovascular repair is a particularly attractive alternative to standard surgical procedures. As mentioned previously, appropriate patient selection depends on specific measurements taken from preoperative CT angiograms.

To protect patients against spinal cord ischemia during these endovascular repairs, many surgeons use cerebrospinal fluid drainage. Fluid is drained to maintain a cerebrospinal fluid pressure of approximately 12 to 14 mmHg. The first step in the repair procedure is to obtain appropriate vascular access for the insertion of the thoracic stent graft. If the femoral artery will not accommodate the necessary sheath, then an iliac artery is exposed. A graft can be sewn to the iliac artery in an end-to-side fashion to facilitate the deployment of the endograft. After 5000 to 10,000 units of heparin are administered, a guidewire and the delivery sheath are inserted into the access artery under fluoroscopic guidance. The endograft is then advanced into the aorta and suitably positioned. Note that when a C-arm is used, the best view of the distal arch and descending thoracic aorta is usually in the left anterior oblique position at an angle of approximately 40 to 50 degrees. The device is then deployed, and the proximal and distal ends are expanded by using a balloon catheter, which optimizes the seal between the device and the aortic wall at this landing zone. An aortogram is then taken to rule out any endoleak, and protamine is administered.

It is common to cover the left subclavian artery with the endograft to lengthen the proximal landing zone.⁸⁴ However, recent findings suggest that the risk of spinal cord complications is heightened when the subclavian artery is covered and not revascularized, presumably because of a loss of collateral circulation to the spinal cord.⁸⁵ To prevent this complication, a carotid to subclavian bypass can be easily constructed to maintain vertebral artery blood flow and minimize neurologic injury (Fig. 22-12).^{86,87} In addition, new

generations of stent grafts are being designed with side branches that can be placed within the left subclavian artery. This feature is particularly attractive if the proximal neck is short or if the patient has a patent left internal thoracic artery to left anterior descending coronary artery bypass.

Fig. 22-12.

Illustration of a hybrid repair of the proximal descending thoracic aorta. **A.** The preoperative representation of the aneurysm shows that establishing a 2-cm proximal landing zone for a stent graft will require covering the origin of the left subclavian artery. **B.** Through a supraclavicular approach, a bypass from the left common carotid artery to the left subclavian artery is performed to reroute circulation and create a landing zone for the stent graft. After the bypass is completed, the left subclavian artery is ligated proximal to the graft. **C.** In the completed hybrid repair, the aneurysm has been excluded successfully by a stent graft that covers the origin of the left subclavian artery, and blood flow to the left vertebral artery and arm is preserved by the bypass graft.

Elephant Trunk Completion

The advent of endograft stenting has provided surgeons with an excellent method of completing elephant trunk repairs endovascularly, rather than taking the open approach through a thoracotomy.⁸⁸ Recall that an elephant trunk is used when an aortic aneurysm extends from the distal arch to the descending thoracic aorta. An endograft can be deployed at the time of elephant trunk construction or during a separate, subsequent procedure.⁸⁹ When the stent is deployed in a retrograde manner in such a second-stage procedure, the procedure is facilitated by placing radiopaque markers at the end of the elephant trunk during the first-stage procedure. This allows the distal end of the trunk to be identified via fluoroscopy. A guidewire can then be manipulated into the trunk and advanced into the ascending aorta to stabilize it during stent deployment. Note that advancing a wire in retrograde fashion from the femoral artery into the elephant trunk can be challenging. Occasionally, the wire must be advanced in an antegrade fashion from a brachial artery.

Thoracoabdominal Aortic Aneurysms

Like the endovascular repair of proximal aortic disease, endovascular thoracoabdominal aortic aneurysm repair remains experimental. However, such repairs have been shown to be feasible in a handful of specialized centers. Endovascular thoracoabdominal aortic aneurysm repairs are quite complex, because at least one of the visceral arteries must be incorporated into the repair. The number of visceral branches that need to be addressed varies with the extent of aortic coverage.⁹⁰ The types of stent grafts used include fenestrated grafts, reinforced fenestrated grafts, and branched grafts, as well as modular combinations of grafts. Graft fenestrations and branch vessels are typically aligned by using inflatable angioplasty balloons. Procedure time is not insignificant, nor is the amount of contrast medium required to obtain the highly detailed images needed to plan these procedures. In addition, some of the stent grafts used in endovascular thoracoabdominal aortic aneurysm repair are custom-made in advance and thus may take several weeks to obtain; therefore, their use is limited to cases of elective repair.⁹¹

It should be noted that, like open thoracoabdominal aortic aneurysm repair, endovascular repair carries risks of paraplegia, renal failure, stroke, and death, despite the apparent benefits of its being a less invasive procedure. Until prospective studies demonstrate consistent and favorable results, endovascular thoracoabdominal aortic aneurysm repair must be considered purely investigational.

Hybrid Repair

As discussed previously, hybrid repairs can be performed in patients with aortic arch aneurysms that extend into the descending thoracic aorta. For example, the arch can be replaced by using the elephant trunk technique (see Fig. 22-6A), after which the descending thoracic aorta can be excluded endovascularly by using the elephant trunk as the proximal landing zone. When the descending thoracic aortic aneurysm only extends into the distal arch (Fig. 22-13), the arch can be debranched by constructing bypass

grafts off of the ascending aorta, then placing stent grafts across the arch and descending thoracic aorta.

Fig. 22-13.

Illustration of a hybrid repair of the distal aortic arch and proximal descending thoracic aorta. **A.** Preoperative representation of the aneurysm shows dilatation of the distal aortic arch, which makes the arch an unsuitable landing zone. **B.** A Y graft is created from 8- and 10-mm grafts. This graft will be used to debranch the arch. **C.** After sternotomy, a small section of the ascending aorta is excluded by a side-biting clamp. The beveled end of the Y graft is sutured to an opening in the aorta. **D.** The 8-mm end of the Y graft is used to bypass the left common carotid artery. **E.** The 10-mm end is used to bypass the innominate artery. **F.** Antegrade deployment of the stent graft can be performed through a conduit graft sewn to the ascending aorta below the Y graft. **G.** Alternatively, retrograde deployment of the stent graft can be performed via the femoral artery. **H.** In the completed hybrid repair, the endovascular graft is properly seated, and the bypass grafts ensure blood flow into the innominate and left common carotid arteries. The left subclavian artery can often be fully occluded by the stent graft without complication. The inset figure depicts an alternate

approach in which the left subclavian artery has been ligated to prevent back-bleeding and type II endoleak.

(Reproduced with permission from Bozinovski et al,⁸⁶ Figs. 1–8. Copyright © Elsevier.)

There have been several reports of hybrid thoracoabdominal aortic aneurysm repair.^{92,93} This approach is gaining momentum, especially in patient-tailored interventions for patients at high surgical risk, such as those who have limited physiologic reserve, are of advanced age, or have significant comorbidities. Hybrid procedures use open surgical techniques to reroute blood supply to the visceral arteries so that their aortic origins can be covered by stent grafts without causing visceral ischemia (see Fig. 22-9). Endovascular methods are then used (either as part of the same procedure or at a later stage) to repair the aortic aneurysm, often with a simple tube stent graft, which is more readily available than the customized, modular stent grafts deployed in strictly endovascular repairs. Several reports of small series suggest that these hybrid repairs produce acceptable outcomes among patients with elevated surgical risk.^{92,93} For low-risk surgical patients, it is likely that open surgical repair will remain the gold standard until the durability of hybrid repairs has been established.

POSTOPERATIVE CONSIDERATIONS

Open Procedures

Aortic anastomoses are often extremely fragile during the early postoperative period. Even brief episodes of postoperative hypertension can disrupt suture lines and precipitate severe bleeding or pseudoaneurysm formation. Therefore, during the initial 24 to 48 hours, meticulous blood pressure control is maintained to protect the integrity of the anastomoses. Generally, we liberally use nitroprusside and IV beta antagonists to keep the mean arterial blood pressure between 80 and 90 mmHg. In patients with extremely friable aortic tissue, such as those with Marfan syndrome, we lower the target range to 70 to 80 mmHg. It is a delicate balancing act, as one must be mindful of spinal cord perfusion and avoid periods of relative hypotension while maintaining these low pressures.

A second threat to anastomotic integrity is graft infection. To reduce the risk of this complication, IV antibiotics are continued throughout the postoperative course until all drains, chest tubes, and central venous lines are removed.

Endovascular Procedures

As experience with descending thoracic aortic stent grafts continues to accumulate, so too do reports of complications specifically related to device deployment. Many of these complications are directly related to manipulation of the delivery system within the iliac arteries and aorta.⁹⁴ Patients with small, calcified, tortuous iliofemoral arteries are at particularly high risk for life-threatening iliac artery rupture. The potential for aortic injury precipitating immediate operation is well described in the abdominal aortic stent graft literature; however, thus far, there are few reports of thoracic aortic rupture during stent graft procedures. A more common and equally deadly complication is acute iatrogenic retrograde dissection into the aortic arch and ascending aorta. There are already several reports of this complication, most involving new-generation devices and requiring emergency repair of the ascending aorta and aortic arch via sternotomy and cardiopulmonary bypass.^{95,96} Such a dissection converts a localized descending thoracic aortic aneurysm into an acute problem involving the entire thoracic aorta.

Another significant complication of descending thoracic aortic stent grafting is endoleak. First-generation stents were associated with an incidence of endoleak of up to 46%; however, this percentage is declining as stent graft technology continues to evolve.^{97,98} An endoleak occurs when there is a persistent flow of blood (visible on radiologic imaging) into the aneurysm sac. These occurrences are not benign, because they lead to continual pressurization of the sac, which can cause expansion or even rupture. This complication is categorized according to the cause of the leak. Type I endoleaks, which result from an incomplete seal between the graft and aorta at attachment sites, are the most unstable and can precipitate aortic rupture. Therefore, aggressive intervention is warranted as soon as such leaks are identified. Type II endoleaks occur when the sac is filled by collateral arteries, such as patent intercostal arteries. These leaks are more benign than type I leaks and can simply be monitored with regular imaging. If the aneurysm sac expands or the leak persists, the collateral arteries can occasionally be occluded by using percutaneous interventions. Type III endoleaks are caused by

either a tear in the graft fabric or an incomplete seal between two devices. This variety of endoleak is rare and should be treated aggressively. Typically, another endograft can be used to cover and seal the leak. Type IV endoleaks are extremely rare and were seen more often with earlier devices made of porous materials through which blood could leak. Type V endoleaks are characterized by endotension, in which there is evidence of aneurysm expansion even though the leak has no identifiable source. Type IV and V endoleaks can be treated by overstenting the existing graft with another stent graft.

Other device-related problems include stent graft misdeployment, device migration, and endograft kinking. Although not all complications related to stent grafts are fatal, endovascular repairs should be performed by expert teams qualified to address the variety of problems that may arise. Also, because late graft-related complications are common, regularly scheduled radiologic imaging surveillance is of the utmost importance.

AORTIC DISSECTION

Pathology and Classification

Aortic dissection, the most common catastrophic event involving the aorta, is a progressive separation of the aortic wall layers that usually occurs after a tear forms in the intima and inner media. As the separation of the layers of the media propagates, at least two channels form (Fig. 22-14): the original lumen, which remains lined by the intima and which is called the *true lumen*, and the newly formed channel within the layers of the media, which is called the *false lumen*. The dissecting membrane separates the true and false lumens. Additional tears in the dissecting membrane that allow communication between the two channels are called *re-entry sites*. Although the separation of layers primarily progresses distally along the length of the aorta, it can also proceed in a proximal direction; this process often is referred to as *proximal extension* or *retrograde dissection*.

Illustration of longitudinal sections of the aortic wall and lumen. Blood flows freely downstream in normal aortic tissue. In classic aortic dissection, blood entering the media through a tear creates a false channel in the wall. Intramural hematomas arise when hemorrhage from the vasa vasorum causes blood to collect within the media; the intima is intact. Penetrating aortic ulcers are deep atherosclerotic lesions that burrow into the aortic wall and allow blood to enter the media. In each of these conditions, the outer aortic wall is severely weakened and prone to rupture.

The extensive disruption of the aortic wall has severe anatomic consequences (Fig. 22-15). First, the outer wall of the false lumen is extremely thin, inflamed, and fragile, which makes it prone to expansion or rupture in the face of ongoing hemodynamic stress. Second, the expanding false lumen can compress the true lumen and cause *malperfusion syndrome* by interfering with blood flow in the

aorta or any of its branch vessels, including the coronary, carotid, intercostal, visceral, renal, and iliac arteries. Finally, when the separation of layers occurs within the aortic root, the aortic valve commissures can become unhinged, which results in acute valvular regurgitation. The clinical consequences of each of these sequelae are addressed in detail in the section on clinical manifestations later.

DISSECTION VS. ANEURYSM

The relationship between dissection and aneurysmal disease requires clarification. Dissection and aneurysm are separate entities, although they often coexist and are mutual risk factors. In most cases, dissection occurs in patients without aneurysms. The subsequent progressive dilatation of the weakened outer aortic wall results in an aneurysm. On the other hand, in patients with degenerative aneurysms, the ongoing deterioration of the aortic wall can lead to a superimposed dissection. The overused term *dissecting aneurysm* should be reserved for this specific situation.

CLASSIFICATION

For management purposes, aortic dissections are classified according to their location and chronicity. Improvements in imaging have increasingly revealed variants of aortic dissection that probably represent different forms along the spectrum of this condition.

Location

Dissections are categorized according to their anatomic location and extent to guide treatment. The two traditional classification schemes that remain in common use are the DeBakey and the Stanford classification systems (Fig. 22-16).^{99,100} In their current forms, both of these schemes describe the segments of aorta that are involved in the dissection, rather than the site of the initial intimal tear. The main drawback of the Stanford classification system is that it does not distinguish between patients with isolated ascending aortic dissection and patients with dissection involving the entire aorta. Both types of patients would be classified as having type A dissections, despite the fact that their treatment, follow-up, and prognosis are substantially different. Borst and associates¹⁰¹ devised a different system of classifying aortic dissections that they contended was simpler and more descriptive than the traditional DeBakey and Stanford schemes. In this system, the ascending aorta and descending aorta are considered independently. This is useful because treatment strategies are chosen according to which segments are involved. For example, patients with isolated ascending aortic dissections often undergo emergent operation. In contrast, when only the descending and thoracoabdominal portions are involved, the initial treatment is usually medical; surgery is reserved for patients in whom complications develop. Patients with dissections that involve both the ascending and descending aorta often undergo surgical repair of the ascending dissection, followed by aggressive medical treatment of the descending dissection.

Chronicity

Aortic dissection also is categorized according to the time elapsed since the initial tear. Dissection is considered acute within the first 14 days after the initial tear; after 14 days, the dissection is considered chronic. Although arbitrary, the distinction between acute and chronic dissections has important implications, not only for decision-making about perioperative management strategies and operative techniques, but also for evaluating surgical results. Figure 22-17 provides an algorithm for the management of acute aortic dissection. In light of the importance of acuity, Borst and associates¹⁰¹ have proposed a third phase—termed *subacute*—to describe the transition between the acute and chronic phases. The subacute period encompasses days 15 through 60 after the initial tear. Although this is past the traditional 14-day acute phase, patients with subacute dissection continue to have extremely fragile aortic tissue, which may complicate operative treatment and increase the risks associated with surgery.

Variants

As noted earlier, advancements in noninvasive imaging of the aorta have revealed variants of aortic dissection (see Fig. 22-14). The recently introduced term *acute aortic syndrome* encompasses classic aortic dissection and its variants. Other aortic syndromes, which were once thought to be rare, include *intramural hematoma (IMH)* and *penetrating aortic ulcer (PAU)*. Although the issue is somewhat

controversial, the current consensus is that, in most cases, these variants of dissection should be treated identically to classic dissection.

An IMH is a collection of blood within the aortic wall, without an intimal tear, that is believed to be due to rupture of the vasa vasorum within the media. The accumulation of blood can result in a secondary intimal tear that ultimately leads to a dissection.¹⁰² Because IMH and aortic dissection represent a continuum, it is possible that IMH is seen less frequently than aortic dissection because IMH rapidly progresses to true dissection. The prevalence of IMH among patients with acute aortic syndromes is approximately 6%, with 16% progressing to full dissection.¹⁰³ An IMH can be classified according to its location (i.e., ascending or descending) and should be treated analogously to classic dissection.¹⁰⁴

A PAU is essentially a disrupted atherosclerotic plaque that projects into the aortic wall and is associated with surrounding hematoma. Eventually, the ulcer can penetrate the aortic wall, which leads to dissection or rupture. The rate of disease progression is higher than that of IMH alone.¹⁰⁵

Etiology and Natural History

Aortic dissection is a lethal condition with a reported incidence of 3.5 per 100,000 in the United States.¹⁰⁶ Without appropriate modern medical or surgical treatment, most patients (approximately 90%) die within 3 months of dissection, mostly from rupture.^{107,108}

Although several risk factors for aortic dissection have been identified, the specific causes remain unknown. Ultimately, any condition that weakens the aortic wall increases the risk of aortic dissection. Common general cardiovascular risk factors, such as smoking, hypertension, atherosclerosis, and hypercholesterolemia, are associated with aortic dissection. Patients with connective tissue disorders, aortitis, bicuspid aortic valve, or pre-existing medial degenerative disease are at risk for dissection, especially if they already have a thoracic aortic aneurysm.¹⁵ Aortic injury during cardiac catheterization or surgery is a common cause of iatrogenic dissection. Other situations that are associated with aortic dissection include cocaine abuse and amphetamine abuse.¹⁰⁹ Advances in the understanding of the molecular mechanisms behind abdominal aortic aneurysms have prompted similar investigations of thoracic aortic dissection.^{110,111}

Clinical Manifestations

The onset of dissection often is associated with severe chest or back pain, classically described as "tearing," that migrates distally as the dissection progresses along the length of the aorta. The location of the pain often indicates which aortic segments are involved. Pain in the anterior chest suggests involvement of the ascending aorta, whereas pain in the back and abdomen generally indicates involvement of the descending and thoracoabdominal aorta. Additional clinical sequelae of acute aortic dissection are best considered in terms of the dissection's potential anatomic manifestations at each level of the aorta (see Fig. 22-15 and Table 22-4). Thus, potential complications of dissection of the aorta (and involved secondary arteries) are highly varied, including, but not limited to, cardiac ischemia (coronary artery) or tamponade, stroke (brachiocephalic arteries), paraplegia or paraparesis (intercostal arteries), mesenteric ischemia (superior mesenteric artery), kidney failure (renal arteries), and limb ischemia or loss of motor function (brachial or femoral arteries).

Table 22-4 Anatomic Complications of Aortic Dissection and Their Associated Symptoms and Signs	
Anatomic Manifestation	Symptoms and Signs
Aortic valve insufficiency	Dyspnea
	Murmur
	Pulmonary rales
	Shock
Coronary malperfusion	Chest pain with characteristics of angina
	Nausea, vomiting

	Shock
	Ischemic changes on electrocardiogram
	Elevated levels of cardiac enzymes
Pericardial tamponade	Dyspnea
	Jugular venous distention
	Pulsus paradoxus
	Muffled cardiac tones
	Shock
	Low-voltage electrocardiogram
Subclavian or iliofemoral artery malperfusion	Cold, painful extremity
	Extremity sensory and motor deficits
	Peripheral pulse deficit
Carotid artery malperfusion	Syncope
	Focal neurologic deficit (transient or persistent)
	Carotid pulse deficit
	Coma
Spinal malperfusion	Paraplegia
	Incontinence
Mesenteric malperfusion	Nausea, vomiting
	Abdominal pain
Renal malperfusion	Oliguria or anuria
	Hematuria

Ascending aortic dissection can directly injure the aortic valve, causing regurgitation. The severity of the regurgitation varies with the degree of commissural disruption, which ranges from partial separation of only one commissure, producing mild valvular regurgitation, to full separation of all three commissures and complete prolapse of the valve into the left ventricle, producing severe acute heart failure. Patients with acute aortic valve regurgitation may report worsening dyspnea.

Ascending dissections also can extend into the coronary arteries or shear the coronary ostia off of the true lumen, causing acute coronary occlusion; when this occurs, it most often involves the right coronary artery. The sudden disruption of coronary blood flow can cause a myocardial infarction. Because symptoms and signs consistent with myocardial ischemia are produced, this presentation can mask the presence of aortic dissection, which results in delayed diagnosis and treatment.

The thin and inflamed outer wall of a dissected ascending aorta often produces a serosanguineous pericardial effusion that can accumulate and cause tamponade. Suggestive signs include jugular venous distention, muffled heart tones, pulsus paradoxus, and low-voltage electrocardiogram (ECG) tracings. Free rupture into the pericardial space produces rapid tamponade and is generally fatal.

As the dissection progresses, any branch vessel from the aorta can become involved, which results in compromised blood flow and ischemic complications (i.e., *malperfusion*). Therefore, depending on which arteries are involved, the dissection can produce acute stroke, paraplegia, hepatic failure, bowel infarction, renal failure, or a threatened ischemic limb.

Diagnostic Evaluation

Because of the variations in severity and the wide variety of potential clinical manifestations, the diagnosis of acute aortic dissection can be challenging.^{112–114} Only 3 out of every 100,000 patients who present to an emergency department with acute chest, back, or abdominal pain are eventually diagnosed with aortic dissection. Not surprisingly, diagnostic delays are common; delays beyond 24 hours after hospitalization occur in up to 39% of cases. Unfortunately, delays in diagnosis lead to delays in treatment, which can have

disastrous consequences. The European Society of Cardiology Task Force on Aortic Dissection stated, "The main challenge in managing acute aortic dissection is to suspect and thus diagnose the disease as early as possible."¹¹² A high index of suspicion is critical, particularly in younger, atypical patients, who may have connective tissue disorders or other, less common risk factors.

Most patients with acute aortic dissection (80 to 90%) experience severe pain in the chest, back, or abdomen.^{112–114} The pain usually occurs suddenly, has a sharp or tearing quality, and often migrates distally as the dissection progresses along the aorta. For classification purposes (acute vs. subacute vs. chronic), the onset of pain is generally considered to represent the beginning of the dissection process. Most of the other common symptoms either are nonspecific or are caused by the secondary manifestations of dissection.

A discrepancy between the extremities in pulse, blood pressure, or both is the classic physical finding in patients with aortic dissection. It often occurs because of changes in flow in the true and false lumens, and it does not necessarily indicate extension into an extremity branch vessel. Involvement of the aortic arch often creates differences between the right and left arms, whereas descending aortic dissection often causes differences between the upper and lower extremities. Like symptoms, most of the physical signs after dissection are related to the secondary manifestations and therefore vary considerably (Table 22-4). For example, signs of stroke or a threatened ischemic limb may dominate the physical findings in patients with carotid or iliac malperfusion, respectively.

Unfortunately, laboratory studies are of little help in diagnosing acute aortic dissection. There has been recent interest in using D-dimer level to aid in making this diagnosis. Several reports have demonstrated that D-dimer is an extremely sensitive indicator of acute aortic dissection; elevated levels are found in approximately 97% of affected patients.¹¹⁵ Tests that are commonly used to detect acute coronary events—including ECG and tests for serum markers of myocardial injury—deserve special consideration and need to be interpreted carefully. Normal ECGs and serum marker levels in patients with acute chest pain should raise suspicion about the possibility of aortic dissection. It is important to remember that ECG changes and elevated serum marker levels associated with myocardial infarction do not exclude the diagnosis of aortic dissection, because dissection can cause coronary malperfusion. Ultimately, although the issue has not been well studied, ECGs seem to have little utility for detecting or ruling out dissection. Similarly, although chest x-rays (CXRs) may show a widened mediastinum or abnormal aortic contour, up to 16% of patients with dissection have a normal-appearing CXR.¹¹⁴ The value of the CXR for detecting aortic dissection is limited, with a sensitivity of 67% and a specificity of 86%.¹¹⁶

Once the diagnosis of dissection is considered, the thoracic aorta should be imaged with CT, MRA, or echocardiography. The accuracy of these noninvasive imaging tests has all but eliminated the need for diagnostic aortography in most patients with suspected aortic dissection. Currently, the diagnosis usually is established with contrast-enhanced CT. The classic diagnostic feature is a double-lumen aorta (Fig. 22-18). In addition, CT scans provide essential information about the segments of the aorta involved; the acuity of the dissection; aortic dilatation, including the presence of pre-existing degenerative aneurysms; and the development of threatening sequelae, including pericardial effusion, early aortic rupture, and branch vessel compromise. Although MRA also provides excellent imaging, the MR suite is not well suited for critically ill patients. In patients who cannot undergo contrast-enhanced CT or MRA, transthoracic echocardiography can be used to establish the diagnosis. Transesophageal echocardiography (TEE) is excellent for determining the presence of dissection, aneurysm, and IMH in the ascending aorta.

Computed tomographic scan showing chronic aortic dissection in the distal aorta. The dissecting membrane (*arrow*) has separated the aorta into two channels—the true and false lumens.

Contrast-enhanced CT has a sensitivity of 98% and a specificity of 87% for diagnosis of aortic dissection. Although MRA is now considered the gold standard, with both a sensitivity and a specificity of 98%, CT scanning is the preferred imaging modality in the emergency department, mainly because of its swift image acquisition.¹¹⁷ In appropriate hands, TEE has a demonstrated sensitivity and specificity as high as 98 and 95%, respectively.¹¹⁸ Furthermore, TEE offers important information about ventricular function and aortic valve competency. Finally, TEE is the diagnostic modality of choice for hemodynamically unstable patients in whom the diagnosis of ascending dissection is suspected; ideally, these patients should be taken to the operating room, where the TEE can be performed and, if the TEE is confirmatory, surgery can be started immediately.

In selected patients with ascending aortic dissection (i.e., those who have evidence of pre-existing coronary artery disease), coronary angiography is performed before surgery. Specific relative indications in these patients include a history of angina or myocardial infarction, a recent myocardial perfusion study with abnormal results, previous coronary artery bypass or angioplasty, and acute ischemic changes on ECG. Contraindications include hemodynamic instability, aortic rupture, and pericardial effusion.¹¹⁹ In our practice, patients with acute aortic dissections rarely undergo coronary angiography. However, all patients presenting for elective repair of chronic ascending dissections have diagnostic coronary angiograms taken.

Of note, when malperfusion of the renal, visceral, or lower extremity arteries develops, the patient is usually treated in an angiography suite or hybrid operating room. Although the dissection usually is diagnosed on CT scan, these patients undergo aortography, during which the mechanism of the malperfusion is ascertained and, if possible, corrected. Hence, aortography may be obsolete as a diagnostic test for dissection, but it is beneficial for patients with malperfusion.

Treatment

INITIAL ASSESSMENT AND MANAGEMENT

Regardless of the location of the dissection, the initial treatment is the same for all patients with suspected or confirmed acute aortic dissection (see Fig. 22-17). Furthermore, because of the potential for rupture before the diagnosis is confirmed, aggressive pharmacologic management is started once there is clinical suspicion of dissection, and this treatment is continued during the diagnostic evaluation. The goals of pharmacologic treatment are to stabilize the dissection and prevent rupture.

Patients are monitored closely in an intensive care unit. Indwelling radial arterial catheters are used to monitor blood pressure and optimize titration of antihypertensive agents. Blood pressures in a malperfused limb can underrepresent the central aortic pressure; therefore, blood pressure is measured in the arm with the best pulse. Central venous catheters assure reliable IV access for delivering vasoactive medications. Pulmonary artery catheters are reserved for patients with severe cardiopulmonary dysfunction.

In addition to confirming the diagnosis of dissection and defining its acuity and extent, the initial evaluation focuses on determining whether any of several life-threatening complications are present. Particular attention is paid to changes in neurologic status, peripheral pulses, and urine output. Serial laboratory studies—including arterial blood gas concentrations, complete blood cell count, prothrombin and partial thromboplastin times, and serum levels of electrolytes, creatinine, blood urea nitrogen, and liver enzymes—are useful for detecting organ ischemia and optimizing management.

The initial management strategy, commonly described as *antihypertensive therapy* or *blood pressure control*, focuses on reducing aortic wall stress, the force of left ventricular ejection, chronotropy, and the rate of change in blood pressure (dP/dT). Reductions in dP/dT are achieved by lowering both cardiac contractility and blood pressure. The drugs initially used to accomplish these goals include IV beta-adrenergic blockers, direct vasodilators, calcium channel blockers, and angiotensin-converting enzyme inhibitors. These agents are used to achieve a heart rate between 60 and 80 bpm, a systolic blood pressure between 100 and 110 mmHg, and a mean arterial blood pressure between 60 and 75 mmHg. These hemodynamic targets are maintained as long as urine output remains adequate and neurologic function is not impaired. Achieving adequate pain control with IV opiates, such as morphine and fentanyl, is important for maintaining acceptable blood pressure control.

Beta antagonists are administered to all patients with acute aortic dissections unless there are strong contraindications, such as severe heart failure, bradyarrhythmia, high-grade atrioventricular conduction block, or bronchospastic disease. Esmolol can be useful in patients with bronchospastic disease because it is a cardioselective, ultra-fast-acting agent with a short half-life. Labetalol, which causes both nonselective beta blockade and postsynaptic α_1 -blockade, reduces systemic vascular resistance without impairing cardiac output. Doses of beta antagonists are titrated to achieve a heart rate of 60 to 80 bpm. In patients who cannot receive beta antagonists, calcium channel blockers such as diltiazem are an effective alternative. Nitroprusside, a direct vasodilator, can be administered once beta blockade is adequate. When used alone, however, nitroprusside can cause reflex increases in heart rate and contractility, elevated dP/dT, and progression of aortic dissection. Enalapril and other angiotensin-converting enzyme inhibitors are useful in patients with renal malperfusion. These drugs inhibit renin release, which may improve renal blood flow.

TREATMENT OF ASCENDING AORTIC DISSECTION

Acute Ascending Dissection

Ascending aortic repairs performed in the chronic phase of dissection uniformly have better outcomes than repairs performed in the acute phase. Unfortunately, the risk of a fatal complication, such as aortic rupture, during medical management outweighs the risk associated with early operation. Therefore, acute ascending aortic dissection has traditionally been considered an absolute indication for emergency surgical repair. However, specific patient groups may benefit from nonoperative management or delayed operation.¹²⁰ Delayed repair should be considered for patients who (a) present with acute stroke or mesenteric ischemia, (b) are elderly and have substantial comorbidity, (c) are in stable condition and may benefit from transfer to specialized centers, or (d) have undergone a cardiac operation in the remote past. Regarding the last group, it is important that the previous operation not be too recent; dissections that occur during the first 3 weeks after cardiac surgery pose a high risk of rupture and tamponade, and such dissections warrant early operation.¹²¹

In the absence of the circumstances listed earlier, most patients with acute ascending aortic dissection undergo emergent graft replacement of the ascending aorta. The operation is conducted in a manner similar to that described for aneurysms of the transverse aortic arch in the previous section. Immediately before the operation begins, intraoperative TEE is commonly performed to further assess baseline myocardial and valvular function and, if necessary, to confirm the diagnosis. The operation is performed via a median

sternotomy with cardiopulmonary bypass and hypothermic circulatory arrest (Fig. 22-19). In preparation for circulatory arrest, cannulas are placed in the right axillary artery (to provide arterial inflow) and the right atrium (to provide venous drainage).^{96,122} If profound hypothermic circulatory arrest is used, the patient traditionally is cooled until electroencephalographic monitoring shows electrocerebral silence; this generally occurs at nasopharyngeal temperatures of <18°C (64.4°F).¹²³ Alternatively, if antegrade cerebral perfusion can be reliably established, the arch repair can be conducted under deep hypothermia [23° to 25°C (73.4° to 77°F)]. After an appropriate level of cooling has been achieved, cardiopulmonary bypass is stopped, and the ascending aorta is opened. The innominate artery is then occluded with a clamp or snare, and flow from the axillary artery cannula is used to provide selective antegrade cerebral perfusion. A separate perfusion catheter can be placed in the left common carotid artery to ensure perfusion of the left side of the brain. This strategy of performing the distal anastomosis during circulatory arrest, often termed *open distal anastomosis*, obviates the need to place a clamp across the fragile aorta, avoiding further aortic damage. Also, it allows the surgeon to carefully inspect the aortic arch for intimal tears. The entire arch is replaced only if a primary intimal tear is located in the arch or if the arch is aneurysmal; in most acute cases, a less extensive, beveled "hemiarach" repair is adequate.¹²⁴ The distal aortic cuff is prepared by tacking the inner and outer walls together and using surgical adhesive to obliterate the false lumen and strengthen the tissue. A polyester tube graft is sutured to the distal aortic cuff. The anastomosis between the graft and the aorta is fashioned so that blood flow will be directed into the true lumen; this often alleviates any distal malperfusion problems that were present preoperatively. After the distal anastomosis is reinforced with additional adhesive, the graft is deaired and clamped, full cardiopulmonary bypass is resumed, rewarming is initiated, and the proximal portion of the repair is started. In the absence of annuloaortic ectasia or Marfan syndrome—which generally necessitate aortic root replacement—aortic valve regurgitation can be corrected by resuspending the commissures onto the outer aortic wall.¹²⁵ The proximal aortic cuff is prepared with tacking sutures and surgical adhesive before the proximal aortic anastomosis is performed.

Illustration of proximal aortic repair for acute ascending aortic dissection. **A.** This repair requires a median sternotomy and cardiopulmonary bypass. The ascending aorta is opened during hypothermic circulatory arrest, while antegrade cerebral perfusion is delivered via an axillary artery graft (see Fig. 22-8). **B.** The dissecting membrane is removed to expose the true lumen. **C.** Surgical adhesive is used to obliterate the false lumen and strengthen the aorta for the distal anastomosis. A 30-mL balloon catheter is placed in the true lumen to compress the distal false lumen; this helps keep the adhesive within the proximal false lumen, which maximizes the strength of the repair and prevents distal embolization of the adhesive through re-entry sites. A moist gauze sponge is placed in the true lumen to prevent the adhesive from running into the brachiocephalic vessels. **D.** An open distal anastomosis prevents clamp injury of the arch tissue and allows inspection of the arch lumen. A balloon perfusion catheter in the left common carotid artery ensures antegrade perfusion of the left cerebral circulation. If the origin of the dissection (i.e., intimal tear or disruption) does not extensively involve the greater curvature of the aortic arch, and if there is no evidence of a pre-existing arch aneurysm, a beveled, hemi-arch repair is carried out, preserving most of the greater curvature of the arch. The aorta is transected, beginning at the greater curvature immediately proximal to the origin of the innominate artery and extending distally toward the lesser curvature to the level

of the left subclavian artery. Consequently, most of the transverse aortic arch, except for the dorsal segment containing the brachiocephalic arteries, is removed. An appropriately sized, sealed (with collagen or gelatin) Dacron tube graft is selected, and the beveled distal anastomosis is made with continuous 3-0 or 4-0 monofilament suture. **E.** After the anastomosis is covered with additional adhesive and cardiopulmonary bypass is resumed, the aortic valve is assessed. Disrupted commissures are resuspended with pledgeted mattress sutures to restore valvular competence. **F.** The aorta is generally transected at the sinotubular junction, and adhesive is used to obliterate the false lumen within the proximal aortic stump. A moist gauze sponge is placed within the true lumen to prevent the adhesive from injuring the aortic valve leaflets or entering the coronary artery ostia. **G.** After the adhesive has set, the proximal anastomosis is carried out at the sinotubular junction, incorporating the distal margin of the commissures.

In the majority of patients who undergo surgical repair of acute ascending dissection, the dissection persists distal to the site of the operative repair. Extensive dilatation of the descending aorta develops in approximately 25% of the survivors, and rupture of the dilated distal aorta is the most common cause of late death in these patients. Freedom from distal reoperation is reported as 88% at 5 years and 76% at 10 years.¹²⁶ Therefore, after ascending aortic repair, most of these patients require aggressive treatment of the remaining acute descending aortic dissection, as described in detail later.

Chronic Ascending Dissection

Occasionally, patients with ascending aortic dissection present for repair in the chronic phase. In most respects, the operation is similar to that for acute dissection repair. The greater tissue strength in the chronic setting, which makes suturing safer, is a notable difference. In addition, the false lumen is not obliterated at the distal anastomosis; instead, the dissecting membrane is fenestrated into the arch to assure perfusion of both lumens and to prevent postoperative malperfusion complications. Unlike operations for acute dissection, operations for chronic dissection are often aggressive repairs that extend into the arch and root, because the tissues are much less fragile.

TREATMENT OF DESCENDING AORTIC DISSECTION

Nonoperative Management

Nonoperative, pharmacologic management of acute descending aortic dissection results in lower morbidity and mortality rates than surgical treatment does.¹¹⁴ The most common causes of death during nonoperative treatment are aortic rupture and end-organ malperfusion. Therefore, patients are continually reassessed for new complications. At least two serial CT scans—usually obtained on day 2 or 3 and on day 8 or 9 of treatment—are compared with the initial scan to rule out significant aortic expansion.

Once the patient's condition has been stabilized, pharmacologic management is gradually shifted from IV to oral medications. Oral therapy, usually including a beta antagonist, is initiated when systolic pressure is consistently between 100 and 110 mmHg and the neurologic, renal, and cardiovascular systems are stable. Many patients can be discharged after their blood pressure is well controlled with oral agents and after serial CT scans confirm the absence of aortic expansion.

Long-term pharmacologic therapy is important for patients with chronic aortic dissection. Beta blockers remain the drugs of choice.¹²⁷ In a 20-year follow-up study, DeBakey and colleagues¹²⁸ found that inadequate blood pressure control was associated with late aneurysm formation. Aneurysms developed in only 17% of patients with "good" blood pressure control, compared with 45% of patients with "poor" control.

Aggressive imaging follow-up is recommended for all patients with chronic aortic dissection.¹²⁹ Both contrast-enhanced CT and MRA scans provide excellent aortic imaging and facilitate serial comparisons to detect progressive aortic expansion. The first surveillance scan is obtained approximately 6 weeks after the onset of dissection. Subsequent scans are obtained at least every 3 months for the first year, every 6 months for the second year, and annually thereafter. Scans are obtained more frequently in high-risk patients, such as those with Marfan syndrome, and in those in whom significant aortic expansion is detected. For patients who have undergone graft repair of descending aortic dissection, annual CT or MRA scans are also obtained to detect false aneurysm formation or dilatation of unrepaired segments of aorta. Early detection of worrisome changes allows timely, elective intervention before rupture or other

complications develop. The importance of careful follow-up was illustrated by Glower and associates,¹³⁰ who reported long-term outcomes in patients who had undergone repair of chronic aortic dissection. Nearly 20% of late deaths were caused by aortic rupture, and 25% of patients required additional surgical repair during the follow-up period.

Indications for Surgery

Surgery is typically reserved for patients who experience complications.¹³¹ In general terms, surgical intervention for acute descending aortic dissection is intended to prevent or repair ruptures and relieve ischemic manifestations.

During the acute phase of a dissection, the specific indications for operative intervention include aortic rupture, increasing periaortic or pleural fluid volume, rapidly expanding aortic diameter, uncontrolled hypertension, and persistent pain despite adequate medical therapy. Acute dissection superimposed on a pre-existing aneurysm is considered a life-threatening condition and is therefore another indication for operation. Finally, patients who have a history of noncompliance with medical therapy may ultimately benefit more from surgical treatment if they are otherwise reasonable operative candidates.

Acute malperfusion syndromes also warrant intervention. In the recent past, visceral and renal malperfusion were considered indications for operation. Percutaneous interventions, however, have largely replaced open surgery for treatment of these complications. When the endovascular approach is unavailable or unsuccessful, surgical options can be used.

In the chronic phase, the indications for operative intervention for aortic dissections are similar to those for degenerative thoracic aortic aneurysms. These indications include rapid expansion of the aneurysm and other factors that increase the likelihood of rupture. Elective operation is considered when the affected segment has reached a diameter of 6.0 to 6.5 cm or when an aneurysm has enlarged by >1 cm during a 1-year period. A lower threshold often is used for patients with Marfan syndrome.

Endovascular Treatment

Malperfusion Syndrome

Endovascular therapy is routinely used in patients with descending aortic dissection complicated by visceral malperfusion.¹³² Abdominal malperfusion syndrome often is fatal; prompt identification of visceral ischemia and expedited treatment to restore hepatic, GI, and renal perfusion are imperative for a positive outcome. As described in a later section, several open surgical techniques can be used to re-establish blood flow to compromised organs. However, in the acute setting, open surgery is associated with poor outcomes. Therefore, endovascular intervention is the preferred initial approach in this setting. In one endovascular technique known as *endovascular fenestration*, a balloon is used to create a tear in the dissection flap, which allows blood to flow in both the true and false lumens. This technique can be used when a visceral branch is being supplied by an underperfused true or false lumen. Placement of a stent graft in the true lumen of the aorta can resolve a "dynamic" malperfusion. Occasionally, a small stent must be placed directly in the lumen of a visceral or renal artery because the dissection has propagated into the branch, creating "static" malperfusion at the origin.

Iliofemoral malperfusion causing limb-threatening leg ischemia also can be treated via an endovascular approach. However, direct surgical revascularization—usually by placing a femoral-to-femoral arterial bypass graft—is a better option whenever the endovascular procedure cannot be performed expeditiously.

Acute Dissection

There is considerable interest in using endovascular stent grafts to treat uncomplicated acute descending dissection. The goal of this treatment strategy is to use the stent graft to cover the intimal tear, seal the entry site of the dissection, and eventually cause thrombosis of the false lumen. However, whether this approach is more effective than conventional nonoperative management has not been established; therefore, at this time, the use of endografts in patients with classic dissection remains investigational.¹³³ Such procedures take place in a hybrid operating room, where access to the true lumen is gained from the femoral arteries. An aortogram is

taken, and the intimal tear is identified. Note that the diameter of the true lumen is measured on both the aortogram and a preoperative contrast-enhanced CT scan. A stent graft approximately 10% wider in diameter than the true lumen is selected for these cases. Unlike stents deployed in treating most descending thoracic aortic aneurysms, stents deployed in treating descending aortic dissections must *not* be ballooned, because ballooning can cause a new intimal tear, retrograde dissection into the ascending aorta, or even aortic rupture.

Chronic Dissection

Endovascular treatment of chronic descending aortic dissection also is currently under investigation.¹³⁴ These dissections are particularly challenging, because the relative rigidity of the dissecting membrane and the presence of multiple re-entry sites make it difficult to exclude the false lumen. Furthermore, interfering with false lumen perfusion may cause ischemic complications, such as bowel infarction or renal failure. Until the safety and effectiveness of endovascular repair for this condition have been demonstrated, patients with chronic descending aortic dissection should be treated with conventional nonoperative management until indications for open surgical repair develop.

Penetrating Aortic Ulcer

Unlike patients with classic descending aortic dissection, those with PAUs appear to be very well suited for endovascular intervention. Covering the focal ulceration with a stent graft has been shown to be an effective treatment.¹³⁵

Open Repair

Acute Dissection

In patients with acute aortic dissection, surgical repair of the descending thoracic or thoracoabdominal aorta is associated with high morbidity and mortality.¹¹⁴ Therefore, the primary goals of surgery are to prevent fatal rupture and to restore branch vessel perfusion.¹³¹ A limited graft repair of the life-threatening aortic lesion achieves these goals while minimizing risks. Because the most common site of rupture in descending aortic dissection is in the proximal third of the descending thoracic aorta, the upper half of the descending thoracic aorta is usually repaired. The distal half also may be replaced if it exceeds 4 cm in diameter. Graft replacement of the entire thoracoabdominal aorta is not attempted in this setting unless a large coexisting aneurysm mandates this radical approach. Similarly, the repair is not extended into the aortic arch unless the arch is aneurysmal, even if the primary tear is located there. Patients with chronic dissection who require emergency repair because of acute pain or rupture also undergo limited graft replacement of the symptomatic segment.

Because repairing acute dissections entails an increased risk of paraplegia, adjuncts that provide spinal cord protection, such as cerebrospinal fluid drainage and left heart bypass, are used liberally during such repairs,¹³⁶ even if the repair is confined to the upper descending thoracic aorta. Proximal control usually is obtained between the left common carotid and left subclavian arteries; any mediastinal hematoma near the proximal descending thoracic aorta is avoided until proximal control is established. After the aorta is opened, the dissecting membrane is excised from the section undergoing graft replacement. The proximal and distal anastomoses use all layers of the aortic wall, thereby excluding the false lumen in the suture lines and directing all blood flow into the true lumen. Although the relative lack of mural thrombus assures the presence of multiple patent intercostal arteries, extreme tissue fragility may preclude their reattachment.

Malperfusion Syndrome

Lower-extremity ischemia is commonly addressed with surgical extra-anatomic revascularization techniques, such as femoral-to-femoral bypass grafting. In patients with abdominal organ ischemia, flow to the compromised bed must be re-established swiftly. When an endovascular approach is unavailable or unsuccessful, open surgery is necessary. Although they are considered second-line therapies, multiple techniques are available, including graft replacement of the aorta (with flow redirected into the true lumen), open aortic fenestration, and visceral or renal artery bypass.

Chronic Dissection

A more aggressive replacement usually is performed during elective aortic repairs in patients with chronic dissection. In many regards, the operative approach used in these patients is identical to that used for descending thoracic and thoracoabdominal aortic aneurysms, as described in the first half of this chapter (Fig. 22-20). One key difference is the need to excise as much dissecting membrane as possible to clearly identify the true and false lumens and to locate all important branch vessels. When the dissection extends into the visceral or renal arteries, the membrane can be fenestrated, or the false lumen can be obliterated with sutures or intraluminal stents. Asymmetric expansion of the false lumen can create wide separation of the renal arteries. This problem is addressed by reattaching the mobilized left renal artery to a separate opening in the graft or by performing a left renal artery bypass with a side graft. Wedges of dissecting membrane also are excised from the aorta adjacent to the proximal and distal anastomoses, which allows blood to flow through both true and false lumens. When placing the proximal clamp is not technically feasible, hypothermic circulatory arrest can be used to facilitate the proximal portion of the repair.

Illustration of distal aortic repair of a chronic dissection. **A.** Thoracoabdominal incision. **B.** Extent II thoracoabdominal aortic aneurysm resulting from chronic aortic dissection. The patient has previously undergone composite valve graft replacement of the aortic root and ascending aorta. After left heart bypass is initiated, the proximal portion of the aneurysm is isolated by placing clamps on the left subclavian artery, between the left common carotid and left subclavian arteries, and across the middle descending thoracic aorta. **C.** The isolated segment of aorta is opened by using electrocautery. **D.** The dissecting membrane is excised, and bleeding intercostal arteries are oversewn. The aorta is prepared for proximal anastomosis by transecting it distal to the proximal clamp and separating this portion from the esophagus (not shown). **E.** The proximal anastomosis between the aorta and an appropriately sized Dacron graft is completed with continuous polypropylene suture. **F.** After left heart bypass has been stopped and the distal aortic cannula has been removed, the proximal clamp is repositioned onto the graft, the other two clamps are removed, and the remainder of the aneurysm is opened. **G.** The rest of the dissecting membrane is excised, and the openings to the celiac, superior mesenteric, and renal arteries are identified. **H.** Selective visceral perfusion with oxygenated blood from the bypass circuit is delivered through balloon perfusion

catheters placed in the celiac and superior mesenteric arterial ostia. Cold crystalloid is delivered to the renal arteries. The critical intercostal arteries are reattached to an opening cut in the graft. **I.** To minimize spinal cord ischemia, the proximal clamp is repositioned distal to the intercostal reattachment site. A second oval opening is fashioned in the graft adjacent to the visceral vessels. Selective perfusion of the visceral arteries continues during their reattachment to the graft. A separate anastomosis is often required to reattach the left renal artery. **J.** After the balloon perfusion catheters are removed and the visceral anastomosis is completed, the clamp is again moved distally, restoring blood flow to the celiac, renal, and superior mesenteric arteries. The final anastomosis is created between the graft and the distal aorta.

OUTCOMES

Improvements in anesthesia, surgical techniques, and perioperative care have led to substantial improvements in outcome after thoracic aortic aneurysm repair. When performed in specialized centers, these operations are associated with excellent survival rates and acceptable morbidity rates. The interpretation of outcomes data is complicated by site-specific variables, such as the number of years reported and whether data are taken from single-practice centers or from pooled, multi-center, or national registries, and by patient-specific variables, such as type of enrollment, urgency and extent of repair, concomitant procedures performed, and the presence of pre-existing risk factors such as advanced age, previous cardiovascular repair, disease of any system or organ, or connective tissue disorder.

Repair of Proximal Aortic Aneurysms

Risks associated with the open repair of the proximal aorta vary by extent of repair and are greatest for repairs involving total arch replacement. All varieties of aortic root replacement have shown acceptable early mortality rates and few complications. Two groups with 20 and 27 years' experience with composite valve graft replacement reported early mortality rates of 5.6% and 1.9%, respectively, with the more recent repairs having better outcomes.^{137,138} Early mortality rates for stentless porcine tissue root replacements are also low, ranging from 3.6 to 6.0%^{139–143}

Repairs incorporating the ascending aorta and aortic arch have acceptable outcomes, with risk increasing as larger sections of the aortic arch are incorporated into the repair.^{144,145} Reported early mortality rates after stage 1 elephant trunk repairs range from 2.3 to 13.9%.^{56,71,146–148}

The risk of operative death and stroke in these repairs is additionally increased by severe atherosclerosis of the ascending aorta, and a revised surgical strategy is often needed to avoid clamping this section of the aorta. In a review of literature accompanying Zingone and colleagues' own data for 36 such patients, pooled early death rates averaged 9.0% (ranged from 3.7 to 25.0%) and pooled stroke rates averaged 5.3% (ranged from 0 to 17.6%).¹⁴⁹ Their revised patient strategy included the use of hypothermic circulatory arrest in most patients (94%) and resulted in two early deaths (6%), one stroke (3%), and five patients with neurocognitive disturbances (14%). Other studies indicate that the enhanced risk of neurocognitive disturbances in ascending repairs using circulatory arrest are not offset by lower rates of early mortality.^{150,151}

In a report by Kazui and Bashir¹⁵² covering 20 years of experience and 472 consecutive patients who underwent aortic arch repair with selective antegrade cerebral perfusion, early mortality was 9.3% for all repairs and 4.1% for more recent repairs. The stroke rate was 3.2% for permanent deficits and 4.7% for temporary deficits. Recent innovations in aortic arch replacement, such as the use of extra-anatomic grafts and moderate hypothermia, have also produced good results, including early mortality rates ranging from 0 to 4.7%, permanent stroke rates ranging from 0 to 4.0%, and rates of transient neurologic dysfunction ranging from 0 to 4.9%.^{153–155}

Treatment of Acute Ascending Aortic Dissection

The International Registry of Acute Aortic Dissection (IRAD) provides the most comprehensive data on contemporary outcomes in patients with acute aortic dissection. This registry was established in 1996 and has accumulated data from >1600 patients treated for acute aortic dissection at 22 centers in 11 countries. A recent IRAD analysis of data for 682 patients who underwent surgical repair of

acute ascending aortic dissection revealed an inhospital mortality rate of 23.9%. The investigators identified several preoperative predictors of early mortality, including age >70 years, previous cardiac surgery, hypotension or shock at presentation, migrating pain, cardiac tamponade, pulse deficit, and evidence of myocardial ischemia or infarction on ECG.¹⁵⁶

Repair of Distal Aortic Aneurysms

ENDOVASCULAR REPAIR OF DESCENDING THORACIC AORTIC ANEURYSMS

In the earliest series of endovascular repairs of descending thoracic aortic aneurysms, mortality and morbidity were difficult to assess. Most of the reported series were small and contained a large proportion of high-risk patients with substantial comorbidity. For example, in the Stanford experience with "first-generation" stent grafts in 103 patients with descending thoracic aortic aneurysms, the operative mortality rate was 9%, the stroke rate was 7%, the paraplegia/paraparesis rate was 3%, and actuarial survival was only $73 \pm 5\%$ at 2 years. However, 62 patients (60%) were not considered candidates for thoracotomy and open surgical repair; as expected, this group experienced the majority of the morbidity and mortality.⁹⁷ In a follow-up series, the Stanford group reported survival rates of 74% at 1 year and 31% at 5 years after stent grafting in patients who were deemed not to be surgical candidates; in contrast, survival rates were 93% at 1 year and 78% at 5 years ($P < .001$) after stent grafting in patients who were deemed reasonable candidates for conventional open repair.¹⁵⁷ This study also found a 30% incidence of late aortic complications, which stresses the necessity for appropriate follow-up. A recent prospective, nonrandomized, multicenter trial compared 140 patients who underwent endograft exclusion with 94 historical or concurrent patients who underwent open repair. The stent graft group had significantly less morbidity and early mortality than the open repair group, although no significant between-group difference was observed in the rate of stroke (3.6% and 4.3%, respectively).¹⁵⁸ At 5 years, the two groups differed significantly in their aneurysm-related mortality rates (2.8% for endovascular patients and 11.7% for open repair patients) but not in their rates of all-cause mortality (which were 32% and 31%, respectively).¹⁵⁹

The efficacy of endovascular treatment of chronic descending thoracic aortic dissection has not been established. Small series have demonstrated the feasibility of this type of repair.^{117,160} For example, in a recent study of six patients who had undergone such repairs, Czerny and colleagues¹⁶⁰ found no evidence of complication or aneurysmal expansion in any patient during the period between 4 months and 25 months after the procedure. The INSTEAD trial (INvestigation of STEnt grafts in patients with type B Aortic Dissection) involving 136 patients with uncomplicated chronic descending aortic dissection is being conducted to determine whether stent grafting improves all-cause mortality at 1 year when used as an adjunct to medical antihypertensive therapy.¹³⁴ Early results of this randomized trial, which completed enrollment in 2005, already appear to show increased mortality in the stent recipients.¹⁶¹ Thus, at present, the use of stent grafts to treat chronic descending aortic dissection should be considered experimental.

OPEN REPAIR OF DESCENDING THORACIC AND THORACOABDOMINAL AORTIC ANEURYSMS

Contemporary results of open repairs of descending thoracic aortic aneurysms indicate that early mortality rates range from 4.4 to 8.0% and paraplegia rates range from 2.3 to 5.7%; stroke rates are generally lower, ranging from 1.8 to 2.1%.^{162–164} In our series, although the risk of paraplegia increased with the extent of repair, the risk of mortality was greatest for those undergoing repair of the proximal two thirds of the descending aorta.¹⁶² As expected, stroke rates after distal aortic repairs were highest when the clamp site was near the left subclavian artery.

Several studies have compared endovascular and surgical approaches to descending thoracic aortic repair. Some studies found no significant differences in rates of early death, stroke, and paraplegia,^{165–167} whereas others found that surgical patients had higher rates of early mortality (27%)¹⁶⁸ and paraplegia (14%).¹⁵⁸

Contemporary series of open thoracoabdominal aortic repairs show acceptable survival. Reported outcome rates range from 5 to 12% for early mortality, 4 to 9.5% for paraplegia, 1.7 to 5.2% for stroke, and 6 to 12% for renal complications. These series reports generally summarize 10 to 20 years of surgical experience.^{163,169–171} Even for complex thoracoabdominal aortic repairs, such as stage

2 elephant trunk repairs, several centers report acceptable early mortality rates ranging from 0 to 10%.^{56,71,146–148} Worse outcomes are also documented, as in a statewide, nonfederal analysis of 1010 patients in which the early mortality rate was 25%. Of note, 40% of these patients were treated at centers averaging only one thoracoabdominal aortic aneurysm repair per year.¹⁷² Cowan and colleagues,¹⁷³ who examined the influence of familiarity with the procedure on rates of mortality and morbidity after thoracoabdominal aortic aneurysm repair, reported that patients treated at low-volume centers fared less well. Replacing the entire thoracoabdominal aorta (i.e., performing an extent II repair) carries the highest risk of death, bleeding, renal failure, and paraplegia.^{78,163,169}

Treatment of Acute Descending Aortic Dissection

NONOPERATIVE MANAGEMENT

The inhospital mortality rate for patients with acute descending aortic dissection who receive nonoperative treatment is nearly 10%.^{114,174} The primary causes of death during nonoperative management are rupture, malperfusion, and cardiac failure. Risk factors associated with treatment failure—defined as death or need for surgery—include an enlarged aorta, persistent hypertension despite maximal treatment, oliguria, and peripheral ischemia. Among patients who receive nonoperative treatment for descending aortic dissection and who survive the acute period, approximately 90% remain alive 1 year later and approximately 76% are alive 3 years later.¹⁷⁵

ENDOVASCULAR TREATMENT

For malperfusion of the visceral or renal arteries, an endovascular approach is ideal. The Stanford group reported a 93% technical success rate for endovascular reperfusion of an ischemic bed.¹⁷⁶ Their experience with the use of first-generation stents to treat acute complicated descending dissections was also encouraging: Complete thrombosis of the false lumen occurred in 79% of patients. The early mortality rate was 16%, comparable to that associated with open techniques.¹⁷⁷ A recent meta-analysis of observational studies of endovascular stenting, which included 248 patients with acute descending aortic dissection, found a 30-day mortality rate of 9.8%. When compared with mortality rates obtained from IRAD data, this rate is substantially lower than the rate associated with open surgical treatment, but similar to the rate achieved with nonoperative management.¹⁷⁸

OPEN REPAIR

We recently reported our 16-year experience with 76 patients with acute descending aortic dissection. Complexities included emergent (86%) or urgent (14%) repair, rupture (22%), pain (53%), and aneurysm superimposed on the dissection (96%). The 30-day mortality rate was 15%, and the inhospital mortality rate was 22%.¹⁷⁹ There were 5 cases of paraplegia (7%), five strokes (7%), and 15 cases of renal failure (20%). In a recent multicenter study, the IRAD investigators found a 33% inhospital mortality rate among 52 patients with acute dissection who underwent open surgical replacement of the descending thoracic aorta.¹⁸⁰ Another study found that, of patients who survive surgical treatment of acute descending aortic dissection, approximately 96% were alive at 1 year and approximately 83% were alive at 3 years after the procedure.¹⁷⁵

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 23. Arterial Disease >

KEY POINTS

1. Carotid intervention as a preventive strategy should be performed in patients with 50% or greater symptomatic internal carotid artery stenosis, and those with 80% or greater asymptomatic internal carotid artery stenosis. Carotid intervention for asymptomatic stenosis between 60% and 79% remains controversial, and is a function of an operator's stroke rate. The choice of intervention—carotid endarterectomy vs. carotid stenting—remains controversial; currently, carotid endarterectomy appears to be associated with lower stroke rate, whereas carotid stenting is more suitable under certain anatomic or physiologic conditions.
2. Abdominal aortic aneurysms should be repaired when the risk of rupture, determined mainly by aneurysm size, exceeds the risk of death due to perioperative complications or concurrent illness. Endovascular repair is associated with less perioperative morbidity and mortality compared to open reconstruction, and is preferred for high-risk patients who meet specific anatomic criteria.
3. Symptomatic mesenteric ischemia should be treated to improve quality of life and prevent bowel infarction. Operative treatment—bypass—is superior to endovascular intervention, although changes in wire and stent technology have improved the results of mesenteric stenting in recent series.
4. Aortoiliac occlusive disease can be treated with either endovascular means or open reconstruction, depending on patient risk stratification, occlusion characteristics, and symptomatology.
5. Claudication is a marker of extensive atherosclerosis, and is mainly managed with risk factor modification and pharmacotherapy. Only 5% of claudicants will need intervention because of disabling extremity pain. The five-year mortality of a patient with claudication approaches 30%. Patients with rest pain or tissue loss need expeditious evaluation and vascular reconstruction to ameliorate the severe extremity pain and prevent limb loss.
6. For infrainguinal occlusive disease, open revascularization is more durable than endovascular treatment. The latter, however, is associated with significantly less morbidity, may represent the procedure of choice in high-risk patients, and can provide adequate inflow to treat limited areas of tissue loss.

GENERAL APPROACH TO THE VASCULAR PATIENT

Because the vascular system involves every organ system in our body, the symptoms of vascular disease are as varied as those encountered in any medical specialty. Lack of adequate blood supply to target organs typically presents with pain; for example, calf pain with lower extremity (LE) claudication, postprandial abdominal pain from mesenteric ischemia, and arm pain with axillosubclavian arterial occlusion. In contrast, stroke and transient ischemic attack (TIA) are the presenting symptoms from middle cerebral embolization as a consequence of a stenosed internal carotid artery (ICA). The pain syndrome of arterial disease usually is divided clinically into acute and chronic types, with all shades of severity between the two extremes. Sudden onset of pain can indicate complete occlusion of a critical vessel, leading to more severe pain and

critical ischemia in the target organ, resulting in lower limb gangrene or intestinal infarction. Chronic pain results from a slower, more progressive atherosclerotic occlusion, which can be totally or partially compensated by developing collateral vessels. Acute on chronic is another pain pattern in which a patient most likely has an underlying arterial stenosis that suddenly occludes; for example, the patient with a history of calf claudication who now presents with sudden, severe acute limb-threatening ischemia. The clinician should always try to understand and relate the clinical manifestations to the underlying pathologic process.

Vascular History

Appropriate history should be focused on the presenting symptoms related to the vascular system (Table 23-1). Of particular importance in the previous medical history is noting prior vascular interventions (endovascular or open surgical), and all vascular patients should have inquiry made about their prior cardiac history and current cardiac symptoms. Approximately 30% of vascular patients will be diabetic. A history of prior and current smoking status should be noted.

Table 23-1 Pertinent Elements in Vascular History
• History of stroke or transient ischemic attack
• History of coronary artery disease, including previous myocardial infarction and angina
• History of peripheral arterial disease
• History of diabetes
• History of hypertension
• History of tobacco use
• History of hyperlipidemia

The patient with carotid disease in most cases is completely asymptomatic, having been referred based on the finding of a cervical bruit or duplex finding of stenosis. Symptoms of carotid territory TIAs include transient monocular blindness (amaurosis), contralateral weakness or numbness, and dysphasia. Symptoms persisting longer than 24 hours constitute a stroke. In contrast, the patient with chronic mesenteric ischemia is likely to present with postprandial abdominal pain and weight loss. The patient fears eating because of the pain, avoids food, and loses weight. It is very unlikely that a patient with abdominal pain who has not lost weight has chronic mesenteric ischemia.

The patient with LE pain on ambulation has intermittent claudication that occurs in certain muscle groups; for example, calf pain upon exercise usually reflects superficial femoral artery (SFA) disease, while pain in the buttocks reflects iliac disease. In most cases, the pain manifests in one muscle group below the level of the affected artery, occurs only with exercise, and is relieved with rest only to recur at the same location, hence the term *window gazers disease*. Rest pain (a manifestation of severe underlying occlusive disease) is constant and occurs in the foot (not the muscle groups), typically at the metatarsophalangeal junction, and is relieved by dependency. Often, the patient is prompted to sleep with their foot hanging off one side of the bed to increase the hydrostatic pressure.

Vascular Physical Examination

Specific vascular examination should include abdominal aortic palpation, carotid artery examination, and pulse examination of the LE (femoral, popliteal, posterior tibial, and dorsalis pedis arteries). The abdomen should be palpated for an abdominal aortic aneurysm (AAA), detected as an expansile pulse above the level of the umbilicus. It also should be examined for the

presence of bruits. Because the aorta typically divides at the level of the umbilicus, an aortic aneurysm is most frequently palpable in the epigastrium. In thin individuals, a normal aortic pulsation is palpable, while in obese patients even large aortic aneurysms may not be detectable. Suspicion of a clinically enlarged aorta should lead to the performance of an ultrasound scan for a more accurate definition of aortic diameter.

The carotids should be auscultated for the presence of bruits, although there is a higher correlation with coronary artery disease (CAD) than underlying carotid stenosis. A bruit at the angle of the mandible is a significant finding, leading to follow-up duplex scanning. The differential diagnosis is a transmitted murmur from a sclerotic or stenotic aortic valve. The carotid is palpable deep to the sternocleidomastoid muscle in the neck. Palpation, however, should be gentle and rarely yields clinically useful information.

Upper extremity examination is necessary when an arteriovenous graft is to be inserted in patients who have symptoms of arm pain with exercise. Thoracic outlet syndrome can result in occlusion or aneurysm formation of the subclavian artery. Distal embolization is a manifestation of thoracic outlet syndrome; consequently, the fingers should be examined for signs of ischemia and ulceration. The axillary artery enters the limb below the middle of the clavicle, where it can be palpated in thin patients. It usually is easily palpable in the axilla and medial upper arm. The brachial artery is most easily located at the antecubital fossa immediately medial to the biceps tendon. The radial artery is palpable at the wrist anterior to the radius.

For LE vascular examination, the femoral pulse usually is palpable midway between the anterior superior iliac spine and the pubic tubercle. The popliteal artery is palpated in the popliteal fossa with the knee flexed to 45° and the foot supported on the examination table to relax the calf muscles. Palpation of the popliteal artery is a bimanual technique. Both thumbs are placed on the tibial tuberosity anteriorly and the fingers are placed into the popliteal fossa between the two heads of the gastrocnemius muscle. The popliteal artery is palpated by compressing it against the posterior aspect of the tibia just below the knee. The posterior tibial pulse is detected by palpation 2 cm posterior to the medial malleolus. The dorsalis pedis is detected 1 cm lateral to the hallucis longus extensor tendon, which dorsiflexes the great toe and is clearly visible on the dorsum of the foot. Pulses can be graded using either the traditional four-point scale or the basic two-point scale system (Table 23-2). The foot also should be carefully examined for pallor on elevation and rubor on dependency, as these findings are indicative of chronic ischemia. Note should also be made of nail changes and loss of hair. Ulceration and other findings specific to disease states are described in relevant sections below.

Table 23-2 Grading Scales for Peripheral Pulses			
Traditional Scale		Basic Scale	
4+	Normal	2+	Normal
3+	Slightly reduced	1+	Diminished
2+	Markedly reduced	0	Absent
1+	Barely palpable	—	—
0	Absent	—	—

After reconstructive vascular surgery, the graft may be available for examination, depending on its type and course. The in situ LE graft runs in the subcutaneous fat and can be palpated along most of its length. A change in pulse quality, aneurysmal enlargement, or a new bruit should be carefully noted. Axillofemoral grafts, femoral-to-femoral grafts, and arteriovenous access grafts usually can be easily palpated as well.

Noninvasive Diagnostic Evaluation of the Vascular Patient

ANKLE-BRACHIAL INDEX

There is increasing interest in the use of the ankle-brachial index (ABI) to evaluate patients at risk for cardiovascular events. An ABI <0.9 correlates with increased risk of myocardial infarction and indicates significant, although perhaps asymptomatic, underlying peripheral vascular disease. The ABI is determined in the following ways. Blood pressure (BP) is measured in both upper extremities using the highest systolic BP as the denominator for the ABI. The ankle pressure is determined by placing a BP cuff above the ankle and measuring the return to flow of the posterior tibial and dorsalis pedis arteries using a pencil Doppler probe over each artery. The ratio of the systolic pressure in each vessel divided by the highest arm systolic pressure can be used to express the ABI in both the posterior tibial and dorsalis pedis arteries (Fig. 23-1). Normal is more than 1. Patients with claudication typically have an ABI in the 0.5 to 0.7 range, and those with rest pain are in the 0.3 to 0.5 range. Those with gangrene have an ABI of <0.3 . These ranges can vary depending on the degree of compressibility of the vessel. The test is less reliable in patients with heavily calcified vessels. Due to noncompressibility, some patients such as diabetics and those with end-stage renal disease may have an ABI of 1.40 or greater and require additional noninvasive diagnostic testing to evaluate for peripheral arterial disease (PAD). Alternative tests include toe-brachial pressures, pulse volume recordings, transcutaneous oxygen measurements, or vascular imaging (duplex ultrasound).

Fig. 23-1.

Right ABI = ratio of

Higher of the right ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Left ABI = ratio of

Higher of the left ankle systolic pressures (posterior tibial or dorsalis pedis)

Higher arm systolic pressure (left or right arm)

Calculating the ankle-brachial index.

SEGMENTAL LIMB PRESSURES

By placing serial BP cuffs down the LE and then measuring the pressure with a Doppler probe as flow returns to the artery below the cuff, it is possible to determine segmental pressures down the leg. These data can then be used to infer the level of the occlusion. The systolic pressure at each level is expressed as a ratio, with the highest systolic pressure in the upper extremities as the denominator. Normal segmental pressures commonly show high thigh pressures 20 mmHg or greater in

comparison to the brachial artery pressures. The low thigh pressure should be equivalent to brachial pressures. Subsequent pressures should fall by no more than 10 mmHg at each level. A pressure gradient of 20 mmHg between two subsequent levels is usually indicative of occlusive disease at that level. The most frequently used index is the ratio of the ankle pressure to the brachial pressure, the ABI. Normally the ABI is >1.0 , and a value <0.9 indicates some degree of arterial obstruction and has been shown to be correlated with an increased risk of coronary heart disease.¹ Limitations of relying on segmental limb pressures include: (a) missing isolated moderate stenoses (usually iliac) that produce little or no pressure gradient at rest; (b) falsely elevated pressures in patients with diabetes and end-stage renal disease; and (c) the inability to differentiate between stenosis and occlusion.² Patients with diabetes and end-stage renal disease have calcified vessels that are difficult to compress, thus rendering this method inaccurate, due to recording of falsely elevated pressure readings. Noncompressible arteries yield ankle systolic pressures of 250 mmHg or greater and an ABI of >1.40 . In this situation, absolute toe and ankle pressures can be measured to gauge critical limb ischemia. Ankle pressures <50 mmHg or toe pressures <30 mmHg are indicative of critical limb ischemia. The toe pressure is normally 30 mmHg less than the ankle pressure, and a toe-brachial index of <0.70 is abnormal. False-positive results with the toe-brachial index are unusual. The main limitation of this technique is that it may be impossible to measure pressures in the first and second toes due to pre-existing ulceration.

PULSE VOLUME RECORDING

In patients with noncompressible vessels, segmental plethysmography can be used to determine underlying arterial occlusive disease. Cuffs placed at different levels on the leg detect changes in leg volume and produce a pulse volume recording (PVR) when connected to a plethysmograph (Fig. 23-2). To obtain accurate PVR waveforms the cuff is inflated to 60 to 65 mmHg to detect volume changes without causing arterial occlusion. Pulse volume tracings are suggestive of proximal disease if the upstroke of the pulse is not brisk, the peak of the wave tracing is rounded, and there is disappearance of the dicrotic notch.

A. Pulse volume recording is done by connecting blood pressure cuffs and plethysmograph to various levels of the leg. **B.** Typical report of peripheral vascular study with arterial segmental pressure measurement plus Doppler evaluation of the lower extremity.

Although isolated segmental limb pressures and PVR measurements are 85% accurate when compared with angiography in detecting and localizing significant atherosclerotic lesions, when used in combination, accuracy approaches 95%.³ For this reason, it is suggested that these two diagnostic modalities be used in combination when evaluating PAD.

Radiological Evaluation of the Vascular Patient

ULTRASOUND

Ultrasound examinations are relatively time consuming, require experienced technicians, and may not visualize all arterial segments. Doppler waveform analysis can suggest atherosclerotic occlusive disease if the waveforms in the insonated arteries are biphasic, monophasic, or asymmetrical. B-mode ultrasonography provides black and white, real-time images. B-mode ultrasonography does not evaluate blood flow; thus, it cannot differentiate between fresh thrombus and flowing blood,

which have the same echogenicity. Calcification in atherosclerotic plaques will cause acoustic shadowing. B-mode ultrasound probes cannot be sterilized. Use of the B-mode probe intraoperatively requires a sterile covering and gel to maintain an acoustic interface. Experience is needed to obtain and interpret images accurately. Duplex ultrasonography entails performance of B-mode imaging, spectral Doppler scanning, and color flow duplex scanning. The caveat to performance of duplex ultrasonography is meticulous technique by a certified vascular ultrasound technician, so that the appropriate 60° Doppler angle is maintained during insonation with the ultrasound probe. Alteration of this angle can markedly alter waveform appearance and subsequent interpretation of velocity measurements. Direct imaging of intra-abdominal vessels with duplex ultrasound is less reliable because of the difficulty in visualizing the vessels through overlying bowel. These disadvantages currently limit the applicability of duplex scanning in the evaluation of aortoiliac and infrapopliteal disease. In a recent study, duplex ultrasonography had lower sensitivity in the calculation of infrapopliteal vessel stenosis in comparison to conventional digital subtraction or computer tomography angiography.⁴ Few surgeons rely solely on duplex ultrasonography for preoperative planning in LE revascularizations. However, in the hands of experienced ultrasonographers, LE arteries can be assessed accurately by determining the significance of velocity criteria across the arterial stenosis. Duplex scanning is unable to evaluate recently implanted polytetrafluoroethylene (PTFE) and polyester (Dacron) grafts because they contain air, which prevents ultrasound penetration.

COMPUTED TOMOGRAPHY ANGIOGRAPHY

Computed tomography angiography (CTA) is a noninvasive, contrast-dependent method for imaging the arterial system. It depends on IV infusion of iodine-based contrast agents. The patient is advanced through a rotating gantry, which images serial transverse slices. The contrast-filled vessels can be extracted from the slices and rendered in three-dimensional format (Fig. 23-3). The extracted images can also be rotated and viewed from several different directions during postacquisition image processing. This technology has been advanced as a consequence of aortic endografting. CTA provides images for postprocessing that can be used to display the aneurysm in a format that demonstrates thrombus, calcium, lumen, and the outer wall, and allows "fitting" of a proposed endograft into the aneurysm (Fig. 23-4). CTA is increasingly being used to image the carotid bifurcation, and as computing power increases, the speed of image acquisition and resolution will continue to increase. The major limitations of multidetector CTA are use of contrast and presence of artifacts caused by calcification and stents. CTA can overestimate the degree of instent stenosis, while heavy calcification can limit the diagnostic accuracy of the method by causing a "blooming artifact."⁵ The artifacts can be overcome with alteration in image acquisition technique. There are no randomized trials to document the superiority of multidetector CTA over traditional angiography, but there is emerging evidence to support the claim that multidetector CTA has sensitivity, specificity, and accuracy that rival invasive angiography.⁵

Three-dimensional computed tomographic angiogram of an abdominal aortic aneurysm that displays various aneurysm

components, including thrombus, aortic calcification, blood circulation, and aneurysm wall.

MAGNETIC RESONANCE ANGIOGRAPHY

Magnetic resonance angiography (MRA) has the advantage of not requiring iodinated contrast agents to provide vessel opacification (Fig. 23-5). Gadolinium is used as a contrast agent for MRA studies, and as it is generally not nephrotoxic, it can be used in patients with elevated creatinine. MRA is contraindicated in patients with pacemakers, defibrillators, spinal cord stimulators, intracerebral shunts, cochlear implants, and cranial clips. Patients with claustrophobia may require sedation to be able to complete the test. The presence of metallic stents causes artifacts and signal dropout; however, these can be dealt with using alternations in image acquisition and processing. Nitinol stents produce minimal artifact.⁶ Compared to other modalities, MRA is relatively slow and expensive. However, due to its noninvasive nature and decreased nephrotoxicity, MRA is being used more frequently for imaging vasculature in various anatomic distributions.

Magnetic resonance angiogram of aortic arch and carotid arteries. This study can provide a three-dimensional analysis of vascular structures such as aortic arch branches, as well as carotid and vertebral arteries.

DIAGNOSTIC ANGIOGRAPHY

Diagnostic angiography is considered the gold standard in vascular imaging. In many centers, its use is rapidly decreasing due to the development of noninvasive imaging modalities such as duplex arterial mapping, CTA, and MRA. Nevertheless, contrast angiography still remains in widespread use. The essential aspects of angiography are vascular access and catheter

placement in the vascular bed that requires examination. The imaging system and the contrast agent are used to opacify the target vessel. Although in the past this function has largely been delegated to the interventional radiology service, an increasing number of surgeons are performing this procedure and following the diagnostic imaging with immediate surgical or endovascular intervention. There are several considerations when relying on angiography for imaging.

Approximately 70% of atherosclerotic plaques occur in an eccentric location within the blood vessel; therefore, images can be misleading when trying to evaluate stenoses because angiography is limited to a uniplanar "lumenogram." With increased use of intravascular stent deployment, it has been also noted that assessment of stent apposition and stent position in relation to surrounding branches may be inaccurate. Furthermore, angiography exposes the patient to the risks of both ionizing radiation and intravascular contrast. Nevertheless, contrast angiography remains the most common invasive method of vascular investigation for both diagnostic and therapeutic intervention. The angiogram usually provides the final information needed to decide whether or not to proceed with operation or endovascular interventions.

Digital subtraction angiography (DSA) offers some advantages over conventional cut-film angiography, such as excellent visualization despite use of lower volumes of contrast media. In particular when multilevel occlusive lesions limit the amount of contrast reaching distal vessels, supplemental use of digital subtraction angiographic techniques may enhance visualization and definition of anatomy. Intra-arterial DSA uses a portable, axially rotatable imaging device that can obtain views from different angles. DSA also allows for real-time video replay (Fig. 23-6). An entire extremity can be filmed with DSA, using repeated injections of small amounts of contrast agent to obtain sequential angiographic images, the so-called *pulse-chase technique*.

Digital subtraction angiography provides excellent visualization of intravascular circulation with intra-arterial contrast administration. As depicted in this digital subtraction angiography study, multilevel lesions are demonstrated that include a focal left iliac artery stenosis (*large arrow*), right superficial femoral occlusion (*curved arrows*), left superficial femoral stenosis (*small arrow*), and multiple tibial artery stenoses (*arrowheads*).

PREOPERATIVE CARDIAC EVALUATION

The most important and controversial aspect of preoperative evaluation in patients with atherosclerotic disease requiring surgical intervention is the detection and subsequent management of associated CAD.⁷ Several studies have documented the existence of significant CAD in 40 to 50% or more of patients requiring peripheral vascular reconstructive procedures, 10 to 20% of whom may be relatively asymptomatic largely because of their inability to exercise.⁸ Myocardial infarction is responsible for the majority of both early and late postoperative deaths. Most available screening methods lack sensitivity and specificity to predict postoperative cardiac complications. There have been conflicting reports regarding the utility of preoperative dipyridamole-thallium nuclear imaging or dobutamine-echocardiography to stratify vascular patients in terms of perioperative cardiac morbidity and mortality. In nearly one half of patients, thallium imaging proves to be unnecessary because cardiac risk can be predicted by clinical information alone.⁷ Even with coronary angiography, it is difficult to relate anatomic findings to functional significance, and hence, surgical risk. There are no data confirming that percutaneous coronary interventions or surgical revascularization before vascular surgical procedures impacts mortality or incidence of myocardial infarctions. In fact, coronary angiography is associated with its own inherent risks, and patients undergoing coronary artery bypass grafting or coronary percutaneous transluminal angioplasty (PTA) before needed aortoiliac reconstructions are subjected to the risks and complications of both procedures.

The Coronary Artery Revascularization Prophylaxis trial showed that coronary revascularization in patients with peripheral vascular disease and significant CAD, who are considered high risk for perioperative complications, did not reduce overall mortality or perioperative myocardial infarction.⁹ Additionally, patients who underwent prophylactic coronary revascularization had significant delays before undergoing their vascular procedure and increased limb morbidity compared to patients who did not. Studies do support improvement in cardiovascular and overall prognosis with medical optimization of patients. Therefore, use of perioperative beta blockade, as well as use of antiplatelet medication, statins, and angiotensin-converting enzyme (ACE) inhibitors is encouraged in vascular patients.^{10,11}

BASIC PRINCIPLES OF ENDOVASCULAR THERAPY

Cardiovascular disease remains a major cause of mortality in the developed world since the beginning of the twenty-first century. Although surgical revascularization has played a predominant role in the management of patients with vascular disease, the modern treatment paradigms have evolved significantly with increased emphasis of catheter-based percutaneous interventions over the past two decades. The increasing role of this minimally invasive vascular intervention is fueled by various factors, including rapid advances in imaging technology and reduced morbidity and mortality in endovascular interventions, as well as faster convalescence following percutaneous therapy when compared to traditional operations. There is little doubt that, with continued device development and refined image-guided technology, endovascular intervention will provide improved clinical outcomes and play an even greater role in the treatment of vascular disease.

The technique of percutaneous access for both the diagnostic and therapeutic management of vascular disease has resulted in tremendous changes in the practice of several subspecialties, including interventional radiology, invasive cardiology, and vascular surgery. The development of catheter and endoscopic instrumentation allows the vascular surgeon to operate via an intra- or extraluminal route. Endovascular techniques are now able to treat the full spectrum of vascular pathology, including stenoses and occlusions resulting from several etiologies, aneurysmal pathology, and traumatic lesions. Many of these procedures have only recently been developed, and, as such, have not been investigated in a manner that would enable an accurate comparison with the more traditional methods of open surgical intervention. Long-term follow-up for these procedures is frequently lacking. However, because of the potential to treat patients with decreased mortality and morbidity, endovascular skills and techniques are being adopted into mainstream vascular surgery.

Needles and Access

Needles are used to achieve percutaneous vascular access. The size of the needle will be dictated by the diameter of the guidewire used. Most often, an 18-gauge needle is used, as it will accept a 0.035-in guidewire. A 21-gauge micropuncture needle will accept a 0.018-in guidewire. The most popular access needle is the Seldinger needle, which can be used for single- and double-wall puncture techniques.

Femoral arterial puncture is the most common site for access. The common femoral artery (CFA) is punctured over the medial third of the femoral head, which is landmarked using fluoroscopy. The single-wall puncture technique requires a sharp, beveled needle tip and no central stylet. The anterior wall of the vessel is punctured with the bevel of the needle pointing up and pulsatile back-bleeding indicates an intraluminal position. This method is most useful for graft punctures, patients with abnormal clotting profiles, or if thrombolytic therapy is anticipated. Once the needle assumes an intraluminal position, verified by pulsatile back-bleeding, the guidewire may be advanced. This is always passed gently and under fluoroscopic guidance to avoid subintimal dissection or plaque disruption. Double-wall puncture techniques are performed with a blunt needle that has a removable inner cannula. The introducer needle punctures both walls of the artery and is

withdrawn until bleeding is obtained to confirm intraluminal position before advancing a guidewire. There can be troublesome bleeding from the posterior arterial wall puncture; therefore, single puncture techniques are preferred.

Retrograde femoral access is the most common arterial access technique (Fig. 23-7). The advantages of this technique include the size and fixed position of the CFA, as well as the relative ease of compression against the femoral head at the end of the procedure. Care should be taken to avoid puncturing the external iliac artery (EIA) above the inguinal ligament because this can result in retroperitoneal hemorrhage secondary to ineffective compression of the puncture site. Likewise, puncturing too low, at or below the CFA bifurcation can result in thrombosis or pseudoaneurysm formation of the SFA or profunda femoris artery (PFA). Antegrade femoral access is more difficult than retrograde femoral access and there is a greater tendency to puncture the SFA, but it is invaluable when the aortic bifurcation cannot be traversed or when devices are not long enough to reach a lesion from a contralateral femoral access approach. Occasionally, when the distal aorta or bilateral iliac arteries are inaccessible because of the extent of atherosclerotic lesions, scarring, or presence of bypass conduits, the brachial artery must be used to obtain access for diagnostic and therapeutic interventions. The left brachial artery is punctured, as this avoids the origin of the carotid artery and thus decreases the risk of catheter-related emboli to the brain. The artery is accessed with a micropuncture needle just proximal to the antecubital crease. The use of brachial access is associated with a higher risk of thrombosis and nerve injuries than femoral access.

A. Antegrade femoral artery access. The needle is inserted just below the inguinal ligament in the common femoral artery whereby the guidewire is inserted in the ipsilateral superficial femoral artery. **B.** Brachial artery approach. The needle is inserted in a retrograde fashion in the brachial artery just above the antecubital fossa, whereby the guidewire is next inserted in the brachial artery.

Guidewires

Guidewires are used to introduce, position, and exchange catheters. A guidewire generally has a flexible and stiff end. In general, only the flexible end of the guidewire is placed in the vessel. All guidewires are composed of a stiff inner core and an outer tightly coiled spring that allows a catheter to track over the guidewire. There are five essential characteristics of

guidewires: size, length, stiffness, coating, and tip configuration.

Guidewires come in different maximum transverse diameters ranging from 0.011 to 0.038 in. For most aortoiliac procedures, a 0.03-in wire is most commonly used while the smaller diameter 0.018-in guidewires are reserved for selective small vessel angiography, such as infrageniculate or carotid lesions. In addition to diameter size, guidewires come in varying lengths usually ranging from 180 to 260 cm in length. Increasing the length of the wire always makes it more difficult to handle and increases the risk of contamination. While performing a procedure, it is important to maintain the guidewire across the lesion until the completion arteriogram has been satisfactorily completed.

The stiffness of the guidewire is also an important characteristic. Stiff wires allow for passage of large aortic stent graft devices without kinking. They are also useful when trying to perform sheath or catheter exchanges around a tortuous artery. An example of a stiff guidewire is the Amplatz wire. Hydrophilic coated guidewires, such as the Glidewire, have become invaluable tools for assisting in difficult catheterizations. The coating is primed by bathing the guidewire in saline solution. The slippery nature of this guidewire along with its torque capability significantly facilitates passage of this guidewire in difficult catheterizations. Guidewires also come in various tip configurations. Angled tip wires like the angled Glidewire can be steered to manipulate a catheter across a tight stenosis or to select a specific branch of a vessel. The Rosen wire has a soft curled end that makes it ideal for renal artery stenting. The soft curl of this wire prevents it from perforating small renal branch vessels.

Hemostatic Sheaths

The hemostatic sheath is a device through which endovascular procedures are performed. The sheath acts to protect the vessel from injury as wires and catheters are introduced (Fig. 23-8). A one-way valve prevents bleeding through the sheath, and a side port allows contrast or heparin flushes to be administered during the procedure. Sheaths are sized by their inner diameter. The most commonly used sheaths for percutaneous access have a 5Fr to 9Fr inner diameter, but with open surgical exposure of the CFA, sheaths as large as 26Fr can be introduced. Sheaths also vary in length and long sheaths are available so that interventions remote from the site of arterial access can be performed.

All percutaneous endovascular procedures are performed through an introducer sheath (*large arrow*), which provides an access conduit from skin to intravascular compartment. The sheath also acts to protect the vessel from injury as guidewires (*small arrows*) and catheters are introduced.

Catheters

A wide variety of catheters exist that differ primarily in the configuration of the tip. The multiple shapes permit access to vessels of varying dimensions and angulations. Catheters are used to perform angiography, protect the passage of balloons and stents, and can be used to direct the guidewire through tight stenoses or tortuous vessels.

Angioplasty Balloons

Angioplasty balloons differ primarily in their length and diameter, as well as the length of the catheter shaft. As balloon technology has advanced, lower profiles have been manufactured (i.e., the size that the balloon assumes upon deflation). Balloons are used to perform angioplasty on vascular stenoses, to deploy stents, and to assist with additional expansion after insertion of self-expanding stents (Fig. 23-9). Besides length and diameter, operators need to be familiar with several other balloon characteristics. Noncompliant and low-compliance balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliance balloons are the mainstay for peripheral intervention. Lower profile balloons are less likely to get caught during passage through stents and are easier to pull out of sheaths. Under fluoroscopic guidance, balloon inflation is performed until the waist of the atherosclerotic lesion disappears and the balloon is at the full profile. The duration of balloon inflation and pressures used for the angioplasty depend on the indication for the intervention as well as the location and characteristics of the lesion being treated. Frequently, several inflations are required to achieve a full profile of the balloon. Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion. After inflation, most balloons do not regain their preinflation diameter and

assume a larger profile. Trackability, pushability, and crossability of the balloon should all be considered when choosing a particular balloon. Lastly, shoulder length is an important characteristic to consider when selecting a balloon because of the potential to cause injury during performance of PTA in adjacent arterial segments. There is always risk of causing dissection or rupture during PTA, thus a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure, or placing a stent or stent graft if warranted.

A. An artery with luminal narrowing caused by plaque. **B.** A balloon angioplasty catheter is positioned within the diseased artery, which is inflated to enlarge the intravascular channel. **C.** The plaque is compressed with widened flow lumen as the result of balloon angioplasty.

Stents

Vascular stents are commonly used after an inadequate angioplasty with dissection or elastic recoil of an arterial stenosis. They serve to buttress collapsible vessels and help prevent atherosclerotic restenosis. Appropriate indications for primary stenting of a lesion without an initial trial of angioplasty alone are evolving in manners that are dependent on the extent and site of the lesion. Stents are manufactured from a variety of metals, including stainless steel, tantalum, cobalt-based alloy, and nitinol. Vascular stents are classified into two basic categories: balloon-expandable stents and self-expanding stents.

Self-expanding stents (Fig. 23-10) are deployed by retracting a restraining sheath. They usually consist of Elgiloy (a cobalt, chromium, nickel alloy) or nitinol (a shape memory alloy composed of nickel and titanium), the latter of which will contract and assume a heat-treated shape above a transition temperature that depends upon the composition of the alloy. Self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size. The self-expanding stent is mounted on a central shaft and is placed inside an outer sheath. It relies on a mechanical spring-like action to achieve expansion. With deployment of these stents, there is some degree of foreshortening that has to be taken into account when choosing the area of deployment. In this way, self-expanding stents are more difficult to place with absolute precision. There are several advantages related to self-expanding stents. Self-expanding stents generally come in

longer lengths than balloon-expandable stents and are therefore used to treat long and tortuous lesions. Their ability to continually expand after delivery allows them to accommodate adjacent vessels of different size. This makes these stents ideal for placement in the ICA. These stents are always oversized by 1 to 2 mm relative to the largest diameter of normal vessel adjacent to the lesion to prevent immediate migration.

Fig. 23-10.

Self-expanding stents are made of tempered stainless steel or nitinol, an alloy of nickel and titanium, and are restrained when folded inside a delivery catheter. After release from the restraining catheter, the self-expanding stents will expand to a final diameter that is determined by stent geometry, hoop strength, and vessel size.

Balloon-expandable stents are usually composed of stainless steel, mounted on an angioplasty balloon, and deployed by balloon inflation (Fig. 23-11). They can be manually placed on a chosen balloon catheter or obtained premounted on a balloon catheter. The capacity of a balloon-expandable stent to shorten in length during deployment depends on both stent geometry and the final diameter to which the balloon is expanded. These stents are more rigid and are associated with a shorter time to complete endothelialization. They are often of limited flexibility and have a higher degree of crush resistance when compared to self-expanding. This makes them ideal for short-segment lesions, especially those that involve the ostia, such as proximal common iliac or renal artery stenosis.

Fig. 23-11.

In a balloon-expandable stent, the stent is premounted on a balloon catheter. The balloon stretches the stent members beyond their elastic limit. The stent is deployed by full balloon expansion. This type of stent has a higher degree of crush resistance when compared to self-expanding. This makes them ideal for short-segment calcified ostial lesions.

The most exciting area of development in stents is the evolution of drug-eluting stents (DES). These stents are usually composed of nitinol and have various anti-inflammatory drugs bonded to them. Over time, the stents release the drug into the surrounding arterial wall and help prevent restenosis. Numerous randomized controlled trials have proven their benefit in coronary arteries.¹² Clinical studies have similarly proved early efficacy of DES in the treatment of PAD.

Stent Grafts

The combination of a metal stent covered with fabric gave birth to the first stent grafts. Covered stents have been designed with either a surrounding PTFE or polyester fabric and have been used predominantly for treatment of traumatic vascular lesions, including arterial disruption and arteriovenous fistulas (Fig. 23-12). However, these devices may well find a growing role in treatment of iliac or femoral arterial occlusive disease as well as popliteal aneurysms.

A stent graft is a combination of a metal stent covered with fabric that is commonly used for aneurysm exclusion.

Endovascular aneurysm repair using the concept of stent grafts was initiated by Parodi in 1991.¹³ Since that time, a large number of endografts have been inserted under the auspices of clinical trials at first and now as Food and Drug Administration (FDA)-approved devices. Current FDA-approved devices include (a) AneuRx device (Medtronic/AVE, Santa Rosa, Calif), (b) Gore Excluder device (WL Gore & Associates, Flagstaff, Ariz), (c) Endologix Powerlink device (Endologix Inc., Irvine, Calif), (d) Zenith device (Cook Inc., Bloomington, Ind), and (e) Talent device (Medtronic/AVE, Santa Rosa, Calif). All of these devices require that patients have an infrarenal aneurysm with at least a 15-mm proximal aortic neck below the renal arteries, and not $>60^\circ$ of angulation. For those patients with associated common iliac artery (CIA) aneurysmal disease, endovascular treatment can be achieved by initial coil embolization of the ipsilateral hypogastric artery with extension of the endovascular device into the EIA. Clinical trials are underway with devices that will expand indications to aneurysms involving the visceral segment of the abdominal aorta. The FDA has similarly approved several thoracic endografts for the treatment of descending thoracic aortic aneurysm. Early studies have demonstrated short-term efficacy of thoracic aortic devices in the treatment of traumatic aortic transections, and aortic dissections.^{14–16} A larger experience with these devices exists in both Europe and Asia, and trials are underway in the United States with several devices.

CAROTID ARTERY DISEASE

Atherosclerotic occlusive plaque is by far the most common pathology seen in the carotid artery bifurcation. Thirty to 60% of all ischemic strokes are related to atherosclerotic carotid bifurcation occlusive disease. In the following section, discussion will be focused on clinical presentation, diagnosis, and management, including medical therapy, surgical carotid endarterectomy, and stenting of atherosclerotic carotid occlusive disease. In the second part of the section, a brief review will be focused on other less common non-atherosclerotic diseases involving the extracranial carotid artery, including kink and coil, fibromuscular dysplasia (FMD), arterial dissection, aneurysm, radiation arteritis, Takayasu's arteritis, and carotid body tumor.

Epidemiology and Etiology of Carotid Occlusive Disease

Approximately 700,000 Americans suffer a new or recurrent stroke each year.¹⁷ Eighty-five percent of all strokes are

ischemic and 15% are hemorrhagic. Hemorrhagic strokes are caused by head trauma or spontaneous disruption of intracerebral blood vessels. Ischemic strokes are due to hypoperfusion from arterial occlusion, or less commonly due to decreased flow resulting from proximal arterial stenosis and poor collateral network. Common causes of ischemic strokes are cardiogenic emboli (35%), carotid artery disease (30%), lacunar (10%), miscellaneous (10%), and idiopathic (15%).¹⁷ The term *cerebrovascular accident* (CVA) often is used interchangeably to refer to an ischemic stroke. A *transient ischemic attack* (TIA) is defined as a temporary focal cerebral or retinal hypoperfusion state that resolves spontaneously within 24 hours after its onset. However, the majority of TIAs resolve within minutes, and longer lasting neurologic deficits more likely represent a stroke. Recently, the term *brain attack* has been coined to refer to an acute stroke or TIA, denoting the condition as a medical emergency requiring immediate attention, similar to a heart attack.

Stroke due to carotid bifurcation occlusive disease usually is caused by atheroemboli (Fig. 23-13). The carotid bifurcation is an area of low-flow velocity and low-shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance ICA, and the high-resistance external carotid artery. Characteristically, atherosclerotic plaque forms in the outer wall opposite to the flow divider (Fig. 23-14). Atherosclerotic plaque formation is complex, beginning with intimal injury, platelet deposition, smooth muscle cell proliferation, and fibroplasia, and leading to subsequent luminal narrowing. With increasing degree of stenosis in the ICA, flow becomes more turbulent, and the risk of atheroembolization escalates. The severity of stenosis is commonly divided into three categories according to the luminal diameter reduction: mild (less than 50%), moderate (50 to 69%), and severe (70 to 99%). Severe carotid stenosis is a strong predictor for stroke.¹⁸ In turn, a prior history of neurologic symptoms (TIA or stroke) is an important determinant for recurrent ipsilateral stroke. The risk factors for the development of carotid artery bifurcation disease are similar to those causing atherosclerotic occlusive disease in other vascular beds. Increasing age, male gender, hypertension, tobacco smoking, diabetes mellitus, homocysteinemia, and hyperlipidemia are well-known predisposing factors for the development of atherosclerotic occlusive disease.

Stroke due to carotid bifurcation occlusive disease is usually caused by atheroemboli arising from the internal carotid artery, which provides the majority of blood flow to the cerebral hemisphere. With increasing degree of stenosis in the carotid artery, flow becomes more turbulent, and the risk of atheroembolization escalates.

A. The carotid bifurcation is an area of low-flow velocity and low-shear stress. As the blood circulates through the carotid bifurcation, there is separation of flow into the low-resistance internal carotid artery and the high-resistance external carotid artery. **B.** The carotid atherosclerotic plaque typically forms in the outer wall opposite to the flow divider due in part to the effect of the low-shear stress region, which also creates a transient reversal of flow during cardiac cycle.

Clinical Manifestations of Cerebral Ischemia

TIA is a focal loss of neurologic function, lasting for <24 hours. *Crescendo TIAs* refer to a syndrome comprising repeated TIAs within a short period of time that is characterized by complete neurologic recovery in between. At a minimum the term should probably be reserved either for those with daily events or multiple resolving attacks within 24 hours. Hemodynamic TIAs represent focal cerebral events that are aggravated by exercise or hemodynamic stress and typically occur after short bursts of physical activity, postprandially or after getting out of a hot bath. It is implied that these are due to severe extracranial disease and poor intracranial collateral recruitment. *Reversible ischemic neurologic deficits* refer to ischemic focal neurologic symptoms lasting longer than 24 hours but resolving within 3 weeks. When a neurologic deficit lasts longer than 3 weeks, it is considered a *completed stroke*. *Stroke in evolution* refers to progressive worsening of the neurologic deficit, either linearly over a 24-hour period, or interspersed with transient periods of stabilization and/or partial clinical improvement.

The patients who suffer CVAs typically present with three categories of symptoms, including ocular symptoms, sensory/motor deficit, and/or higher cortical dysfunction. The common ocular symptoms associated with extracranial carotid artery occlusive disease include amaurosis fugax and presence of Hollenhorst plaques. Amaurosis fugax, commonly referred to as *transient monocular blindness*, is a temporary loss of vision in one eye that patients typically describe as a window shutter coming

down or gray shedding of the vision. This partial blindness usually lasts for a few minutes and then resolves. Most of these phenomena (>90%) are due to embolic occlusion of the main artery or the upper or lower divisions. Monocular blindness progressing over a 20-minute period suggests a migrainous etiology. Occasionally, the patient will recall no visual symptoms while the optician notes a yellowish plaque within the retinal vessels, which is also known as the *Hollenhorst plaque*. These are frequently derived from cholesterol embolization from the carotid bifurcation and warrant further investigation.

Additionally, several ocular symptoms may be caused by microembolization from the extracranial carotid diseases, including monocular vision loss due to retinal artery or optic nerve ischemia, the ocular ischemia syndrome, and visual field deficits secondary to cortical infarction and ischemia of the optic tracts. Typical motor and/or sensory symptoms associated with CVAs are located in either an ipsilateral or contralateral neurologic deficit. Ischemic events tend to have an abrupt onset, with the severity of the insult being apparent from the onset and not usually associated with seizures or paraesthesia. In contrast, they represent loss or diminution of neurologic function. Furthermore, motor or sensory deficits can be unilateral or bilateral, with the upper and lower limbs being variably affected depending on the site of the cerebral lesion.

The combination of a motor and sensory deficit in the same body territory is suggestive of a cortical thromboembolic event as opposed to lacunar lesions secondary to small vessel disease of the penetrating arterioles. However, a small proportion of the latter may present with a sensorimotor stroke secondary to small vessel occlusion within the posterior limb of the internal capsule. Pure sensory and pure motor strokes and those strokes where the weakness affects one limb only or does not involve the face are more typically seen with lacunar as opposed to cortical infarction. A number of higher cortical functions, including speech and language disturbances, can be affected by thromboembolic phenomena from the carotid artery with the most important clinical example for the dominant hemisphere being dysphasia or aphasia, and visuospatial neglect being an example of nondominant hemisphere injury.

Diagnostic Evaluation

Duplex ultrasonography is the most widely used screening tool to evaluate for atherosclerotic plaque and stenosis of the extracranial carotid artery. It is also commonly used to monitor patients serially for progression of disease, or after intervention (carotid endarterectomy or angioplasty). Duplex ultrasound of the carotid artery combines B-mode gray-scale imaging and Doppler waveform analysis. Characterization of the carotid plaque on gray-scale imaging provides useful information about its composition. However, there are currently no universal recommendations that can be made based solely on the sonographic appearance of the plaque. On the other hand, criteria have been developed and well refined for grading the degree of carotid stenosis based primarily on Doppler-derived velocity waveforms.

The external carotid artery has a high-resistance flow pattern with a sharp systolic peak and a small amount of flow in diastole. In contrast, a normal ICA will have a low-resistance flow pattern with a broad systolic peak and a large amount of flow during diastole. The flow pattern in the common carotid artery (CCA) resembles that in the ICA, as 80% of the flow is directed to the ICA, with waveforms that have broad systolic peaks and a moderate amount of flow during diastole. Conventionally, velocity measurements are recorded in the common, external carotid bulb, and the proximal, mid-, and distal portions of the ICA. Characteristically, the peak systolic velocity is increased at the site of the vessel stenosis. The end-diastolic velocity is increased with a greater degree of stenosis. In addition, stenosis of the ICA can lead to color shifts with color mosaics indicating a poststenotic turbulence. Dampening of the Doppler velocity waveforms are typically seen in areas distal to severe carotid stenosis where blood flow is reduced. It is well known that occlusion of the ipsilateral ICA can lead to a "falsely" elevated velocity on the contralateral side due to an increase in compensatory blood flow. In the presence of a high-grade stenosis or occlusion of the ICA, the ipsilateral CCA displays high flow resistance waveforms, similar to that seen

in the external carotid artery. If there is a significant stenosis in the proximal CCA, its waveforms may be dampened with low velocities.

The Doppler grading systems of carotid stenosis were initially established by comparison to angiographic findings of disease. Studies have shown variability in the measurements of the duplex properties by different laboratories, as well as heterogeneity in the patient population, study design, and techniques. One of the most commonly used classifications was established at the University of Washington School of Medicine in Seattle. Diameter reduction of 50 to 79% is defined by peak systolic velocity >125 cm/sec with extensive spectral broadening. For stenosis in the range of 80 to 99%, the peak systolic velocity is >125 cm/sec and peak diastolic velocity is >140 cm/sec. The ratio of internal carotid to common carotid artery (ICA/CCA) peak systolic velocity has also been part of various ultrasound diagnostic classifications. A ratio >4 is a great predictor of angiographic stenosis of 70 to 99%. A multispecialty consensus panel has developed a set of criteria for grading carotid stenosis by duplex examination (Table 23-3).¹⁹

Table 23-3 Carotid Duplex Ultrasound Criteria for Grading Internal Carotid Artery Stenosis				
Degree of Stenosis (%)	ICA PSV (cm/s)	ICA/CCA PSV Ratio	ICA EDV (cm/s)	Plaque Estimate (%) ^a
Normal	<125	<2.0	<40	None
<50	<125	<2.0	<40	<50
50–69	125–230	2.0–4.0	40–100	≥50
≥70 to less than near occlusion	>230	>4.0	>100	≥50
Near occlusion	High, low, or not detected	Variable	Variable	Visible
Total occlusion	Not detected	Not applicable	Not detected	Visible, no lumen

^aPlaque estimate (diameter reduction) with gray-scale and color Doppler ultrasound. ICA = internal carotid artery; CCA = common carotid artery; PSV = peak systolic velocity; EDV = end-diastolic velocity.

MRA is increasingly being used to evaluate for atherosclerotic carotid occlusive disease and intracranial circulation. MRA is noninvasive and does not require iodinated contrast agents. MRA uses phase contrast or time-of-flight, with either two-dimensional or three-dimensional data sets for greater accuracy. Three-dimensional, contrast-enhanced MRA allows data to be obtained in coronal and sagittal planes with improved image qualities due to shorter study time. In addition, the new MRA techniques allow for better reformation of images in various planes to allow better grading of stenosis. There have been numerous studies comparing the sensitivity and specificity of MRA imaging for carotid disease to duplex and selective contrast angiography.²⁰ Magnetic resonance imaging (MRI) of the brain is essential in the assessment of acute stroke patients. MRI with diffusion-weighted imaging can differentiate areas of acute ischemia, areas still at risk for ischemia (penumbra), and chronic cerebral ischemic changes. However, computed tomographic (CT) imaging remains the most expeditious test in the evaluation of acute stroke patients to rule out intracerebral hemorrhage. Recently, multidetector CTA has gained increasing popularity in the evaluation of carotid disease.²¹ This imaging modality can provide volume rendering, which allows rotation of the object with accurate anatomic structures from all angles (Fig. 23-15). The advantages of CTA over MRA include faster data acquisition time and better spatial resolution. However, grading of carotid stenosis by CTA requires further validation at the time of this writing before it can be widely applied.

A. Carotid computed tomography angiography is a valuable imaging modality that can provide a three-dimensional image reconstruction with high image resolution. A carotid artery occlusion is noted in the internal carotid artery. **B.** The entire segment of extracranial carotid artery is visualized from the thoracic compartment to the base of skull.

Historically, DSA has been the gold standard test to evaluate the extra- and intracranial circulation (Fig. 23-16). This is an invasive procedure, typically performed via a transfemoral puncture, and involves selective imaging of the carotid and vertebral arteries using iodinated contrast. The risk of stroke during cerebral angiography is generally reported at approximately 1%, and is typically due to atheroembolization related to wire and catheter manipulation in the arch aorta or proximal branch vessels. Over the past decades, however, the incidence of neurologic complications following angiography has been reduced, due to the use of improved guidewires and catheters, better resolution digital imaging, and increased experience. Local access complications of angiography are infrequent and include development of hematoma, pseudoaneurysm, distal embolization, or acute vessel thrombosis. Currently, selective angiography is particularly used for patients with suspected intracranial disease and for patients in whom percutaneous revascularization is considered. The techniques of carotid angioplasty and stenting for carotid bifurcation occlusive disease are described in the "Techniques of Carotid Angioplasty and Stenting" section. Preoperative CTA or MRA is routinely utilized to get information about the aortic arch anatomy and presence of concomitant intracranial disease and collateral pathway in planning our strategy for carotid stenting or endarterectomy.

A carotid angiogram reveals an ulcerated carotid plaque (*arrow*) in the proximal internal carotid artery, which also resulted in a high-grade, internal, carotid artery stenosis.

Treatment of Carotid Occlusive Disease

Conventionally, patients with carotid bifurcation occlusive disease are divided into two broad categories: patients without prior history of ipsilateral stroke or TIA (asymptomatic) and those with prior or current ipsilateral neurologic symptoms (symptomatic). It is estimated that 15% of all strokes are preceded by a TIA. The 90-day risk of a stroke in a patient presenting with a TIA is 3 to 17%.¹⁷ According to the Cardiovascular Health Study, a longitudinal, population-based study of CAD and stroke in men and women, the prevalence of TIA in men was 2.7% between the ages of 65 to 69 and 3.6% for ages 75 to 79; the prevalence in women was 1.4% and 4.1%, respectively.²² There have been several studies reporting on the effectiveness of stroke prevention with medical treatment and carotid endarterectomy for symptomatic patients with moderate to severe carotid stenosis. Early and chronic aspirin therapy has been shown to reduce stroke recurrence rate in several large clinical trials.²³

Symptomatic Carotid Stenosis

Currently, most stroke neurologists prescribe both aspirin and clopidogrel for secondary stroke prevention in patients who had experienced a TIA or stroke.¹⁷ In patients with symptomatic carotid stenosis, the degree of stenosis appears to be the most important predictor in determining risk for an ipsilateral stroke. The risk of a recurrent ipsilateral stroke in patients with severe carotid stenosis approaches 40%. Two large multicenter randomized clinical trials, the European Carotid Surgery Trial and the North American Symptomatic Carotid Endarterectomy Trial, have both shown a significant risk reduction in stroke for

patients with symptomatic high-grade stenosis (70 to 99%) undergoing carotid endarterectomy when compared to medical therapy alone.^{24,25} There has been much discussion regarding the different methodology used in the measurement of carotid stenosis and calculation of the life-table data between the two studies, which still led to similar results.²⁶ Findings of these two landmark trials have also been reanalyzed in many subsequent publications. The main conclusions of the trials remain validated and widely acknowledged. Briefly, the North American Symptomatic Carotid Endarterectomy Trial study showed that, for high-grade carotid stenosis, the cumulative risk of ipsilateral stroke was 26% in the medically treated group and 9% in the surgically treated group at 2 years. For patients with moderate carotid artery stenosis (50 to 69%), the benefit of carotid endarterectomy is less but still favorable when compared to medical treatment alone; the 5-year fatal or nonfatal ipsilateral stroke rate was 16% in the surgically treated group vs. 22% in the medically treated group.²⁷ The risk of stroke was similar for the remaining group of symptomatic patients with less than 50% carotid stenosis, whether they had endarterectomy or medical treatment alone. The European Carotid Surgery Trial reported similar stroke risk reduction for patients with severe symptomatic carotid stenosis and no benefit in patients with mild stenosis, when carotid endarterectomy was performed vs. medical therapy.²⁵

The optimal timing of carotid intervention after acute stroke, however, remains debatable. Earlier studies showed an increased rate of postoperative stroke exacerbation and conversion of a bland to hemorrhagic infarction when carotid endarterectomy was carried out within 5 to 6 weeks after acute stroke. The dismal outcome reported in the early experience was likely related to poor patient selection. The rate of stroke recurrence is not insignificant during the interval period and may be reduced with early intervention for symptomatic carotid stenosis. Contemporary series have demonstrated acceptable low rates of perioperative complications in patients undergoing carotid endarterectomy within 4 weeks after acute stroke.²⁷ In a recent retrospective series, carotid artery stenting, when performed early (<2 weeks) after the acute stroke, was associated with higher mortality than when delayed (>2 weeks).²⁸

ASYMPTOMATIC CAROTID STENOSIS

Whereas there is universal agreement that carotid revascularization (endarterectomy or stenting) is effective in secondary stroke prevention for patients with symptomatic moderate and severe carotid stenosis, the management of asymptomatic patients remains an important controversy to be resolved. Generally, the detection of carotid stenosis in asymptomatic patients is related to the presence of a cervical bruit or based on screening duplex ultrasound findings. In one of the earlier observational studies, the authors showed that the annual rate of occurrence of neurologic symptoms was 4% in a cohort of 167 patients with asymptomatic cervical bruits followed prospectively by serial carotid duplex scan.²⁹ The mean annual rate of carotid stenosis progression to a greater than 50% stenosis was 8%. The presence of or progression to a greater than 80% stenosis correlated highly with either the development of a total occlusion of the ICA or new symptoms. The major risk factors associated with disease progression were cigarette smoking, diabetes mellitus, and age. This study supported the contention that it is prudent to follow a conservative course in the management of asymptomatic patients presenting with a cervical bruit.

One of the first randomized clinical trials on the treatment of asymptomatic carotid artery stenosis was the Asymptomatic Carotid Atherosclerosis Study, which evaluated the benefits of medical management with antiplatelet therapy vs. carotid endarterectomy.³⁰ Over a 5-year period, the risk of ipsilateral stroke in individuals with a carotid artery stenosis greater than 60% was 5.1% in the surgical arm. On the other hand, the risk of ipsilateral stroke in patients treated with medical management was 11%. Carotid endarterectomy produced a relative risk reduction of 53% over medical management alone. The results of a larger randomized trial from Europe, The Asymptomatic Carotid Surgery Trial, confirmed similar beneficial

stroke risk reduction for patients with asymptomatic greater than 70% carotid stenosis undergoing endarterectomy compared to medical therapy.³¹ An important point derived from this latter trial was that even with improved medical therapy, including the addition of statin drugs and clopidogrel, medical therapy was still inferior to endarterectomy in the primary stroke prevention for patients with high-grade carotid artery stenosis. It is generally agreed that asymptomatic patients with severe carotid stenosis (80 to 99%) are at significantly increased risk for stroke and stand to benefit from either surgical or endovascular revascularization. However, revascularization for asymptomatic patients with a less severe degree of stenosis (60 to 79%) remains controversial.

Carotid Endarterectomy vs. Angioplasty and Stenting

Currently, the argument is no longer that medical therapy alone is inferior to surgical endarterectomy in stroke prevention for severe carotid stenosis. Rather, the debate now revolves around whether carotid angioplasty and stenting produces the same benefit that has been demonstrated by carotid endarterectomy. Since carotid artery stenting was approved by the FDA in 2004 for clinical application, this percutaneous procedure has become a treatment alternative in patients who are deemed "high-risk" for endarterectomy (Table 23-4). In contrast to many endovascular peripheral arterial interventions, percutaneous carotid stenting represents a much greater challenging procedure, because it requires complex, catheter-based skills using the 0.014-in guidewire system and distal protection device. Moreover, current carotid stent devices predominantly use the monorail guidewire system that requires more technical agility, in contrast to the over-the-wire catheter system that is routinely used in peripheral interventions. This percutaneous intervention often requires balloon angioplasty and stent placement through a long carotid guiding sheath via a groin approach. Poor technical skills can result in devastating treatment complications such as stroke, which can occur due in part to plaque embolization during the balloon angioplasty and stenting of the carotid artery. Because of these various procedural components that require high technical proficiency, many early clinical investigations of carotid artery stenting, which included physicians with little or no carotid stenting experience, resulted in alarmingly poor clinical outcomes. A recent Cochrane review noted that, before 2006, a total of 1269 patients had been studied in five randomized controlled trials comparing percutaneous carotid intervention and surgical carotid reconstruction.³² Taken together, these trials revealed that carotid artery stenting had a greater procedural risk of stroke and death when compared to carotid endarterectomy (odds ratio 1.33; 95% CI 0.86–2.04). Additionally, greater incidence of carotid restenosis was noted in the stenting group than the endarterectomy cohorts. However, the constant improvement of endovascular devices, procedural techniques, and adjunctive pharmacologic therapy will likely improve the treatment success of percutaneous carotid intervention. Critical appraisals of these trials comparing the efficacy of carotid stenting vs. endarterectomy are available for review.³³ Several ongoing clinical trials will undoubtedly provide more insights on the efficacy of carotid stenting in the near future.

Table 23-4 Conditions Qualifying Patients as "High Surgical Risk" for Carotid Endarterectomy	
Anatomical Factors	Physiological Factors
• High carotid bifurcation (above C2 vertebral body)	• Age ≥80 y
• Low common carotid artery (below clavicle)	• Left ventricular ejection fraction ≤30%
• Contralateral carotid occlusion	• New York Heart Association Class III/IV congestive heart failure
• Restenosis of ipsilateral prior carotid endarterectomy	• Unstable angina: Canadian Cardiovascular Society Class III/IV angina pectoris

• Previous neck irradiation	
• Prior radical neck dissection	• Recent myocardial infarction
• Contralateral laryngeal nerve palsy	• Clinically significant cardiac disease (congestive heart failure, abnormal stress test, or need for coronary revascularization)
• Presence of tracheostomy	
	• Severe chronic obstructive pulmonary disease
	• End-stage renal disease on dialysis

Surgical Techniques of Carotid Endarterectomy

Although carotid endarterectomy is one of the earliest vascular operations ever described and its techniques have been perfected in the last two decades, surgeons continue to debate many aspects of this procedure. For instance, there is no universal agreement with regard to the best anesthetic of choice, the best intraoperative cerebral monitoring, whether to "routinely" shunt, open vs. eversion endarterectomy, and patch vs. primary closure. Various anesthetic options are available for a patient undergoing carotid endarterectomy including general, local, and regional anesthesia. Typically, the anesthesia of choice depends on the preference of the surgeon, anesthesiologist, and patient. However, depending on the anesthetic given, the surgeon must decide whether intraoperative cerebral monitoring is necessary or intra-arterial carotid shunting will be used. In general, if the patient is awake, then his or her abilities to respond to commands during carotid clamp period determine the adequacy of collateral flow to the ipsilateral hemisphere. On the other hand, intraoperative electroencephalogram or transcranial power Doppler (TCD) has been used to monitor for adequacy of cerebral perfusion during the clamp period for patients undergoing surgery under general anesthesia. Focal ipsilateral decreases in amplitudes and slowing of electroencephalogram waves are indicative of cerebral ischemia. Similarly, a decrease to less than 50% of baseline velocity in the ipsilateral middle cerebral artery is a sign of cerebral ischemia. For patients with poor collateral flow exhibiting signs of cerebral ischemia, intra-arterial carotid shunting with removal of the clamp will restore cerebral flow for the remaining part of the surgery. Stump pressures have been used to determine the need for intra-arterial carotid shunting. Some surgeons prefer to shunt all patients on a routine basis and do not use intraoperative cerebral monitoring.

The patient's neck is slightly hyperextended and turned to the contralateral side, with a roll placed between the shoulder blades. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation (Fig. 23-17). The platysma is divided completely. Typically, tributaries of the anterior jugular vein are ligated and divided. The dissection is carried medial to the sternocleidomastoid. The superior belly of the omohyoid muscle is usually encountered just anterior to the CCA. This muscle can be divided. The carotid fascia is incised and the CCA is exposed. The CCA is mobilized cephalad toward the bifurcation. The dissection of the carotid bifurcation can cause reactive bradycardia related to stimulation of the carotid body. This reflex can be blunted with injection of lidocaine 1% into the carotid body or reversed with administration of IV atropine. A useful landmark in the dissection of the carotid bifurcation is the common facial vein. This vein can be ligated and divided. Frequently, the twelfth cranial nerve (hypoglossal nerve) traverses the carotid bifurcation just behind the common facial vein. The external carotid artery is mobilized just enough to get a clamp across. Often, a branch of the external carotid artery crossing to the sternocleidomastoid can be divided to allow further cephalad mobilization of the ICA. For high bifurcation, division of the posterior belly of the digastric muscle is helpful in establishing distal exposure of the ICA.

Fig. 23-17.

To perform carotid endarterectomy, the patient's neck is slightly hyperextended and turned to the contralateral side. An oblique incision is made along the anterior border of the sternocleidomastoid muscle centered on top of the carotid bifurcation.

IV heparin sulfate (1 mg/kg) is routinely administered just before carotid clamping. The ICA is clamped first using a soft, noncrushing vascular clamp to prevent distal embolization. The external and common carotid arteries are clamped subsequently. A longitudinal arteriotomy is made in the distal CCA and extended into the bulb and past the occlusive plaque into the normal part of the ICA. Endarterectomy is carried out to remove the occlusive plaque (Fig. 23-18). If necessary, a temporary shunt can be inserted from the CCA to the ICA to maintain continuous antegrade cerebral blood flow (Fig. 23-19). Typically, a plane is teased out from the vessel wall, and the entire plaque is elevated and removed. The distal transition line in the ICA where the plaque had been removed must be examined carefully and should be smooth. Tacking sutures are placed when an intimal flap remains in this transition to ensure no obstruction to flow (Fig. 23-20). The occlusive plaque is usually removed from the origin of the external carotid artery using the eversion technique. The endarterectomized surface is then irrigated and any debris removed. A patch (autogenous saphenous vein, synthetic such as polyester, PTFE, or biologic material) is sewn to close the arteriotomy (Fig. 23-21). Whether patch closure is necessary in all patients and which patch is the best remain controversial. However, most surgeons agree that patch closure is indicated particularly for the small vessel (<7 mm). The eversion technique also has been advocated for removing the plaque from the ICA. In the eversion technique, the ICA is transected at the bulb, the edges of the divided vessel are everted, and the occluding plaque is "peeled" off the vessel wall. The purported advantages of the eversion technique are no need for patch closure and a clear visualization of the

distal transition area. Reported series have not shown a clear superiority of one technique over the others. Surgeons will likely continue to use the technique of their choice. Just before completion of the anastomosis to close the arteriotomy, it is prudent to flush the vessels of any potential debris. When the arteriotomy is closed, flow is restored to the external carotid artery first and to the ICA second. IV protamine sulfate can be given to reverse the effect of heparin anticoagulation following carotid endarterectomy. The wound is closed in layers. After surgery, the patient's neurologic condition is assessed in the operating room (OR) before transfer to the recovery area.

A. An autologous or synthetic patch can be used to close the carotid arteriotomy incision, which maintains the luminal patency. **B.** A completion closure of carotid endarterectomy incision using a synthetic patch.

COMPLICATIONS OF CAROTID ENDARTERECTOMY

Most patients tolerate carotid endarterectomy very well and typically are discharged home within 24 hours after surgery.

Complications after endarterectomy are infrequent but can be potentially life threatening or disabling. Acute ipsilateral stroke is a dreaded complication following carotid endarterectomy. Cerebral ischemia can be due to either intraoperative or postoperative events. Embolizations from the occlusive plaque or prolonged cerebral ischemia are potential causes of intraoperative stroke. The most common cause of postoperative stroke is due to embolization. Less frequently, acute carotid artery occlusion can cause acute postoperative stroke. This is usually due to carotid artery thrombosis related to closure of the arteriotomy, an occluding intimal flap, or distal carotid dissection. When patients experience acute symptoms of neurologic ischemia after endarterectomy, immediate intervention may be indicated. Carotid duplex scan can be done expeditiously to assess patency of the extracranial ICA. Re-exploration is mandated for acute carotid artery occlusion. Cerebral angiography can be useful if intracranial revascularization is considered.

Local complications related to surgery include excessive bleeding and cranial nerve palsies. Postoperative hematoma in the neck after carotid endarterectomy can lead to devastating airway compromise. Any expanding hematoma should be evacuated and active bleeding stopped. Securing an airway is critical and can be extremely difficult in patients with large postoperative neck hematomas. The reported incidence of postoperative cranial nerve palsies after carotid endarterectomy varies from 1 to 30%.³⁵ Well-recognized injuries involve the marginal mandibular, vagus, hypoglossal, superior laryngeal, and recurrent laryngeal nerves. Often these are traction injuries but can also be due to severance of the respective nerves.

Techniques of Carotid Angioplasty and Stenting

Percutaneous carotid artery stenting has become an accepted alternative treatment in the management of patients with carotid bifurcation disease (Fig. 23-22). The perceived advantages of percutaneous carotid revascularization are related to the minimal invasiveness of the procedure compared to surgery. There are anatomical conditions based on angiographic evaluation in which carotid artery stenting should be avoided due to increased procedural-related risks (Table 23-5). In preparation for carotid stenting, the patient should be given oral clopidogrel 3 days before the intervention if the patient was not already taking the drug. The procedure is done in either the OR with angiographic capabilities or in a dedicated angiography room. The patient is placed in the supine position. The patient's BP and cardiac rhythm are closely monitored.

A. Carotid angiogram demonstrated a high-grade stenosis of the left internal carotid artery. **B.** Completion angiogram demonstrating a satisfactory result following a carotid stent placement.

Table 23-5 Unfavorable Carotid Angiographic Appearance in Which Carotid Stenting Should Be Avoided

- | |
|-------------------------------------------------------|
| • Extensive carotid calcification |
| • Polypoid or globular carotid lesions |
| • Severe tortuosity of the common carotid artery |
| • Long segment stenoses (>2 cm in length) |
| • Carotid artery occlusion |
| • Severe intraluminal thrombus (angiographic defects) |
| • Extensive middle cerebral artery atherosclerosis |

To gain access to the carotid artery, a retrograde transfemoral approach is most commonly used as the access site for carotid intervention. Using the Seldinger technique, a diagnostic 5F or 6F sheath is inserted in the CFA. A diagnostic arch aortogram is obtained. The carotid artery to be treated is then selected using a 5F diagnostic catheter, and contrast is injected to show the carotid anatomy. It is important to assess the contralateral carotid artery, vertebrbasilar, and intracranial circulation if these are not known based on the preoperative, noninvasive studies. Once the decision is made to proceed with carotid artery stenting, with the tip of the diagnostic catheter still in the CCA, a 0.035-in, 260-cm long stiff glide wire is placed in the ipsilateral external carotid artery. Anticoagulation with IV bivalirudin bolus (0.75mg/kg) followed by an

infusion rate of 2.5 mg/kg per hour for the remainder of the procedure is routinely administered. Next, the diagnostic catheter is withdrawn and a 90-cm 6F guiding sheath is advanced into the CCA over the stiff glide wire. It is critical not to advance the sheath beyond the occlusive plaque in the carotid bulb. The stiff wire is then removed and preparation is made to deploy the distal embolic protection device (EPD). Several distal EPDs are available (Table 23-6). The EPD device is carefully deployed beyond the target lesion. With regard to the carotid stents, there are several stents that have received approval from the FDA and are commercially available for carotid revascularization (Table 23-7). All current carotid stents use the rapid-exchange monorail 0.014-in platform. The size selection is typically based on the size of CCA. Predilatation using a 4-mm balloon may be necessary to allow passage of the stent delivery catheter. Once the stent is deployed across the occlusive plaque, postdilatation is usually performed using a 5.5-mm or less balloon. It's noteworthy that balloon dilation of the carotid bulb may lead to immediate bradycardia due to stimulation of the glossopharyngeal nerve. The EPD is then retrieved and the procedure is completed with removal of the sheath from the femoral artery. The puncture site is closed using an available closure device or with manual compression. Throughout the procedure, the patient's neurologic function is closely monitored. The bivalirudin infusion is stopped, and the patient is kept on clopidogrel (75 mg daily) for at least 1 month and aspirin indefinitely.

Table 23-6 Commonly Used Embolic Protection Devices (EPDs)		
Mechanism	Name of EPD	Pore Size (micrometers)

COMPLICATIONS OF CAROTID STENTING

Although there have been no randomized trials comparing carotid stenting with and without EPD, the availability of EPDs

appears to have reduced the risk of distal embolization and stroke. The results of the various clinical trials and registries of carotid stenting have been reported and compared. It is well known that distal embolization as detected by TCD is much more frequent with carotid stenting, even with EPD, when compared to carotid endarterectomy. However, the clinical significance of the distal embolization detected by TCD is not clear, as most are asymptomatic. Acute carotid stent thrombosis is rare. The incidence of instant carotid restenosis is not well known but is estimated at 10 to 30%. Duplex surveillance shows elevated peak systolic velocities within the stent after carotid stenting can occur frequently. However, velocity criteria are being formulated to determine the severity of instant restenosis after carotid stenting by ultrasound duplex.³⁶ It appears that systolic velocities exceeding 300 to 400 cm/s would represent greater than 70 to 80% restenosis. Bradycardia and hypotension occurs in up to 20% of patients undergoing carotid stenting.³⁷ Systemic administration of atropine is usually effective in reversing the bradycardia. Other technical complications of carotid stenting are infrequent and include carotid artery dissection, and access site complications such as groin hematoma, femoral artery pseudoaneurysm, distal embolization, and acute femoral artery thrombosis.

Non-Atherosclerotic Disease of the Carotid Artery

CAROTID COIL AND KINK

A carotid coil consists of an excessive elongation of the ICA producing tortuosity of the vessel (Fig. 23-23). Embryologically, the carotid artery is derived from the third aortic arch and dorsal aortic root, and is uncoiled as the heart and great vessels descend into the mediastinum. In children, carotid coils appear to be congenital in origin. In contrast, elongation and kinking of the carotid artery in adults is associated with the loss of elasticity and an abrupt angulation of the vessel. Kinking is more common in women than men. Cerebral ischemic symptoms caused by kinks of the carotid artery are similar to those from atherosclerotic carotid lesions, but are more likely due to cerebral hypoperfusion than embolic episodes. Classically, sudden head rotation, flexion, or extension can accentuate the kink and provoke ischemic symptoms. Most carotid kinks and coils are found incidentally on carotid duplex scan. However, interpretation of the Doppler frequency shifts and spectral analysis in tortuous carotid arteries can be difficult because of the uncertain angle of insonation. Cerebral angiography, with multiple views taken in neck flexion, extension, and rotation, is useful in the determination of the clinical significance of kinks and coils.

Excessive elongation of the carotid artery can result in carotid kinking (*arrow*), which can compromise cerebral blood flow and lead to cerebral ischemia.

FIBROMUSCULAR DYSPLASIA

FMD usually involves medium-sized arteries that are long and have few branches (Fig. 23-24). Women in the fourth or fifth decade of life are more commonly affected than men. Hormonal effects on the vessel wall are thought to play a role in the pathogenesis of FMD. FMD of the carotid artery is commonly bilateral, and in about 20% of patients, the vertebral artery also is involved.³⁸ An intracranial saccular aneurysm of the carotid siphon or middle cerebral artery can be identified in up to 50% of the patients with FMD. Four histological types of FMD have been described in the literature. The most common type is medial fibroplasia, which may present as a focal stenosis or multiple lesions with intervening aneurysmal outpouchings. The disease involves the media with the smooth muscle being replaced by fibrous connective tissue. Commonly, mural dilations and microaneurysms can be seen with this type of FMD. Medial hyperplasia is a rare type of FMD, with the media demonstrating excessive amounts of smooth muscle. Intimal fibroplasia accounts for 5% of all cases and occurs equally in both sexes. The media and adventitia remain normal, and there is accumulation of subendothelial mesenchymal cells with a loose matrix of connective tissue causing a focal stenosis in adults. Finally, premedial dysplasia represents a type of FMD with elastic tissue accumulating between the media and adventitia. FMD also can involve the renal and the external iliac arteries. It is estimated that approximately 40% of patients with FMD present with a TIA due to embolization of platelet aggregates.³⁸ DSA demonstrates the characteristic "string of beads" pattern, which represents alternating segments of stenosis and dilatation. The string of beads can also be shown noninvasively by CTA or MRA. FMD should be suspected when an increased velocity is detected across a stenotic segment without associated atherosclerotic changes on carotid duplex

ultrasound. Antiplatelet medication is the generally accepted therapy for asymptomatic lesions. Endovascular treatment is recommended for patients with documented lateralizing symptoms. Surgical correction is rarely indicated.

A carotid fibromuscular dysplasia with typical characteristics of multiple stenosis with intervening aneurysmal outpouching dilatations. The disease involves the media, with the smooth muscle being replaced by fibrous connective tissue.

CAROTID ARTERY DISSECTION

Dissection of the carotid artery accounts for approximately 20% of strokes in patients younger than 45 years of age. The etiology and pathogenesis of spontaneous carotid artery dissection remains incompletely understood. Arterial dissection involves hemorrhage within the media, which can extend into the subadventitial and subintimal layers. When the dissection extends into the subadventitial space, there is an increased risk of aneurysm formation. Subintimal dissections can lead to intramural clot or thrombosis. Traumatic dissection is typically a result of hyperextension of the neck during blunt trauma, neck manipulation, strangulation, or penetrating injuries to the neck. Even in supposedly spontaneous cases, a history of preceding unrecognized minor neck trauma is not uncommon. Connective disorders such as Ehlers-Danlos syndrome, Marfan syndrome, alpha1-antitrypsin deficiency, or FMD may predispose to carotid artery dissection. Iatrogenic dissections also can occur due to catheter manipulation or balloon angioplasty.

Typical clinical features of carotid artery dissection include unilateral neck pain, headache, and ipsilateral Horner's syndrome in up to 50% of patients, followed by manifestations of the cerebral or ocular ischemia and cranial nerve palsies. Neurologic

deficits can result either because of hemodynamic failure (caused by luminal stenosis) or by an artery to artery thromboembolism. The ischemia may cause TIAs or infarctions, or both. Catheter angiography has been the method of choice to diagnose arterial dissections, but with the advent of duplex ultrasonography, MRI/MRA, and CTA, most dissections can now be diagnosed using noninvasive imaging modalities (Fig. 23-25). The dissection typically starts in the ICA distal to the bulb. Uncommonly, the dissection can start in the CCA, or is an extension of a more proximal aortic dissection. Medical therapy has been the accepted primary treatment of symptomatic carotid artery dissection. Anticoagulation (heparin and warfarin) and antiplatelet therapy have been commonly used, although there have not been any randomized studies to evaluate their effectiveness. The prognosis depends on the severity of neurologic deficit but is generally good in extracranial dissections. The recurrence rate is low. Therapeutic interventions have been reserved for recurrent TIAs or strokes, or failure of medical treatment. Endovascular options include intra-arterial stenting, coiling of associated pseudoaneurysms, or more recently, deployment of covered stents.

Carotid ultrasound reveals a patient with a carotid artery dissection in which carotid flow is separated in the true flow lumen (*long arrow*) from the false lumen (*short arrow*).

CAROTID ARTERY ANEURYSMS

Carotid artery aneurysms are rare, encountered in less than 1% of all carotid operations (Fig. 23-26). The true carotid artery aneurysm generally is due to atherosclerosis or medial degeneration. The carotid bulb is involved in most carotid aneurysms, and bilaterality is present in 12% of the patients. Patients typically present with a pulsatile neck mass. The available data suggest that, untreated, these aneurysms lead to neurologic symptoms from embolization. Thrombosis and rupture of the carotid aneurysm is rare. Pseudoaneurysms of the carotid artery can result from injury or infection. Mycotic aneurysms often involve syphilis in the past, but are now more commonly associated with peritonsillar abscesses caused by *Staphylococcus aureus* infection. FMD and spontaneous dissection of the carotid artery can lead to the formation of true aneurysms or pseudoaneurysms. Whereas conventional surgery has been the primary mode of treatment in the past, carotid aneurysms are currently being treated more commonly using endovascular approaches.³⁹

CAROTID BODY TUMOR

The carotid body originates from the third branchial arch and from neuroectodermal-derived neural crest lineage. The normal carotid body is located in the adventitia or periadventitial tissue at the bifurcation of the CCA (Fig. 23-27). The gland is innervated by the glossopharyngeal nerve. Its blood supply is derived predominantly from the external carotid artery, but also can come from the vertebral artery. Carotid body tumor is a rare lesion of the neuroendocrine system. Other glands of neural crest origin are seen in the neck, parapharyngeal spaces, mediastinum, retroperitoneum, and adrenal medulla. Tumors involving these structures have been referred to as *paraganglioma*, *glomus tumor*, or *chemodectoma*. Approximately 5 to 7% of carotid body tumors are malignant. Although chronic hypoxemia has been invoked as a stimulus for hyperplasia of carotid body, approximately 35% of carotid body tumors are hereditary. The risk of malignancy is greatest in young patients with familial tumors.

A. A carotid body tumor (arrow) located adjacent to the carotid bulb. **B.** Following periadventitial dissection, the carotid body tumor is removed.

Symptoms related to the endocrine products of the carotid body tumor are rare. Patients usually present between the fifth and seventh decade of life with an asymptomatic lateral neck mass. The diagnosis of carotid body tumor requires confirmation on imaging studies. Carotid duplex scan can localize the tumor to the carotid bifurcation, but CT or MR imaging usually is required to further delineate the relationship of the tumor to the adjacent structures. Classically, a carotid body tumor will widen the carotid bifurcation. The Shamblin classification describes the tumor extent: I. tumor is <5 cm and relatively free of vessel involvement; II. tumor is intimately involved but does not encase the vessel wall; and III. tumor is intramural and encases the carotid vessels and adjacent nerves.⁴⁰ With good resolution CT and MR imaging, arteriography usually is not required. However, arteriography can provide an assessment of the vessel invasion and intracranial circulation, and allows for preoperative embolization of the feeder vessels, which has been reported to reduce intraoperative blood loss. Surgical resection is the recommended treatment for suspected carotid body tumor.

CAROTID TRAUMA

Blunt or penetrating trauma to the neck can cause injury to the carotid artery. Notwithstanding the massive bleeding from carotid artery transection, injury to the carotid artery can result in carotid dissection, thrombosis, or pseudoaneurysm formation. Carotid duplex ultrasound can be useful to locate the site of injury in the cervical segment of the carotid artery. Spiral CTA has become the modality of choice to detect extracranial carotid artery injury. Confirmation of carotid injury by contrast cerebral angiography remains the gold standard diagnostic test. Injuries to the cervical segment of the common and

internal carotid arteries can be repaired surgically. Acute carotid artery thrombosis usually is treated medically with anticoagulation if the patient is asymptomatic. Revascularization should be considered for patients presenting with ongoing cerebral ischemia related to carotid artery thrombosis. Traumatic carotid artery dissection can cause cerebral ischemia due to thromboembolization, decreased flow, or thrombosis. Commonly, the dissection involves the distal portion of the cervical and petrous segment of the ICA. Medical management with antiplatelet or anticoagulation usually is adequate for uncomplicated traumatic carotid dissection. In patients with pseudoaneurysms of the carotid artery that are located in a segment that is out of surgical reach, the use of selective coil embolization of the pseudoaneurysm or exclusion of the pseudoaneurysm by a covered stent graft has been reported. Bare metal stent has been used with success in the treatment of traumatic carotid artery dissection.

ABDOMINAL AORTIC ANEURYSM

In spite of more than 50,000 patients undergoing elective repair of abdominal aortic aneurysm (AAA) each year in the United States, approximately 15,000 patients die annually as a result of ruptured aneurysm, making it the tenth leading cause of death in men in this country.⁴¹ The incidence appears to be increasing, and this is due in part to improvements in diagnostic imaging and, more importantly, is a result of a growing elderly population. With early diagnosis and timely intervention, aneurysm rupture–related death is largely preventable. Conventional treatment of an AAA involves replacing the aneurysmal segment of the aorta with a prosthetic graft, with the operation performed through a large abdominal incision. Techniques for this open abdominal surgery have been refined, adapted, and extensively studied by vascular surgeons over the past four decades. Despite a well-documented, low perioperative mortality rate of 2 to 3% in large academic institutions, the thought of undergoing an open abdominal aortic operation often provokes a sense of anxiety in many patients due in part to the postoperative pain associated with the large abdominal incision as well as the long recovery time needed before the patient can return to normal physical activity.

The most common location of aortic aneurysms is the infrarenal aorta. Endovascular stent graft placement represents a revolutionary and minimally invasive treatment for infrarenal AAAs that only requires 1 to 2 days of hospitalization, and the patient can return to normal physical activity within 1 week. The concept of using an endoluminal device in the management of vascular disease was first proposed by Dotter and colleagues, who successfully treated a patient with iliac occlusion using transluminal angioplasty in 1964.⁴² Nearly three decades later, Parodi and colleagues reported the first successful endovascular repair of AAA using a stent graft device.¹³ Since then, a variety of stent graft technologies have been developed to treat the AAA. The rapid innovation of this new treatment modality has undoubtedly captured the attention of patients with aortic aneurysms as well as physicians who practice endovascular therapy. Physicians in general should be knowledgeable regarding available treatment options to provide adequate evaluation and education to patients and their families. The following discussion is to outline the treatment options for AAAs, including conventional repair and endovascular approach. Advantages and potential complications of these treatments also will be addressed.

Natural History of Aortic Aneurysm

The natural history of an AAA is to expand and rupture. AAA exhibits a "staccato" pattern of growth, where periods of relative quiescence may alternate with expansion. Therefore, although an individual pattern of growth cannot be predicted, average aggregate growth is approximately 3 to 4 mm/y. There is some evidence to suggest that larger aneurysms may expand faster than smaller aneurysms, but there is significant overlap between the ranges of growth rates at each strata of size.

Rupture risk appears to be directly related to aneurysm size as predicted by Laplace's law. Although more sophisticated methods of assessing rupture risk based on finite element analysis of wall stress is under active investigation, maximum transverse diameter remains the standard method of risk assessment for aneurysm rupture. In the past, AAA rupture risk has been overestimated. More recently, two landmark studies have served to better define the natural history of AAA.^{43,44} Based on best available evidence, the annualized risk of rupture is given in Table 23-8. The rupture risk is quite low for aneurysms <5.5 cm and begins to rise exponentially thereafter. This size can serve as an appropriate threshold for recommending elective repair provided one's surgical mortality is below 5%. For each size strata, however, women appear to be at higher risk for rupture than men, and a lower threshold of 4.5 to 5.0 cm may be reasonable in good-risk patients. Although data are less compelling, a pattern of rapid expansion of >0.5 cm within 6 months can be considered a relative indication for elective repair. Aneurysms that fall below these indications may safely be followed with CT or ultrasound at 6-month intervals, with long-term outcomes equivalent to earlier surgical repair. Interestingly, in the ADAM study, 80% of all patients with AAA who were followed in this manner eventually came to repair within 5 years.⁴⁴

Table 23-8 Annualized Risk of Rupture of Abdominal Aortic Aneurysm (AAA) Based on Size			
Description	Diameter of Aorta (cm)	Estimated Annual Risk of Rupture (%)	Estimated 5-y Risk of Rupture (%) ^a
Normal aorta	2–3	0	0 (unless AAA develops)
Small AAA	4–5	1	5–10
Moderate AAA	5–6	2–5	30–40
Large AAA	6–7	3–10	>50
Very large AAA	>7	>10	Approaching 100

^aThe estimated 5-y risk is more than five times the estimated annual risk because over that 5 y, the AAA, if left untreated, will continue to grow in size.

Unless symptomatic or ruptured, AAA repair is a prophylactic repair. The rationale for recommending repair is predicated on the assumption that the risk of aneurysm rupture exceeds the combined risk of death from all other causes such as cardiopulmonary disease and cancer. On the other hand, our limitation in predicting timing and cause of death is underscored by the observation that over 25% of patients who were deemed unfit for surgical repair because of their comorbidities died from rupture of their aneurysms within 5 years.

Clinical Manifestations

Most AAAs are asymptomatic, and they are usually found incidentally during work-up for chronic back pain or kidney stones. Physical examination is neither sensitive nor specific except in thin patients. Large aneurysms may be missed in the obese, while normal aortic pulsations may be mistaken for an aneurysm in thin individuals. Rarely, patients present with back pain and/or abdominal pain with a tender pulsatile mass. Patients with these symptoms must be treated as if they had a rupture until proven otherwise. If the patient is hemodynamically stable and the aneurysm is intact on a CT scan, the patient is admitted for BP control with IV antihypertensive agents and repaired usually within 12 to 24 hours or at least during the same hospitalization. In contrast, patients who are hemodynamically unstable with a history of acute back pain and/or syncope, and a known unrepaired AAA or a pulsatile abdominal mass should be immediately taken to the OR with a

presumed diagnosis of a ruptured AAA.

Overall mortality of AAA rupture is 71 to 77%, which includes all out-of-hospital and inhospital deaths, as compared to 2 to 6% for elective open surgical repair.⁴⁵ Nearly one half of all patients with ruptured AAA will die before reaching the hospital. For the remainder, surgical mortality is 45 to 50% and has not substantially changed in the last 30 years.

Relevant Anatomy

An AAA is defined as a pathologic focal dilation of the aorta that is >30 mm or 1.5 times the adjacent diameter of the normal aorta (Fig. 23-28). Male aortas tend to be larger than female, and there is generalized growth of the aortic diameter with each decade of life. Ninety percent of AAA are infrarenal in location and have a fusiform morphology. There is a higher predilection for juxtarenal and suprarenal AAA in women as compared to men. Concomitant common iliac and/or hypogastric artery aneurysms can be found in 20 to 25% of patients. Although the etiology of most aortic aneurysms is atherosclerotic, clinically significant peripheral occlusive disease is unusual and present in less than 10% of all cases.

An operative view of an infrarenal aortic aneurysm.

Although extravascular anatomy is important for open surgical repair of AAA, intravascular anatomy and aortoiliac morphology are important for endovascular repair. Pertinent anatomic dimensions include the diameter of the proximal, nondilated, infrarenal aortic neck, which can range from 18 to 30 mm, CIA, from 8 to 16 mm, and external iliac arteries, 6 to

10 mm. Morphologically, the aortic neck can manifest complex angulation above and below the renal arteries due to a combination of elongation and anterolateral displacement by the posterior bulge of the aneurysmal aorta. Furthermore, the shape of the proximal neck is rarely tubular, but often is conical, reverse conical, or barrel shaped. Distally, the iliac arteries can have severe tortuosity with multiple compound turns. Although not significant from a hemodynamic standpoint, severe iliac calcifications combined with extreme tortuosity can pose a formidable challenge during endovascular repair.

Diagnostic Evaluation

Preoperative evaluation should include routine history and physical examination with particular attention to (a) any symptoms referable to the aneurysm, which may impact the timing of repair, (b) a history of pelvic surgery or radiation, in the event retroperitoneal exposure is required or interruption of hypogastric circulation is planned, (c) claudication suggestive of significant iliac occlusive disease, (d) LE bypass or other femoral reconstructive procedures, and (e) chronic renal insufficiency or contrast allergy.

Cross-sectional imaging is required for definitive evaluation of AAA. Although ultrasound is safe, widely available, relatively accurate, and inexpensive, and, therefore, is the screening modality of choice, the CT scan remains the gold standard for determination of anatomic eligibility for endovascular repair. Size of AAA may differ up to 1 cm between CT and ultrasound, and, during longitudinal follow-up, comparisons should be made between identical modalities. With modern multirow detector scanners, a timed-bolus IV contrast enhanced, 2.5 to 3.0-mm slice spiral CT of the chest, abdomen, and pelvis can be performed in <30 seconds with a single breath hold. Extremely high-resolution images are obtained with submillimeter spatial resolution (Fig. 23-29). Proper window level and width (brightness and contrast) is important for discrimination among aortic wall, calcific plaque, thrombus, and lumen. The only major drawback to CT is the risk of contrast nephropathy in diabetics and in patients with renal insufficiency.

High resolution of image displaying an aortic aneurysm (*arrow*) can be achieved with multidetector computed tomographic angiography.

The spiral technique further affords the ability for three-dimensional reconstruction. Three-dimensional reconstructions can yield important morphologic information that is critical to endovascular therapy. Using third-party software, these images can be viewed and manipulated on a desktop computer and so-called "center-line" (transverse slices perpendicular to the central flow-lumen of the aorta) diameter and length measurements obtained. Conventional angiography has a minimal role in the current management of AAA. Angiography is invasive with an increased risk of complications. Indications for angiography are isolated to concomitant iliac occlusive disease (present in less than 10% of patients with AAA) and unusual renovascular anatomy.

Surgical Repair of Abdominal Aortic Aneurysm

General anesthesia is necessary when performing a conventional open AAA repair. Although a retroperitoneal incision is a well-accepted surgical approach, a midline transabdominal incision remains the more common approach for open aortic aneurysm operation. Because the abdominal incision can lead to significant pain and discomfort, an epidural catheter can be placed before the operation for postoperative analgesic infusion to provide pain control. Once the abdominal cavity is opened, the small intestines and transverse colon are retracted to expose the retroperitoneum overlying the AAA. The retroperitoneum is next divided, followed by isolation of both proximal and distal segments of the AAA. IV heparin (100 IU/kg) is given, followed by clamping of the proximal and distal segments of the aneurysm. The aneurysm sac is opened next, and a prosthetic graft is used to reconstruct the aorta. If the aneurysm only involved the abdominal aorta, a tube graft

can be used to replace the aorta (Fig. 23-30). If the aneurysm extends distally to the iliac arteries, a prosthetic bifurcated graft is used for either an aortobi-iliac or aortobifemoral bypass reconstruction (Fig. 23-31). The overlying aneurysm sac and the retroperitoneum are closed to cover the prosthetic bypass graft to minimize potential bowel contact to the graft. Small and large intestines are returned to the abdominal cavity followed by the closure of the abdominal fascia and skin.

Intraoperative view of a bifurcated graft used to repair an aortic aneurysm.

ADVANTAGES AND RISKS OF OPEN ABDOMINAL AORTIC ANEURYSM REPAIR

The main advantage of a conventional open repair is that the AAA is permanently eliminated because it is entirely replaced by a prosthetic aortic graft. The risk of aneurysm recurrence or delayed rupture no longer exists. As a result, long-term imaging surveillance is not needed with these patients. In contrast, the long-term efficacy of endovascular repair remains unclear. Consequently, long-term imaging surveillance is critical to ensure that the aortic aneurysm remains properly sealed by the stent graft. Other potential advantages of open repair include direct assessment of the circulatory integrity of the colon. If signs of colonic ischemia become evident after aortic bypass grafting, a concomitant mesenteric artery bypass can be performed to revascularize the colonic circulation. In addition, open repair permits the surgeons to explore for other abdominal pathologies such as GI tumors, liver mass, or cholelithiasis.

As for the risks associated with open repair, cardiac complications, in the form of either myocardial infarction or arrhythmias, remain the most common morbidity, with an incidence between 2 and 6%.⁴⁶ Another significant complication is renal failure or transient renal insufficiency as a result of perioperative hypotension, atheromatous embolization, inadvertent injury to the ureter, preoperative contrast-induced nephropathy, or suprarenal aortic clamping. Although the incidence of renal failure is less than 2% in elective aneurysm repair, it can occur in more than 20% of patients after repair of a ruptured AAA.⁴⁶

Ischemic colitis is a devastating potential complication after open repair. The likelihood of such a complication is highest in those who had a prior colon resection and undergo repair of a ruptured AAA, due to the loss of collateral blood supply to the rectosigmoid colon. It is estimated that 5% of patients who undergo elective aneurysm repair will develop partial-thickness

ischemic colitis but without significant clinical sequelae.⁴⁷ However, if the partial-thickness ischemia progresses to full-thickness gangrene and peritonitis, mortality can be as high as 90%.⁴⁷

The incidence of prosthetic graft infection ranges between 1 and 4% after open repair.⁴⁷ It is more common in those who undergo repair of a ruptured AAA. If the prosthetic graft is not fully covered by the aneurysm sac or retroperitoneum, intestinal adhesion with subsequent bowel erosion may occur, resulting in an aortoenteric fistula. The predominant sign of such a complication is massive hematemesis, and it typically occurs years after the operation. Despite these potential complications, however, the majority of patients who undergo successful elective open repair have an uneventful recovery.

Endovascular Repair of Abdominal Aortic Aneurysm

More than a decade has passed since the first report of human implantation of a homemade stent graft for endovascular repair of an AAA by Parodi in 1991.³ Several prospective clinical trials across different devices and analysis of large Medicare administrative databases and meta-analyses of published literature have consistently demonstrated significantly decreased operative time, blood loss, hospital length of stay, and overall perioperative morbidity and mortality of endovascular repair as compared to open surgical repair. For patients who are at increased risk for surgery because of age or comorbidity, endovascular repair is a superior, minimally invasive alternative.

The principle of endovascular repair of AAA involves the implantation of an aortic stent graft that is fixed proximally and distally to the nonaneurysmal aortoiliac segment, and thereby endoluminally excludes the aneurysm from the aortic circulation (Fig. 23-32). Unlike open surgical repair, endovascular treatment does not remove or eliminate the aneurysm sac, which therefore is subjected to potential aneurysm expansion or even rupture as persistent aneurysm sac pressurization may occur following endograft implantation. Importantly, aortic branches such as lumbar arteries or the inferior mesenteric artery (IMA) are ligated, which can lead to persistent aneurysm pressurization and aneurysm expansion. Currently, five devices are available for elective repair of intact infrarenal AAA: (a) AneuRx device (Medtronic/AVE, Santa Rosa, Calif), (b) Gore Excluder device (WL Gore & Associates, Flagstaff, Ariz), (c) Endologix Powerlink device (Endologix Inc., Irvine, Calif), (d) Zenith device (Cook Inc., Bloomington, Ind), and (e) Talent device (Medtronic/AVE, Santa Rosa, Calif). Despite some differences in physical appearance, mechanical properties, and materials, they will be discussed collectively in this chapter. They are all modular devices consisting of a primary device or main body and one or two iliac limbs that insert into the main body to complete the repair. Depending on the device, there are varying degrees of flexibility in the choice of iliac limbs that can be matched to the main body, which can impact the customizability for a particular anatomy.

PATIENT SELECTION FOR ENDOVASCULAR AORTIC ANEURYSM REPAIR

Anatomic eligibility for endovascular repair is mainly based on three areas: the proximal aortic neck, CIAs, and the external iliac and common femoral arteries, which relate to the proximal and distal landing zones or fixation sites and the access vessels, respectively. The requirements for the proximal aortic neck are a diameter of 18 to 28 mm and a minimum length of 15 mm (Table 23-9). Usually, multiple measurements of the diameter are taken along the length of the neck to assess its shape. All diameter measurements are midwall to midwall of the vessel. Secondary considerations include mural calcifications (<50% circumference), luminal thrombus (<50% circumference), and angulation (<45°). Presence of a significant amount of any one of these secondary features in combination with a relatively short proximal neck may compromise successful short- and long-term fixation of the stent graft and exclusion of the aneurysm. The usual distal landing zone is the CIA. The EIA may serve as an alternate site when the ipsilateral CIA is aneurysmal or ectatic. The treatable diameters of CIAs range from 8 to 20 mm, and there should be at least 20 mm of patent artery of uniform diameter to allow adequate fixation. And finally, at least one of two common femoral and external iliac arteries must be at least 7 mm in diameter to safely introduce the main delivery sheath. Slightly smaller iliac diameters may be tolerated depending on the specific device and in the absence of severe tortuosity and calcific disease. Difficult access is one of the main causes of increased procedural times and intraoperative complications. Using these criteria, approximately 60% of all AAA are anatomic candidates for endovascular repair.

Table 23-9 Ideal Characteristics of an Aneurysm for Endovascular Abdominal Aortic Aneurysm Repair

Neck length (mm)	>15
Neck diameter (mm)	>18, <32
Aortic neck angle (°)	<60
Neck mural calcification (% circumference)	<50
Neck luminal thrombus (% circumference)	<50
Common iliac artery diameter (mm)	between 8–20
Common iliac artery length (mm)	>20
External iliac artery diameter (mm)	>7

The next step in the preoperative planning is device selection. Typically, the proximal diameter of the main device is oversized by 10 to 20% of the nominal diameter of the aortic neck. Distally, the iliac limbs are oversized by 1 to 4 mm depending on the individual device's instructions for use. The biggest challenge to proper device selection remains determining the optimal length from the renal arteries to the hypogastric arteries. Despite availability of sophisticated three-dimensional reconstructions, the exact path that a device will take from the proximal aortic neck to the distal iliac arteries is difficult to predict. It is dependent on a host of factors related to the mechanical properties of the stent graft and the morphology of the aortoiliac flow lumen. "Plumb-line" measurements of axial CT images can be quite inaccurate, typically grossly underestimating the length, while center-line measurements usually overestimate the length. Angiographic measurements using a marker catheter are invasive, require contrast and radiation exposure, and also are inaccurate because the marker catheter fails to take into account the stiffness of the stent graft. The consequences of not choosing the correct length of the device include inadvertent coverage of the hypogastric artery if too long and the need for additional devices if too short.

ADVANTAGES AND RISKS OF ENDOVASCULAR REPAIR

The obvious advantage of an endovascular AAA repair is its minimally invasive nature. Typically, patients who undergo this procedure stay in the hospital for only 1 to 3 days, in contrast to the 5- to 10-day stay required after conventional open surgical repair. In most clinical practices, patients who have had an endovascular repair are routinely transferred to a general vascular ward from the postanesthesia recovery unit, avoiding admission to a more costly intensive care unit (ICU).

Because an abdominal incision is not necessary in endovascular repair, the procedure is particularly beneficial in patients with severe pulmonary disease such as chronic obstructive pulmonary disease or emphysema. Patients can sustain adequate breathing in the postoperative period, thereby avoiding respiratory complications or prolonged mechanical ventilation. Because the abdominal cavity has not been entered, the risk of GI complications such as ileus, ventral hernia, or bowel obstruction due to intestinal adhesion also is greatly reduced. Moreover, regional or epidural anesthesia can be used, avoiding the risks associated with general anesthesia in patients with severe cardiopulmonary dysfunction.

Despite its many advantages, endovascular repair does have potential complications. Because the stent graft device is attached endoluminally within the abdominal aorta, an endoleak due to incomplete stent graft exclusion of the aneurysm can occur. With this type of leak, blood flow persists outside the lumen of the endoluminal graft but within an aneurysm sac. A meta-analysis of 1118 patients who underwent successful endovascular repair found an endoleak incidence of 24%.⁴⁸ Although a small endoleak usually poses little clinical significance because it will typically become thrombosed spontaneously, a large or persistent endoleak may lead to continuous aneurysm perfusion and ultimately to aneurysm rupture. The rupture

rate following an endovascular AAA repair has been reported to be <0.8%.⁴⁹

Stent graft iliac limb dysfunction resulting in thrombosis has been reported following endovascular repair.^{16,48} One possible cause is aneurysm remodeling, resulting in a shortening in the aortic length, which can cause the stent graft to kink. Alternatively, progression of an underlying iliac atherosclerotic lesion may cause compression of the iliac limb and ultimately result in graft-limb occlusion. Treatment options include thrombolysis or graft thrombectomy to determine the underlying cause and possibly additional stent graft placement. Renal artery occlusion may occur due to improper stent graft positioning or migration.^{16,46,48} Graft limb separation or dislocation also has been reported.^{16,46,48}

In patients with AAA and concurrent iliac artery aneurysms who undergo preoperative coil embolization of the internal iliac artery, 20 to 45% experience symptoms of pelvic ischemia.⁵⁰ These symptoms may include buttock claudication, impotence, gluteal skin sloughing, and colonic ischemia. Other complications pertaining to endovascular repair relate to the access site and include groin hematoma and wound infection. Occasionally, the stent graft device can malfunction by either failing to deploy or dislodging during the deployment procedure.^{16,49} If the device cannot be salvaged or rescued endoluminally, open surgical repair of the aneurysm may be necessary.

TECHNICAL CONSIDERATIONS OF ENDOVASCULAR AORTIC ANEURYSM REPAIR

Although endovascular AAA repair may be performed in any venue with appropriate digital fluoroscopic imaging capability, due to the need for absolute sterility and aseptic technique, it is most safely performed in a surgical suite. The patient is prepped and draped just as in open AAA repair. Patients with renal insufficiency should be started on perioperative oral *N*-acetylcysteine and sodium bicarbonate infusion to reduce the risk of contrast nephropathy. A variety of anesthetic options may be used. Regional anesthesia may be appropriate for patients with pulmonary disease. There are reports of success with local anesthetics alone, as the incisions are typically smaller than a typical open inguinal hernia repair.⁵¹

Bilateral transverse oblique incisions are made just below the inguinal ligament to expose approximately 2 to 3 cm of common femoral arteries and obtain proximal control. Special attention is paid to avoid the groin crease to decrease the risk of wound complications. Some have advocated a completely percutaneous access using the "pre-close" technique with the Perclose suture-mediated vascular closure device (Abbott Perclose, Redwood City, Calif). Review of reported series on this technique suggest a technical success rate of 95% for medium size sheaths ranging from 12F to 16F, and 75% success for 18F to 24F sizes.

Transfemoral access is obtained using standard Seldinger technique. Initial soft-tipped starter guidewires are exchanged for stiff guidewires that are advanced to the thoracic arch. IV heparin at 80 IU/kg is administered and the activated clotting time is maintained at 200 to 250 seconds. These guidewires provide the necessary support for the subsequent introduction of the large-diameter delivery catheters and devices. In the absence of special anatomic considerations, the primary device is inserted through the right side and the contralateral iliac limb is inserted through the left side. After administration of heparin, the delivery catheter or the introducer sheath is advanced to the L1–L2 vertebral space, which typically marks the location of the renal arteries. An angiographic catheter is advanced from the contralateral femoral artery to the same level.

A road-mapping aortogram is obtained to localize the renal arteries. The primary device is rotated to the desired orientation and deployed immediately below the lowest renal artery (Fig. 23-33). The angiographic catheter is replaced with a directional catheter and an angled guidewire, and the opening for the contralateral limb on the main device is cannulated. Intrastent passage of the guidewire is confirmed, and the angled guidewire is replaced with a stiff guidewire. The contralateral iliac limb is inserted into the docking opening of the primary device and deployed. A completion angiogram is

performed looking for patency of the renal and hypogastric arteries, the device limbs, proximal and distal fixation, and endoleak. Adjunctive interventions, including additional devices, balloons, bare stents, etc., are performed as needed. The procedure is concluded with routine repairs of the femoral arteries and closure of the groin incisions. The patients are recovered in the recovery room for 2 to 4 hours and admitted to the general care floor. Although in the past, patients were admitted to the ICU, this is rarely needed. Most patients can be started on a regular diet that evening and discharged the next morning.

A. During an endovascular aortic aneurysm repair, the main endograft device is inserted through a femoral artery approach. **B.** The device is deployed in the aorta just below the renal arteries. **C.** A contralateral iliac endograft device is inserted through a contralateral gate opening that is next deployed. **D.** Completion deployment of the endograft device should fully exclude an aortic aneurysm while arterial flow to the renal and hypogastric arteries should remain patent.

SURVEILLANCE FOLLOWING ENDOVASCULAR AORTIC ANEURYSM REPAIR

Lifelong follow-up is essential to the long-term success after endovascular AAA repair. Indeed, one may go so far as to say that absence of appropriate follow-up is tantamount to not having had a repair at all. A triple-phase (noncontrast, contrast,

delayed) spiral CT scan and a four-view (anteroposterior, lateral, and two obliques) abdominal x-ray should be obtained within the first month. Subsequent imaging can be obtained at 6-month intervals in the first 1 to 2 years and yearly thereafter. After the first 6 months, patients who cannot travel easily may obtain their studies locally and submit them for review. The CT scan is for detection of endoleaks, subtle proximal migrations, and changes in aneurysm size. The abdominal x-ray gives a "bird's-eye" view of the overall morphology of the stent graft. Subtle changes in conformation of the iliac limbs relative to each other and/or the spine can provide early signs of impending component separation or loss of fixation. Further, stent fractures and/or suture breaks that can compromise long-term device integrity sometimes only can be detected on a plain film and not on a CT scan.

Results from Clinical Studies Comparing Endovascular vs. Open Repair

The primary success rate after endovascular repair of AAA has been reported to be as high as 95%.^{16,45} The less invasive nature of this procedure is appealing to many physicians and patients. In addition, virtually all reports indicate decreased blood loss, transfusion requirements, and length of ICU and hospital stay for endovascular repair of AAAs when compared to the standard surgical approach.^{16,45,52} With the advent of bifurcated grafts and improved delivery systems in the future, the only real limitation will be cost. When evaluating the literature for results from clinical series, it is important to look at a comparison of endoluminal vs. open repair, device specific outcome, and cost analysis studies.

Early reports on results with endovascular repair were often flawed due to selection biases. This is because from its inception, endovascular repair has been used mostly in patients who are at higher risk for open repair. At the same time, only patients with favorable anatomy including less tortuosity and the presence of a suitable infrarenal neck were considered for endovascular repair. Randomization is also difficult because most patients who anatomically qualify for endovascular repair would withdraw from the study if randomized to open repair. Consequently, there are very few randomized, controlled trials that have compared outcomes in patients with similar risk factors and anatomy that are eligible for both types of repair. Two such European trials have published short-term outcome data that are unbiased in design.

The DREAM trial is a multicenter randomized trial that compared open vs. endovascular repair among a group of 345 patients at 28 European centers using multiple different devices including: Gore, AneuRx, and Zenith.⁵³ Patients were included only if they were considered to be candidates for both types of repairs. The operative mortality rate was 4.6% in the operative group vs. 1.2% in the endoluminal group at 30 days. When looking at the combined rate of operative mortality and severe complications, there was an incidence of 9.8% in the open-repair vs. 4.7% in the endoluminal group. The difference here was largely due to the higher frequency of pulmonary complications seen in the open group. There was a higher incidence of graft-related complications in the endoluminal group. There was no difference in the nonvascular-local complication rate among the two groups.

The EVAR-1 trial is also a multicenter randomized trial that compared open to endoluminal repair.⁵² This study was conducted on 1082 patients at 34 centers in the United Kingdom using all available devices. Short-term mortality at 30 days was 4.7% in the open and 1.7% in the endoluminal group. The inhospital mortality rate was also increased in the open when compared to the endoluminal group (6.2 to 2.1%). As expected, the secondary-intervention rate was higher in the endoluminal group (9.8 to 5.8%). Complication rates were not reported with the EVAR-1 trial. There are criticisms that can be applied to both of these trials. Patients had to be eligible for either type of repair to be included in the study. Consequently, these findings cannot be generalized for patients who are too sick to undergo open surgery or in those patients whose anatomy precludes them from undergoing endovascular repair.

DEVICE-SPECIFIC OUTCOME

Matsmura and associates compared endoluminal to open repair using the Excluder device.⁵⁴ In their review, they demonstrated a 30-day mortality rate of 1% along with an endoleak rate of 17 and 20% at 1 and 2-year intervals.⁵⁴ The limb narrowing, limb migration, and trunk migration were all 1% at 2 years. There were no deployment failures or early conversions. There was an annual 7% reintervention rate. Aneurysm growth was demonstrated in 14% of patients at 2 years. The Zenith device by Cook has been studied by Greenberg and associates, who compared standard surgical repair to endoluminal repair in low-risk patients as well as endoluminal repair in high-risk patients.⁵⁵ They reported a 30-day mortality rate of 3.5% that was equal to the open group. The rate of endoleak was 7.4 and 5.4% at 1 and 2-year intervals. There was a 5.3% migration of 5 mm after 1 year. Freedom from rupture was 100% in the low-risk and 98.9% in the high-risk endoluminal group at 2 years. Experience with the AneuRx device has been reported by Zarins and associates.⁵⁶ In their 4-year review, they found a 30-day mortality rate of 2.8%. Endoleak rate at 4 years was 13.9%, aneurysm enlargement was 11.5%, and stent graft migration was 9.5%. Freedom from rupture was noted to be 98.4% at 4 years. Criado and associates have reported on their 1-year experience with the Talent LPS device by Medtronic.⁵⁷ They report a 30-day mortality rate of 0.8%. Endoleak rate was 10%. Three deployment failures were noted, and freedom from rupture was 100%. Aneurysm growth and migration rates were divided into three different neck-size groups. Patients with a wide neck (>26 mm) had a 3% growth and migration rate. Narrow-neck patients (<26 mm) had a 1% growth rate and a 2% migration rate. Interestingly, short-neck patients (<15 mm) had no aneurysm growths and a 2% migration rate.

COST ANALYSIS

The current climate of cost containment and limited reimbursement for health care services mandates a critical analysis of the economic impact of any new medical technology on the market. The in-hospital costs for both endovascular and open repair include graft cost, OR fees, radiology, pharmacy, ancillary care, ICU charges, and floor charges. Despite the improved morbidity and mortality rates, several early studies have reported no cost benefit with the application of endovascular repair.^{58,59} The limiting factor appears to be the cost of the device. Despite commercialization of endovascular repair, the device costs are still in the range of \$5000 to \$6000 with no signs of abating. A recent report by Angle and associates further corroborates previous studies.⁶⁰ In their review, despite decreased hospital and ICU stays and use of pharmacy and respiratory services, cost of endovascular repair was 1.74 times greater than the standard surgical approach. In addition, these cost analysis studies are centered on in-hospital costs and do not even begin to address secondary costs such as postoperative surveillance that is required with endovascular repair.

Classification and Management of Endoleak

An endoleak is an extravasation of contrast outside the stent graft and within the aneurysm sac (Fig. 23-34). It can be present in up to 20 to 30% of all endovascular AAA repairs in the early postoperative period.⁶¹ In general, over one half of these endoleaks will resolve spontaneously during the first 6 months, resulting in a 10% incidence of chronic endoleaks in all cases beyond the first year of follow-up. Endoleaks can be detected using conventional angiography, contrast CT (Fig. 23-35), MRA (magnetic resonance angiography), and color flow duplex ultrasound. Although there is no recognized gold standard, in practice, angiography is considered the least sensitive but most specific for characterizing the source of the endoleak, while the CT scan is the most sensitive but least specific. Widespread availability and reliability that is relatively independent of technique have made the CT scan the de facto standard imaging modality for postoperative surveillance. Conversely, routine use of duplex ultrasound and MRA has been limited by the lack of proper equipment and local expertise.

On the other hand, investigational techniques such as time-resolved MRA may provide greater sensitivity and specificity than either angiography or CT in the future.

A computed tomographic scan demonstrating an endoleak (*small arrow*) as evidenced by contrast flow outside the aortic endograft (*long arrow*).

Four types of endoleaks have been described (Table 23-10). *Type I endoleak* refers to fixation-related leaks that occur at the proximal or distal attachment sites. These represent less than 5% of all endoleaks and are seen as an early blush of contrast into the aneurysm sac from the proximal or distal ends of the device during completion angiography.^{61,62} Although seen as a marker of poor patient selection or inadequate repair, over 80% of these leaks spontaneously seal in the first 6 months. Persistent type I endoleaks, on the other hand, require prompt treatment. *Type II endoleak* refers to retrograde flow originating from a lumbar, inferior mesenteric, accessory renal, or hypogastric artery. They are the most common type of endoleak, accounting for 20 to 30% of all cases, and about one half resolve spontaneously. On angiography, they are seen as a late filling of the aneurysm sac from a branch vessel(s). Type II endoleaks carry a relatively benign natural history and do not merit intervention unless associated with aneurysm growth. *Type III endoleaks* refer to a failure of device integrity or component separation from modular systems. If detected intraoperatively or in the early perioperative period, it is usually from inadequate overlap between two stent grafts, while in the late period, it may be from a fabric tear or junctional separation from conformational changes of the aneurysm. Regardless of the etiology or timing, these should be promptly repaired. And lastly, *type IV endoleak* refers to the diffuse, early blush seen during completion angiography due to graft porosity and/or suture holes of some Dacron-based devices. It does not have any clinical significance and usually cannot be seen after 48 hours and heparin reversal. Endoleaks that have initially been considered type IV that persist become type III endoleaks by definition, as it indicates a more significant material defect than simple porosity or a suture hole.

Table 23-10 Endoleak Classification	
Classification	Description
Type I endoleak	Attachment site leak
Type II endoleak	Side branch leak caused by lumbar or inferior mesenteric artery
Type III endoleak	Junctional leak (of overlapping endograft components)
Type IV endoleak	Endograft fabric or porosity leak

ENDOTENSION FOLLOWING ENDOVASCULAR AORTIC ANEURYSM REPAIR

In approximately 5% of cases after an apparently successful endovascular repair, the aneurysm continues to grow without any demonstrable endoleak.⁶³ This phenomenon has been described as *endotension*. Although it was initially thought that an endoleak was really present but simply not detected, cases have been reported where the aneurysm has been surgically opened and the contents were completely devoid of any blood and no extravasation could be found. The mechanism of continued pressurization of the aneurysm sac following successful exclusion from the arterial circulation remains unsolved at this time. One putative mechanism has been linked to a transudative process related to certain expanded PTFE graft materials.⁶⁴ More importantly, however, the natural history of these enlarging aneurysms without endoleaks is unknown, but to date there has been no evidence to suggest that they carry an increased risk of rupture. Conservatively speaking, until further, long-term data become available, if the patient is a suitable surgical risk, elective open conversion should be considered.

SECONDARY INTERVENTIONS FOLLOWING ENDOVASCULAR AORTIC ANEURYSM REPAIR

There is approximately a 10 to 15% per year risk of secondary interventions following endovascular AAA repair.^{16,55,65} These procedures are critical in the long-term success of the primary procedure in prevention of aneurysm rupture and

aneurysm-related death. These secondary procedures, in order of frequency, include proximal or distal extender placement for migrations, highly-selective or translumbar embolization for type II endoleaks, direct surgical or laparoscopic branch vessel ligations, bridging cuffs for component separations, and late open surgical conversions.

Multiple large series have reported an annual rupture rate of approximately 1 to 1.5% per year after endovascular repair.^{16,55,65} The EUROSTAR registry reports a rupture rate of 2.3% over a 15-month period in patients with an endoleak, compared with 0.3% in those without.⁶⁶ Various causes of late ruptures have been reported in the literature, although presence of a persistent endoleak with aneurysm enlargement remains a common culprit for this complication. It has been shown that even successfully excluded aneurysm can lead to the development of attachment-site leaks and device failure, caused in part by aneurysm remodeling resulting in stent migration or kinking.⁶⁷

Treatment of rupture may be open conversion or endovascular stent graft placement. May and associates reported a mortality rate of 43% in those patients who underwent open conversion.⁶⁸ Emergent endovascular repair should be considered in these patients because it is potentially much faster and incurs less physiologic stress than open conversion. Several reports have shown that endovascular repair can be performed successfully in patients previously treated with endoluminal prostheses.^{69,70}

MESENTERIC ARTERY DISEASE

Vascular occlusive disease of the mesenteric vessels is a relatively uncommon but potentially devastating condition that generally presents in patients more than 60 years of age, is three times more frequent in women, and has been recognized as an entity since 1936.⁷¹ The incidence of such a disease is low and represents 2% of the revascularization operations for atheromatous lesions. The most common cause of mesenteric ischemia is atherosclerotic vascular disease. Autopsy studies have demonstrated splanchnic atherosclerosis in 35 to 70% of cases.⁷² Other etiologies exist and include FMD, panarteritis nodosa, arteritis, and celiac artery (CA) compression from a median arcuate ligament, but they are unusual and have an incidence of one in nine compared to that of atherosclerosis.

Chronic mesenteric ischemia is related to a lack of blood supply in the splanchnic region and is caused by disease in one or more visceral arteries: the celiac trunk, the SMA, and the IMA. Mesenteric ischemia is thought to occur when two of the three visceral vessels are affected with severe stenosis or occlusion; however, in as many as 9% of cases, only a single vessel is involved [superior mesenteric artery (SMA) in 5% and celiac trunk in 4% of cases].⁷³ This disease process may evolve in a chronic fashion, as in the case of progressive luminal obliteration due to atherosclerosis. On the other hand, mesenteric ischemia can occur suddenly, as in the case of thromboembolism. Despite recent progress in perioperative management and better understanding in pathophysiology, mesenteric ischemia is considered one of the most catastrophic vascular disorders, with mortality rates ranging from 50 to 75%. Delay in diagnosis and treatment are the main contributing factors in its high mortality. It is estimated that mesenteric ischemia accounts for one in every 1000 hospital admissions in this country. The prevalence is rising due in part to the increased awareness of this disease, the advanced age of the population, and the significant comorbidity of these elderly patients. Early recognition and prompt treatment before the onset of irreversible intestinal ischemia are essential to improve the outcome.

Anatomy and Pathophysiology

Mesenteric arterial circulation is remarkable for its rich collateral network. Three main mesenteric arteries provide the arterial perfusion to the GI system: the CA, SMA, and IMA. In general, the CA provides arterial circulation to the foregut (distal esophagus to duodenum), hepatobiliary system, and spleen; the SMA supplies the midgut (jejunum to midcolon); and the

IMA supplies the hindgut (midcolon to rectum). The CA and SMA arise from the ventral surface of the infradiaphragmatic suprarenal abdominal aorta, while the IMA originates from the left lateral portion of the infrarenal aorta. These anatomic origins in relation to the aorta are important when a mesenteric angiogram is performed to determine the luminal patency. To fully visualize the origins of the CA and SMA, it is necessary to perform both an anteroposterior and a lateral projection of the aorta because most arterial occlusive lesions occur in the proximal segments of these mesenteric trunks.

Because of the abundant collateral flow between these mesenteric arteries, progressive diminution of flow in one or even two of the main mesenteric trunks is usually tolerated, provided that uninvolved mesenteric branches can enlarge over time to provide sufficient compensatory collateral flow. In contrast, acute occlusion of a main mesenteric trunk may result in profound ischemia due to lack of sufficient collateral flow. Collateral network between the CA and the SMA exist primarily through the superior and inferior pancreaticoduodenal arteries. The IMA may provide collateral arterial flow to the SMA through the marginal artery of Drummond, the arc of Rioloan, and other unnamed retroperitoneal collateral vessels termed *meandering mesenteric arteries* (Fig. 23-36). Lastly, collateral visceral vessels may provide important arterial flow to the IMA and the hindgut through the hypogastric arteries and the hemorrhoidal arterial network.

An aortogram showing a prominent collateral vessel that is the arc of Rioloan (*arrow*) in a patient with an inferior mesenteric artery occlusion. This vessel network provides collateral flow between the superior mesenteric artery and inferior mesenteric artery.

Regulation of mesenteric blood flow is largely modulated by both hormonal and neural stimuli, which characteristically

regulate systemic blood flow. In addition, the mesenteric circulation responds to the GI contents. Hormonal regulation is mediated by splanchnic vasodilators such as nitric oxide, glucagon, and vasoactive intestinal peptide. Certain intrinsic vasoconstrictors such as vasopressin can diminish the mesenteric blood flow. On the other hand, neural regulation is provided by the extensive visceral autonomic innervation.

Clinical manifestation of mesenteric ischemia is predominantly postprandial abdominal pain, which signifies that the increased oxygen demand of digestion is not met by the GI collateral circulation. The postprandial pain frequently occurs in the midabdomen, suggesting that the diversion of blood flow from the SMA to supply the stomach impairs perfusion to the small bowel. This leads to transient anaerobic metabolism and acidosis. Persistent or profound mesenteric ischemia will lead to mucosal compromise with release of intracellular contents and by-products of anaerobic metabolism to the splanchnic and systemic circulation. Injured bowel mucosa allows unimpeded influx of toxic substances from the bowel lumen with systemic consequences. If full-thickness necrosis occurs in the bowel wall, intestinal perforation ensues, which will lead to peritonitis. Concomitant atherosclerotic disease in cardiac or systemic circulation frequently compounds the diagnostic and therapeutic complexity of mesenteric ischemia.

Types of Mesenteric Artery Occlusive Disease

There are three major mechanisms of visceral ischemia involving the mesenteric arteries, which include: (a) acute mesenteric ischemia, which can be either embolic or thrombotic in origin; (b) chronic mesenteric ischemia; and (c) nonocclusive mesenteric ischemia. Despite the variability of these syndromes, a common anatomic pathology is involved in these processes. The SMA is the most commonly involved vessel in acute mesenteric ischemia. Acute thrombosis occurs in patients with underlying mesenteric atherosclerosis, which typically involves the origin of the mesenteric arteries while sparing the collateral branches. In acute embolic mesenteric ischemia, the emboli typically originate from a cardiac source and frequently occur in patients with atrial fibrillation or following myocardial infarction (Figs. 23-37 and 23-38). Nonocclusive mesenteric ischemia is characterized by a low flow state in otherwise normal mesenteric arteries, and most frequently occurs in critically ill patients on vasopressors. Finally, chronic mesenteric ischemia is a functional consequence of a long-standing atherosclerotic process that typically involves at least two of the three main mesenteric vessels. The gradual development of the occlusive process allows the development of collateral vessels that prevent the manifestations of acute ischemia, but are not sufficient to meet the high postprandial intestinal oxygen requirements, giving rise to the classical symptoms of postprandial abdominal pain and the resultant food fear.

A lateral mesenteric angiogram showing an abrupt cutoff of the proximal superior mesenteric artery, which is consistent with superior mesenteric artery embolism (*arrow*).

Several less common syndromes of visceral ischemia involving the mesenteric arteries can also cause serious debilitation. Chronic mesenteric ischemic symptoms can occur due to extrinsic compression of the CA by the diaphragm, which is termed the *median arcuate ligament syndrome*, or *celiac artery compression syndrome*. Acute visceral ischemia may occur following an aortic operation, due to ligation of the IMA in the absence of adequate collateral vessels. Furthermore, acute visceral ischemia may develop in aortic dissection that involves the mesenteric arteries, or after coarctation repair. Finally, other unusual causes of ischemia include mesenteric arteritis, radiation arteritis, and cholesterol emboli.

Clinical Manifestations

Abdominal pain out of proportion to physical findings is the classic presentation in patients with acute mesenteric ischemia and occurs following an embolic or thrombotic ischemic event of the SMA. Other manifestations include sudden onset of abdominal cramps in patients with underlying cardiac or atherosclerotic disease, often associated with bloody diarrhea, as a result of mucosal sloughing secondary to ischemia. Fever, nausea, vomiting, and abdominal distention are some common but nonspecific manifestations. Diffuse abdominal tenderness, rebound, and rigidity are late signs and usually indicate bowel infarction and necrosis.

Clinical manifestations of chronic mesenteric ischemia are more subtle owing to the extensive collateral development. However, when intestinal blood flow is unable to meet the physiologic GI demands, mesenteric insufficiency ensues. The classic symptoms include postprandial abdominal pain, "food fear," and weight loss. Persistent nausea, and occasionally diarrhea, may coexist. Diagnosis remains challenging, and most of the patients will undergo an extensive and expensive GI tract work-up for the above symptoms before referral to a vascular service.

The typical patients who develop nonocclusive mesenteric ischemia are elderly patients. Comorbidities include congestive

heart failure, acute myocardial infarction with cardiogenic shock, hypovolemic or hemorrhagic shock, sepsis, pancreatitis, and administration of digitalis or vasoconstrictor agents such as epinephrine. Abdominal pain is only present in approximately 70% of these patients. When present, the pain is usually severe but may vary in location, character, and intensity. In the absence of abdominal pain, progressive abdominal distention with acidosis may be an early sign of ischemia and impending bowel infarction.

Abdominal pain due to narrowing of the origin of the CA may occur as a result of extrinsic compression or impingement by the median arcuate ligament (Fig. 23-39). This condition is known as *celiac artery compression syndrome* or *median arcuate ligament syndrome*. Angiographically, there is CA compression that augments with deep expiration, and poststenotic dilatation. The CA compression syndrome has been implicated in some variants of chronic mesenteric ischemia. Most patients are young females between 20 and 40 years of age. Abdominal symptom is nonspecific, but the pain is localized in the upper abdomen, which may be precipitated by meals.

Diagnostic Evaluation

The differential diagnosis of acute mesenteric ischemia includes other causes of severe abdominal pain of acute onset, such as perforated viscus, intestinal obstruction, pancreatitis, cholecystitis, and nephrolithiasis. Laboratory evaluation is neither

sensitive nor specific in distinguishing these various diagnoses. In the setting of mesenteric ischemia, complete blood count may reveal hemoconcentration and leukocytosis. Metabolic acidosis develops as a result of anaerobic metabolism. Elevated serum amylase may indicate a diagnosis of pancreatitis, but is also common in the setting of intestinal infarction. Finally, increased lactate levels, hyperkalemia, and azotemia may occur in the late stages of mesenteric ischemia.

Plain abdominal radiographs may provide helpful information to exclude other causes of abdominal pain such as intestinal obstruction, perforation, or volvulus, which may exhibit symptoms mimicking intestinal ischemia. Pneumoperitoneum, pneumatosis intestinalis, and gas in the portal vein may indicate infarcted bowel. In contrast, radiographic appearance of an adynamic ileus with a gasless abdomen is the most common finding in patients with acute mesenteric ischemia.

Upper endoscopy, colonoscopy, or barium radiography does not provide any useful information when evaluating acute mesenteric ischemia. Moreover, barium enema is contraindicated if the diagnosis of mesenteric ischemia is being considered. The intraluminal barium can obscure accurate visualization of mesenteric circulation during angiography. In addition, intraperitoneal leakage of barium can occur in the setting of intestinal perforation, which can lead to added therapeutic challenges during mesenteric revascularization.

Diagnosis of chronic mesenteric ischemia can be more challenging. Usually, before the evaluation by a vascular service, the patients have undergone an extensive work-up for the symptoms of chronic abdominal pain, weight loss, and anorexia. Rarely, the vascular surgeon is the first to encounter a patient with the above symptoms. In this situation, it is advisable to keep in mind that mesenteric ischemia is a rare entity, and that a full diagnostic work-up that should include CT scan of the abdomen and evaluation by a gastroenterologist should be performed. Mesenteric occlusive disease may coexist with malignancy, and symptoms of mesenteric vessel stenosis may be the result of extrinsic compression by a tumor.

Duplex ultrasonography is a valuable noninvasive means of assessing the patency of the mesenteric vessels. Moneta and associates evaluated the use of duplex ultrasound in the diagnosis of mesenteric occlusive disease in a blinded prospective study.^{74,75} A peak systolic velocity in the SMA >275 cm/s demonstrated a sensitivity of 92%, specificity of 96%, and an overall accuracy of 96% for detecting more than 70% stenosis. The same authors found sensitivity and specificity of 87% and 82%, respectively, with an accuracy of 82% in predicting more than 70% celiac trunk stenosis. Duplex has been successfully used for follow-up after open surgical reconstruction or endovascular treatment of the mesenteric vessels to assess recurrence of the disease. Finally, spiral computed tomography with three-dimensional reconstruction (Fig. 23-40) as well as MRA (Fig. 23-41) have been promising in providing clear radiographic assessment of the mesenteric vessels.

Fig. 23-40.

A cross-sectional view of a magnetic resonance angiography provides a clear view of the luminal patency of the superior mesenteric artery.

The definitive diagnosis of mesenteric vascular disease is made by biplanar mesenteric arteriography, which should be performed promptly in any patient with suspected mesenteric occlusion. It typically shows occlusion or near-occlusion of the CA and SMA at or near their origins from the aorta. In most cases, the IMA has been previously occluded secondary to diffuse infrarenal aortic atherosclerosis. The differentiation of the different types of mesenteric arterial occlusion may be suggested with biplanar mesenteric arteriogram. Mesenteric emboli typically lodge at the orifice of the middle colic artery, which creates a "meniscus sign" with an abrupt cutoff of a normal proximal SMA several centimeters from its origin on the aorta. Mesenteric thrombosis, in contrast, occurs at the most proximal SMA, which tapers off at 1 to 2 cm from its origin. In the case of chronic mesenteric occlusion, the appearance of collateral circulation is typically present. Nonocclusive mesenteric ischemia produces an arteriographic image of segmental mesenteric vasospasm with a relatively normal appearing main SMA trunk (Fig. 23-42).

Fig. 23-42.

Mesenteric arteriogram showing nonocclusive mesenteric ischemia as evidenced by diffuse spasm of intestinal arcades with poor filling of intramural vessels.

Mesenteric arteriography also can play a therapeutic role. Once the diagnosis of nonocclusive mesenteric ischemia is made on the arteriogram, an infusion catheter can be placed at the SMA orifice and vasodilating agents such as papaverine can be

administered intra-arterially. The papaverine infusion may be continued postoperatively to treat persistent vasospasm, a common occurrence following mesenteric reperfusion. Transcatheter thrombolytic therapy has little role in the management of thrombotic mesenteric occlusion. Although thrombolytic agents may transiently recannulate the occluded vessels, the underlying occlusive lesions require definitive treatment. Furthermore, thrombolytic therapy typically requires a prolonged period of time to restore perfusion, during which the intestinal viability will be difficult to assess.

A word of caution would be appropriate here regarding patients with typical history of chronic intestinal angina who present with an acute abdomen and classical findings of peritoneal irritation. Arteriography is the gold standard for the diagnosis of mesenteric occlusive disease; however, it can be a time-consuming diagnostic modality. In this group of patients, immediate exploration for assessment of intestinal viability and vascular reconstruction is the best choice.

Surgical Repair

ACUTE EMBOLIC MESENTERIC ISCHEMIA

Initial management of patients with acute mesenteric ischemia includes fluid resuscitation and systemic anticoagulation with heparin to prevent further thrombus propagation. Significant metabolic acidosis not responding to fluid resuscitation should be corrected with sodium bicarbonate. A central venous catheter, peripheral arterial catheter, and a Foley catheter should be placed for hemodynamic status monitoring. Appropriate antibiotics are given before surgical exploration. The operative management of acute mesenteric ischemia is dictated by the cause of the occlusion. It is helpful to obtain a preoperative mesenteric arteriogram to confirm the diagnosis and to plan appropriate treatment options. However, the diagnosis of mesenteric ischemia frequently cannot be established before surgical exploration; and therefore, patients in a moribund condition with acute abdominal symptoms should undergo immediate surgical exploration, avoiding the delay required to perform an arteriogram.

The primary goal of surgical treatment in embolic mesenteric ischemia is to restore arterial perfusion with removal of the embolus from the vessel. The abdomen is explored through a midline incision, which often reveals variable degrees of intestinal ischemia from the midjejunum to the ascending or transverse colon. The transverse colon is lifted superiorly, and the small intestine is reflected toward the right upper quadrant. The SMA is approached at the root of the small bowel mesentery, usually as it emerges from beneath the pancreas to cross over the junction of the third and fourth portions of the duodenum. Alternatively, the SMA can be approached by incising the retroperitoneum lateral to the fourth portion of the duodenum, which is rotated medially to expose the SMA. Once the proximal SMA is identified and controlled with vascular clamps, a transverse arteriotomy is made to extract the embolus, using standard balloon embolectomy catheters. In the event the embolus has lodged more distally, exposure of the distal SMA may be obtained in the root of the small bowel mesentery by isolating individual jejunal and ileal branches to allow a more comprehensive thromboembolectomy. Following the restoration of SMA flow, an assessment of intestinal viability must be made, and nonviable bowel must be resected. Several methods have been described to evaluate the viability of the intestine, which include intraoperative IV fluorescein injection and inspection with a Wood's lamp, and Doppler assessment of antimesenteric intestinal arterial pulsations. A second-look procedure should be considered in many patients, and is performed 24 to 48 hours following embolectomy. The goal of the procedure is reassessment of the extent of bowel viability, which may not be obvious immediately following the initial embolectomy. If nonviable intestine is evident in the second-look procedure, additional bowel resections should be performed at that time.

ACUTE THROMBOTIC MESENTERIC ISCHEMIA

Thrombotic mesenteric ischemia usually involves a severely atherosclerotic vessel, typically the proximal CA and SMA. Therefore, these patients require a reconstructive procedure to the SMA to bypass the proximal occlusive lesion and restore adequate mesenteric flow. The saphenous vein is the graft material of choice, and prosthetic materials should be avoided in patients with nonviable bowel, due to the risk of bacterial contamination if resection of necrotic intestine is performed. The bypass graft may originate from either the aorta or iliac artery. Advantages from using the supraceliac infradiaphragmatic aorta as opposed to the infrarenal aorta as the inflow vessel include a more smooth graft configuration with less chance of kinking, and the absence of atherosclerotic disease in the supraceliac aortic segment. Exposure of the supraceliac aorta is technically more challenging and time consuming than that of the iliac artery, which, unless calcified, is an appropriate inflow. Patency rates are similar regardless of inflow vessel choice.⁷⁶

CHRONIC MESENTERIC ISCHEMIA

The therapeutic goal in patients with chronic mesenteric ischemia is to revascularize mesenteric circulation and prevent the development of bowel infarction. Mesenteric occlusive disease can be treated successfully by either transaortic endarterectomy or mesenteric artery bypass. Transaortic endarterectomy is indicated for ostial lesions of patent CA and SMA. A left medial rotation is performed, and the aorta and the mesenteric branches are exposed. A lateral aortotomy is performed, encompassing both the CA and SMA orifices. The visceral arteries must be adequately mobilized so that the termination site of endarterectomy can be visualized. Otherwise, an intimal flap may develop, which can lead to early thrombosis or distal embolization.

For occlusive lesions located 1 to 2 cm distal to the mesenteric origin, mesenteric artery bypass should be performed. Multiple mesenteric arteries are typically involved in chronic mesenteric ischemia, and both the CA and SMA should be revascularized whenever possible. In general, bypass grafting may be performed either antegrade from the supraceliac aorta or retrograde from either the infrarenal aorta or iliac artery. Both autogenous saphenous vein grafts and prosthetic grafts have been used with satisfactory and equivalent success. An antegrade bypass also can be performed using a small-caliber bifurcated graft from the supraceliac aorta to both the CA and SMA, which yields an excellent long-term result.⁷⁶

CELIAC ARTERY COMPRESSION SYNDROME

The decision to intervene in patients with CA compression syndrome should be based on both an appropriate symptom complex and the finding of CA compression in the absence of other findings to explain the symptoms. The treatment goal is to release the ligamentous structure that compresses the proximal CA and to correct any persistent stricture by bypass grafting. The patient should be cautioned that relief of the celiac compression cannot be guaranteed to relieve the symptoms. In a number of reports on endovascular management of chronic mesenteric ischemia, the presence of CA compression syndrome has been identified as a major factor of technical failure and recurrence. Therefore, angioplasty and stenting should not be undertaken if extrinsic compression of the CA by the median arcuate ligament is suspected based on preoperative imaging studies. Open surgical treatment should be performed instead.^{77,78}

Endovascular Treatment

CHRONIC MESENTERIC ISCHEMIA

Endovascular treatment of mesenteric artery stenosis or short segment occlusion by balloon dilatation or stent placement represents a less invasive therapeutic alternative to open surgical intervention, particularly in patients whose medical comorbidities place them in a high operative risk category. Endovascular therapy is also suited to patients with recurrent

disease or anastomotic stenosis following previous open mesenteric revascularization. Prophylactic mesenteric revascularization is rarely performed in the asymptomatic patient undergoing an aortic procedure for other indications.⁷⁹ However, the natural history of untreated chronic mesenteric ischemia may justify revascularization in some minimally symptomatic or asymptomatic patients if the operative risks are acceptable, because the first clinical presentation may be acute intestinal ischemia in as many as 50% of the patients, with a mortality rate that ranges from 15 to 70%.⁷⁹ This is particularly true when the SMA is involved. Mesenteric angioplasty and stenting is particularly suitable for this patient subgroup given its low morbidity and mortality. Because of the limited experience with stent use in mesenteric vessels, appropriate indications for primary stent placement have not been clearly defined. Guidelines generally include calcified ostial stenoses, high-grade eccentric stenoses, chronic occlusions, and significant residual stenosis greater than 30% or the presence of dissection after angioplasty. Restenosis after PTA is also an indication for stent placement.⁸⁰

ACUTE MESENTERIC ISCHEMIA

Catheter-directed thrombolytic therapy is a potentially useful treatment modality for acute mesenteric ischemia, which can be initiated with intra-arterial delivery of thrombolytic agent into the mesenteric thrombus at the time of diagnostic angiography. Various thrombolytic medications, including urokinase (Abbokinase, Abbott Laboratory, North Chicago, Ill) or recombinant tissue plasminogen activator (Activase, Genentech, South San Francisco, Calif), have been reported to be successful in a small series of case reports. Catheter-directed thrombolytic therapy has a higher probability of restoring mesenteric blood flow success when performed within 12 hours of symptom onset. Successful resolution of a mesenteric thrombus will facilitate the identification of the underlying mesenteric occlusive disease process. As a result, subsequent operative mesenteric revascularization or mesenteric balloon angioplasty and stenting may be performed electively to correct the mesenteric stenosis. There are two main drawbacks with regard to thrombolytic therapy in mesenteric ischemia. Percutaneous, catheter-directed thrombolysis (CDT) does not allow the possibility to inspect the potentially ischemic intestine following restoration of the mesenteric flow. Additionally, a prolonged period of time may be necessary to achieve successful CDT, due in part to serial angiographic surveillance to document thrombus resolution. An incomplete or unsuccessful thrombolysis may lead to delayed operative revascularization, which may further necessitate bowel resection for irreversible intestinal necrosis. Therefore, catheter-directed thrombolytic therapy for acute mesenteric ischemia should only be considered in selected patients under a closely scrutinized clinical protocol.

NONOCCLUSIVE MESENTERIC ISCHEMIA

The treatment of nonocclusive mesenteric ischemia is primarily pharmacologic with selective mesenteric arterial catheterization followed by infusion of vasodilatory agents such as tolazoline or papaverine. Once the diagnosis is made on the mesenteric arteriography (see Fig. 23-42), intra-arterial papaverine is given at a dose of 30 to 60 mg/h. This must be coupled with the cessation of other vasoconstricting agents. Concomitant IV heparin should be administered to prevent thrombosis in the cannulated vessels. Treatment strategy thereafter is dependent on the patient's clinical response to the vasodilator therapy. If abdominal symptoms improve, mesenteric arteriography should be repeated to document the resolution of vasospasm. The patient's hemodynamic status must be carefully monitored during papaverine infusion, as significant hypotension can develop in the event that the infusion catheter migrates into the aorta, which can lead to systemic circulation of papaverine. Surgical exploration is indicated if the patient develops signs of continued bowel ischemia or infarction as evidenced by rebound tenderness or involuntary guarding. In these circumstances, papaverine infusion should be continued intraoperatively and postoperatively. The OR should be kept as warm as possible, and warm irrigation fluid and laparotomy pads should be used to prevent further intestinal vasoconstriction during exploration.

TECHNIQUES OF ENDOVASCULAR INTERVENTIONS

To perform endovascular mesenteric revascularization, intraluminal access is performed via a femoral or brachial artery approach. Once an introducer sheath is placed in the femoral artery, an anteroposterior and lateral aortogram just below the level of the diaphragm is obtained with a pigtail catheter to identify the origin of the CA and SMA. Initial catheterization of the mesenteric artery can be performed using a variety of selective angled catheters, which include the RDC, Cobra-2, Simmons I (Boston Scientific/Meditech, Natick, Mass), or SOS Omni catheter (AngioDynamics, Queensbury, NY). Once the mesenteric artery is cannulated, systemic heparin (5000 IU) is administered IV. A selective mesenteric angiogram is then performed to identify the diseased segment, which is followed by the placement of a 0.035-in or less traumatic 0.014- to 0.018-in guidewire to cross the stenotic lesion. Once the guidewire is placed across the stenosis, the catheter is carefully advanced over the guidewire across the lesion. In the event that the mesenteric artery is severely angulated as it arises from the aorta, a second stiffer guidewire (Amplatz or Rosen Guidewire, Boston Scientific) may be exchanged through the catheter to facilitate the placement of a 6F guiding sheath (Pinnacle, Boston Scientific).

With the image intensifier angled in a lateral position to fully visualize the proximal mesenteric segment, a balloon angioplasty is advanced over the guidewire through the guiding sheath and positioned across the stenosis. The balloon diameter should be chosen based on the vessel size of the adjacent normal mesenteric vessel. Once balloon angioplasty is completed, a postangioplasty angiogram is necessary to document the procedural result. Radiographic evidence of either residual stenosis or mesenteric artery dissection constitutes suboptimal angioplasty results that warrant mesenteric stent placement. Moreover, atherosclerotic involvement of the proximal mesenteric artery or vessel orifice should be treated with a balloon-expandable stent placement. These stents can be placed over a low profile 0.014- or 0.018-in guidewire system. It is preferable to deliver the balloon-mounted stent through a guiding sheath, which is positioned just proximal to the mesenteric orifice while the balloon-mounted stent is advanced across the stenosis. The stent is next deployed by expanding the angioplasty balloon to its designated inflation pressure. The balloon is then deflated and carefully withdrawn through the guiding sheath.

Completion angiogram is performed by hand injecting a small volume of contrast through the guiding sheath. It is critical to maintain the guidewire access until a satisfactory completion angiogram is obtained. If the completion angiogram reveals suboptimal radiographic results, such as residual stenosis or dissection, additional catheter-based intervention can be performed through the same guidewire. These interventions may include repeat balloon angioplasty for residual stenosis or additional stent placement for mesenteric artery dissection. During the procedure, intra-arterial infusion of papaverine or nitroglycerine can be used to decrease vasospasm. Administration of antiplatelet agents is also recommended, for at least 6 months or even indefinitely if other risk factors of cardiovascular disease are present.

COMPLICATIONS OF ENDOVASCULAR TREATMENT

Complications are not common and rarely become life threatening. These include access site thrombosis, hematomas, and infection. Dissection can occur during PTA and is managed with placement of a stent. Balloon-mounted stents are preferred over the self-expanding ones because of the higher radial force and the more precise placement. Distal embolization has also been reported but it never resulted in acute intestinal ischemia, likely due to the rich network of collaterals already developed.⁸¹

Clinical Results of Interventions for Mesenteric Ischemia

The first successful percutaneous angioplasty of the SMA was reported in 1980. Since 1995, 11 series and multiple scattered case reports have reported results from endovascular management of mesenteric occlusive disease.^{76,81} In a literature review, Aburahma and associates showed that endovascular intervention had an overall technical success rate of 91%, early and late pain relief of 84 and 71%, respectively, and 30-day morbidity and mortality rates of 16.4 and 4.3, respectively. The average patency was 63% during an average 26-month follow-up.⁸¹

In a recent review of the literature from published series since 1995, restenosis was developed in 22% of patients during 24.5 months of average follow-up.⁷⁶ The long-term clinical relief without reintervention was 82%. Among the patients that had a technical failure, 15 were ultimately diagnosed with median arcuate ligament syndrome and underwent successful surgical treatment, an observation that emphasizes the need for careful patient selection. Interestingly, the addition of selective stenting after PTA that was started in 1998 slightly increases the technical success rate, but is not correlated with any substantial overall clinical benefit or improved, long-term patency rates.

In contrast to the endovascular treatment, open surgical techniques have achieved an immediate clinical success that approaches 100%, a surgical mortality rate from 0 to 17%, and an operative morbidity rate that ranges from 19 to 54% in a number of different series.^{76,78,79} AbuRahma and colleagues reported their experience of endovascular interventions of 22 patients with symptomatic mesenteric ischemia due to either SMA or CA stenosis.⁸¹ They noted excellent initial technical and clinical success rates, which were 96% (23/24) and 95% (21/22), respectively, with no perioperative mortality or major morbidity. During a mean follow-up of 26 months (range 1 to 54 months), the primary late clinical success rate was 61% and freedom from recurrent stenosis was 30%. The freedom from recurrent stenosis rates at 1, 2, 3, and 4 years were 65%, 47%, 39%, and 13%, respectively. The authors concluded that mesenteric stenting, which provides excellent early results, is associated with a relatively high incidence of late restenosis.⁸¹

Several studies have attempted to compare the endovascular to standard open surgical approach.^{83,84} The results of the open surgery appear to be more durable, but tend to be associated with higher morbidity and mortality rates and an overall longer hospital stay. In one study that compared the clinical outcome of open revascularization with percutaneous stenting for patients with chronic mesenteric ischemia, 28 patients underwent endovascular treatment and 85 patients underwent open mesenteric bypass grafting.⁸⁴ Both patient cohorts had similar baseline comorbidities and symptom duration, so there was no difference in early in-hospital complication or mortality rates. Moreover, both groups had similar 3-year cumulative recurrent stenosis and mortality rates. However, patients treated with mesenteric stenting had a significantly higher incidence of recurrent symptoms. The authors concluded that operative mesenteric revascularization should be offered to patients with low surgical risk.⁸⁴

Based on the above results one could argue that mesenteric angioplasty and stenting demonstrate an inferior technical and clinical success rate. Long-term patency rates appear to also be superior with the open technique. There is a general consensus, however, that the endovascular approach is associated with lower morbidity and mortality rates and is therefore more suitable for high-risk patients. One should also keep in mind that practices representing standard of care for stent placement today were absent in the early era of endovascular experience. These include perioperative heparinization and short-term antiplatelet therapy, use of stents with higher radial force, routine use of postoperative surveillance with arterial duplex and early reintervention to prevent a high-grade stenosis to progress to occlusion, and placement of drug-eluting stents (DES).

RENAL ARTERY DISEASE

Obstructive lesions of the renal artery can produce hypertension, resulting in a condition known as *renovascular hypertension*, which is the most common form of hypertension amenable to therapeutic intervention, and affects 5 to 10% of all hypertensive patients in the United States.⁸⁵ Patients with renovascular hypertension are at an increased risk for irreversible end-organ dysfunction, including permanent kidney damage, if inadequate pharmacologic therapies are used to control the BP. The majority of patients with renal artery obstructive disease have vascular lesions of either atherosclerotic disease or fibrodysplasia involving the renal arteries. The proximal portion of the renal artery represents the most common location for the development of atherosclerotic disease. It is well established that renal artery intervention, either by surgical or endovascular revascularization, provides an effective treatment for controlling renovascular hypertension as well as preserving renal function. The decision for intervention is complex, and needs to take into consideration a variety of anatomic, physiologic, and clinical features, unique for the individual patient.

Etiology

Approximately 80% of all renal artery occlusive lesions are caused by atherosclerosis, which typically involves a short segment of the renal artery ostia, and represents spillover disease from a severely atheromatous aorta (Fig. 23-43).⁸⁶ Atherosclerotic lesions are bilateral in two thirds of patients. Individuals with this disease commonly present during the sixth decade of life. Men are affected twice as frequently as women. Atherosclerotic lesions in other territories such as the coronary, mesenteric, cerebrovascular, and peripheral arterial circulation are common. When a unilateral lesion is present, the disease process equally affects the right and left renal artery.⁸⁷

Occlusive disease of the renal artery typically involves the renal ostium (*arrow*) as a spillover plaque extension from aortic atherosclerosis.

The second most common cause of renal artery stenosis is FMD, which accounts for 20% of cases, and is most frequently

encountered in young, often multiparous women.⁸⁸ FMD of the renal artery represents a heterogeneous group of lesions that can produce histopathologic changes in the intima, media, or adventitia. The most common variety consists of medial fibroplasia, in which thickened fibromuscular ridges alternate with attenuated media producing the classic angiographic "string of beads" appearance (Figs. 23-44 and 23-45). The cause of medial fibroplasia remains unclear. Most common theories involve a modification of arterial smooth muscle cells in response to estrogenic stimuli during the reproductive years, unusual traction forces on affected vessels, and mural ischemia from impairment of vasa vasorum blood flow.⁸⁸ Fibromuscular hyperplasia usually affects the distal two thirds of the main renal artery, and the right renal artery is affected more frequently than the left. Other less common causes of renal artery stenosis include renal artery aneurysm (compressing the adjacent normal renal artery), arteriovenous malformations, neurofibromatosis, renal artery dissections, renal artery trauma, Takayasu's arteritis, and renal arteriovenous fistula.

Magnetic resonance angiography of the abdominal aorta revealed the presence of a left renal artery fibromuscular dysplasia (arrows).

Clinical Manifestations

Renovascular hypertension is the most common sequelae of renal artery occlusive disease. Its prevalence varies from 2% in patients with diastolic BP >100 mmHg, to almost 30% in those with diastolic BP over 125 mmHg.⁸⁶ Clinical features that may indicate the presence of renovascular hypertension include the following: (a) systolic and diastolic upper abdominal bruits, (b) diastolic hypertension of >115 mmHg, (c) rapid onset of hypertension after the age of 50 years, (d) a sudden worsening of mild to moderate essential hypertension, (e) hypertension that is difficult to control with three or more antihypertensives, (f) development of renal insufficiency after ACE inhibitors, and (g) development of hypertension during childhood.

All patients with significant hypertension, especially elevated diastolic BP, must be considered as suspect for renovascular disease. Young adults with hypertension have a great deal to gain by avoiding lifelong treatment if renovascular hypertension is diagnosed and corrected. Appropriate diagnostic studies and intervention must be timely instituted to detect the possibility of renovascular hypertension in patients with primary hypertension who present for clinical evaluation.

Diagnostic Evaluation

The diagnostic requisites for renovascular hypertension include both hypertension and renal artery stenosis. Impairment of the renal function may coexist, although the occurrence of renal insufficiency before the development of hypertension is uncommon. Nearly all diagnostic studies for renovascular hypertension evaluate either the anatomic stenosis or renal parenchymal dysfunction attributed to the stenosis. This section provides an overview of the strengths and limitations of the most common tests used in the diagnostic evaluation of the patient with suspected renovascular hypertension before intervention.

Captopril renal scanning is a functional study that assesses renal perfusion before and after administration of the ACE inhibitor captopril. Captopril inhibits the secretion of angiotensin II. Through this mechanism it reduces the efferent arteriole vasoconstriction and, as a result, the glomerular filtration rate (GFR). The test consists of a baseline renal scan, and a second renal scan after captopril administration. Positive result indicates that captopril administration (a) increases the time to peak activity to more than 11 minutes or (b) the GFR ratio between sides increases to greater than 1.5:1 compared to a normal baseline scan. Significant parenchymal disease limits the reliability of this study.

Renal artery duplex ultrasonography is a noninvasive test of assessing renal artery stenosis both by visualization of the vessel and measurement of the effect of stenosis on blood flow velocity and waveforms. The presence of a severe renal artery stenosis correlates with peak systolic velocities of >180 cm/s and the ratio of these velocities to those in the aorta of >3.5 (Table 23-11). Renal artery duplex is a technically demanding examination, requiring a substantial amount of operator expertise. In addition, the presence of bowel gas and obesity make the exam difficult to perform and interpret. However, in experienced hands and with appropriate patient selection, it can be a high-yield examination and is typically the initial screening test for patients with suspected renal artery occlusive disease.

Table 23-11 Renal Duplex Diagnostic Criteria		
Renal Artery Diameter Reduction	Renal Artery PSV	RAR
Normal	<180 cm/s	<3.5
$<60\%$	≥ 180 cm/s	<3.5
$\geq 60\%$	≥ 180 cm/s	≥ 3.5
Occlusion	No signal	No signal

PSV = peak systolic velocity; RAR = renal-to-aortic ratio.

Selective catheterization of the renal vein via a femoral vein approach for assessing renin activity is a more invasive test of detecting the physiologic sequelae of renal artery stenosis. If unilateral disease is present the affected kidney should secrete high levels of renin while the contralateral kidney should have low renin production. A ratio between the two kidneys, or the renal vein renin ratio, of >1.5 is indicative of functionally important renovascular hypertension, and it also predicts a favorable response from renovascular revascularization. Because this study assesses the ratio between the two kidneys, it is not useful in patients with bilateral disease because both kidneys may secrete abnormally elevated renin levels.

The renal:systemic renin index (RSRI) is calculated by subtracting systemic renin activity from individual renal vein renin activity and dividing the remainder by systemic renin activity. This value represents the contribution of each kidney to renin production. In the absence of renal artery stenosis, the renal vein renin activity from each kidney is typically 24% or 0.24 higher than the systemic level. As the result, the total of both kidneys' renin activity is usually 48% greater than the systemic activity, a value that represents a steady state of renal renin activity. The RSRI of the affected kidney in patients with renovascular hypertension is >0.24 . In the case of unilateral renal artery stenosis with normal contralateral kidney, the increase in ipsilateral renin release is normally balanced by suppression of the contralateral kidney renin production, which results in a drop in its RSRI to <0.24 . Bilateral renal artery disease may negate the contralateral compensatory response, and the autonomous release of renin from both diseased kidneys may result in the sum of the individual RSRI's being considerably >0.48 . The prognostic value of RSRI remains limited in that approximately 10% of patients with favorable clinical response following renovascular revascularization do not exhibit contralateral renin suppression. As a result, the use of RSRI must be applied with caution in the management of patients with renovascular hypertension.

MRA with IV gadolinium contrast enhancement has been increasingly used for renal artery imaging because of its ability to provide high-resolution images (Figs. 23-46 and 23-47) while using a minimally nephrotoxic agent. Flow void may be inaccurately interpreted as occlusion or stenosis in MRA. Therefore, unless the quality of the image analysis software is superior, MRA should be interpreted with caution and used in conjunction with other modalities before making plans for operative or endovascular treatment.

Magnetic resonance angiography of the abdominal aorta revealed bilateral ostial renal artery stenosis (*arrows*).

DSA remains the gold standard to assess renal artery occlusive disease. A flush aortogram is performed first so that any accessory renal arteries can be detected and the origins of all the renal arteries are adequately displayed. The presence of collateral vessels circumventing a renal artery stenosis strongly supports the hemodynamic importance of the stenosis. A pressure gradient of 10 mmHg or greater is necessary for collateral vessel development, which also is associated with activation of the renin-angiotensin cascade.

Treatment Indications

The therapeutic goals in patients with renovascular disease include: (a) improved BP control to prevent end-organ damage on systems such as the cerebral, coronary, pulmonary, and peripheral circulations; and (b) preservation and possibly improvement of the renal function (Table 23-12).

Table 23-12 Indications for Renal Artery Revascularization

Angiography criteria

- Fibromuscular dysplasia lesion
- Pressure gradient >20 mmHg
- Affected/unaffected kidney renin ratio >1.5:1

Clinical criteria

- Refractory or rapidly progressive hypertension

• Hypertension associated with flash pulmonary edema without coronary artery disease
• Rapidly progressive deterioration in renal function
• Intolerance to antihypertensive medications
• Chronic renal insufficiency related to bilateral renal artery occlusive disease or stenosis to a solitary functioning kidney
• Dialysis-dependent renal failure in a patient with renal artery stenosis but without another definite cause of end-stage renal disease
• Recurrent congestive heart failure or flash pulmonary edema not attributable to active coronary ischemia

The indications for endovascular treatment for renal artery occlusive disease include 70% or greater stenosis of one or both renal arteries and at least one of the following clinical criteria:

- Inability to adequately control hypertension despite appropriate antihypertensive regimen.
- Chronic renal insufficiency related to bilateral renal artery occlusive disease or stenosis to a solitary functioning kidney.
- Dialysis-dependent renal failure in a patient with renal artery stenosis but without another definite cause of end-stage renal disease.
- Recurrent congestive heart failure or flash pulmonary edema not attributable to active coronary ischemia.

Before 1990, the most common treatment modality in patients with renal artery occlusive disease was surgical revascularization, with either renal artery bypass grafting or renal artery endarterectomy. The advancement of endovascular therapy in the past decade has led to various minimally invasive treatment strategies such as renal artery balloon angioplasty or stenting to control hypertension or to preserve renal function.

Surgical Reconstruction

The typical approach for surgical renal artery revascularization involves a midline xiphoid-to-pubis incision. The posterior peritoneum is incised, and the duodenum is mobilized to the right, starting at the ligament of Treitz. The left renal hilum can be exposed by extending the retroperitoneal dissection to the left along the avascular plane along the inferior border of the pancreas. Mobilization of the left renal vein is essential in these cases and can be achieved by dividing the gonadal, ilio-lumbar, and adrenal veins. The proximal portion of the right renal artery can be exposed through the base of the mesentery by retraction of the left renal vein cephalad and the vena cava to the right. Accessing the most distal portion of the right renal artery requires a Kocher maneuver and duodenal mobilization. Another approach useful for treating bilateral renal artery lesions involves mobilization of the entire small bowel and the right colon, with a dissection that starts at the ligament of Treitz, and proceeds toward the cecum and then along the line of Todd in the right paracolic gutter. Simultaneous dissection along the inferior border of the pancreas provides additional visualization of the left renal artery. Finally, division of the diaphragmatic crura that encircle the suprarenal aorta may sometimes be necessary to achieve suprarenal clamping.

TYPES OF SURGICAL RECONSTRUCTION

Aortorenal bypass is the most frequently performed reconstruction of ostial occlusive renal artery disease. After proximal and distal control is obtained, an elliptical segment of the aorta is excised, and the proximal anastomosis is performed in end-to-side fashion. Autologous vein is the preferred conduit. If the vein is not suitable, then prosthetic material can be used. An end-to-end anastomosis is then performed between the conduit of choice and the renal artery using either a 6-0 or 7-0 polypropylene suture. The length of the arteriotomy needs to be at least three times the diameter of the renal artery to

prevent anastomotic restenosis. If the surgeon plans to perform a side-to-side anastomosis between the conduit and the renal artery, then it is performed first, and the aortic anastomosis follows.

Endarterectomy, either transrenal or transaortic, is an alternative to bypass for short ostial lesions, or in patients with multiple renal arteries. The transrenal endarterectomy is performed with a transverse longitudinal incision on the aorta that extends into the diseased renal artery. After the plaque removal, the arteriotomy is closed with a prosthetic patch.

Transaortic endarterectomy is well suited for patients with multiple renal arteries and short ostial lesions. The aorta is opened longitudinally and aortic sleeve endarterectomy is performed, followed by eversion endarterectomy of the renal arteries. Adequate mobilization of the renal arteries is essential for a safe and complete endarterectomy.

Hepatorenal and splenorenal bypass are alternative options of revascularizations for patients who might not tolerate aortic clamping, or for those with calcified aorta that precludes adequate control. For hepatorenal bypass, a right subcostal incision is used, and the hepatic artery is exposed with an incision in the lesser omentum. A Kocher maneuver is performed, the right renal vein is identified and mobilized, and the right renal artery is identified and controlled posteriorly to the vein. The greater saphenous vein is the conduit of choice. The anastomosis is performed end to side with the common hepatic artery, and end to end with the renal artery anterior to the inferior vena cava. The splenorenal bypass is performed via a left subcostal incision. The splenic artery is mobilized from the lesser sac, brought through a retropancreatic plane, and anastomosed end to end to the renal artery.

Reimplantation of the renal artery is an attractive option of reconstruction in children, or in adults with ostial lesions. A redundant renal artery is a prerequisite for the procedure. After mobilization, the artery is transected and spatulated, eversion endarterectomy is performed, if necessary, and an end-to-side anastomosis with the aorta is created.

Clinical Results of Surgical Repair

Results reflect the need for performance of renal artery bypass in high-volume and experienced centers. In a review from a large tertiary center, 92% of the patients with non-atherosclerotic vascular disease had good response to hypertension, but only 43% were completely cured and were taken off antihypertensives.⁸⁹ Patients younger than 45 years old fare better with a cure rate of 68% and an improvement rate of 32%. In patients with atherosclerotic renal artery disease, the cure rate was even smaller (12%), and the overall response to hypertension rate was 85%. The operative mortality was 3.1% and 0% in the atherosclerotic and non-atherosclerotic groups, respectively.

Renal function improvement occurs within the first week of the operation in approximately two thirds of the patients. A progressive decrease in the GFR is seen after this initial improvement, but the rate of decrease is less compared to the group of patients who did not respond at all to operative intervention. Up to three fourths of patients were permanently removed from dialysis in a large series.⁹⁰ Favorable response of renal function to revascularization improves overall survival.

Endovascular Treatment

Endovascular treatment of renal artery occlusive disease was first introduced by Grüntzig who successfully dilated a renal artery stenosis using a balloon catheter technique. This technique requires passage of a guidewire under fluoroscopic control typically from a femoral artery approach to across the stenosis in the renal artery. A balloon-dilating catheter is passed over the guidewire and positioned within the area of stenosis and inflated to produce a controlled disruption of the arterial wall. Alternatively, a balloon-mounted, expandable stent can be used to primarily dilate the renal artery stenosis. Completion angiography usually is performed to assess the immediate results. The technical aspect of an endovascular renal artery

revascularization is discussed in Techniques of Renal Artery Angioplasty and Stenting below.

TECHNIQUES OF RENAL ARTERY ANGIOPLASTY AND STENTING

Access to the renal artery for endovascular intervention is typically performed via a femoral artery approach, although a brachial artery approach can be considered in the event of severe aortoiliac occlusive disease, aortoiliac aneurysm, or severe caudal renal artery angulation. Once an introducer sheath is placed in the femoral artery, an aortogram is performed with a pigtail catheter placed in the suprarenal aorta. Additional oblique views are frequently necessary to more precisely visualize the orifice of the stenosed renal artery and thoroughly assess the presence of accessory renal arteries. Noniodinated contrast agents such as carbon dioxide and gadolinium can be used in endovascular renal intervention in patients with renal dysfunction or history of allergic reaction.

After systemic heparinization, catheterization of the renal artery can be performed using a variety of selective angled catheters including the RDC, Cobra-2, Simmons I, or SOS Omni catheter (Boston Scientific/Meditech, Natick, Mass; Cook, Bloomington, Ind; Medtronic, Santa Rosa, Calif, Cordis, Warren, NJ; or AngioDynamics, Queensbury, NY). A selective renal angiogram is then performed to confirm position, and the lesion is crossed with either a 0.035-in or a 0.018- to 0.014-in guidewire. It is important to maintain the distal wire position without movement in the tertiary renal branches while guiding sheath placement to reduce the possibility of parenchymal perforation and spasm. A guiding sheath or a guiding catheter is then advanced at the orifice of the renal artery to provide a secure access for balloon and stent deployment.

Balloon angioplasty is performed with a balloon sized to the diameter of the normal renal artery adjacent to the stenosis. Choosing a balloon with a 4-mm diameter is a reasonable first choice. The luminal diameter of the renal artery can be further assessed by comparing it to the fully inflated balloon. Such a comparison may provide a reference guide to determine whether renal artery dilatation with a larger diameter angioplasty balloon is necessary.

Once balloon angioplasty of the renal artery is completed, an angiogram is performed to document the procedural result. Radiographic evidence of either residual stenosis or renal artery dissection constitutes suboptimal angioplasty results, which warrants an immediate renal artery stent placement. Moreover, atherosclerotic involvement of the very proximal renal artery that involves the vessel orifice typically requires stent placement. A balloon-expandable stent is typically used, and is positioned in such a way so that it protrudes into the aorta by 1 to 2 mm. The size of the stent is determined by the size of the renal artery, taking into account a desirable 10 to 20% oversizing. After the stent deployment, the angiogram is repeated and, upon a satisfactory result, the devices are withdrawn. It is critical to maintain the guidewire access across the renal lesion until satisfactory completion angiogram is obtained. Spasm of the branches of the renal artery will usually respond to nitroglycerin 100 to 200 mcg administered through the guiding sheath directly into the renal artery.

While endovascular therapy of renal artery occlusive disease is considerably less invasive than conventional renal artery bypass operation, complications relating to this treatment modality can occur. In a study in which Guzman and colleagues compared the complications following renal artery angioplasty and surgical revascularization, the authors noted that major complication rates following endovascular and surgical treatment were 17% and 31%, respectively. In contrast, significantly greater minor complications were associated with the endovascular cohort, which was 48%, in contrast to 7% in the surgical group.⁹¹ In a prospective randomized study that compared the clinical outcome of renal artery balloon angioplasty vs. stenting for renal ostial atherosclerotic lesion, comparable complications rates were found in the two groups, which were 39% and 43%, respectively. However, the incidence of restenosis rate at 6 months was significantly higher in the balloon angioplasty cohort than the stenting group, which was 48% in contrast to 14% at 6 months. This study underscores the

clinical superiority of renal stenting compared to renal balloon angioplasty alone in patients with ostial stenosis.

Deterioration in renal function, albeit transient, is a common complication following endovascular renal artery intervention. This is most likely the combined result of the use of iodinated contrast, and the occurrence of renal parenchymal embolism due to wire and catheter manipulation. In most cases, this is a temporary problem, as supportive care with adequate fluid hydration is sufficient to reverse the renal dysfunction. However, transient hemodialysis may become necessary in approximately 1% of patients. Other complications include vascular access complications (bleeding, hematoma, femoral nerve injury, arteriovenous fistula, and pseudoaneurysm), target vessel dissection, perinephric hematoma, early postoperative renal artery thrombosis, and extremity atheroembolism from thrombus in the aorta or the iliac arteries.

Clinical Results of Endovascular Interventions

PERCUTANEOUS TRANSLUMINAL BALLOON ANGIOPLASTY

FMD of the renal artery is the most common treatment indication for percutaneous, transluminal balloon angioplasty. Patients with symptomatic FM, such as hypertension or renal insufficiency, usually respond well to renal artery balloon angioplasty alone.⁹³ In contrast, balloon angioplasty generally is not an effective treatment for patients with renal artery stenosis or proximal occlusive disease of the renal artery, due to the high incidence of restenosis with balloon angioplasty alone. In the latter group of patients, primary stent placement is the preferred endovascular treatment. The long-term benefit of renal artery balloon angioplasty in patients with FMD was reported by Surowiec and colleagues.⁹³ They followed 14 patients who underwent 19 interventions on 18 renal artery segments. The technical success rate of balloon angioplasty for FMD was 95%. Primary patency rates were 81%, 69%, 69%, and 69% at 2, 4, 6, and 8 years, respectively. Assisted primary patency rates were 87%, 87%, 87%, and 87% at 2, 4, 6, and 8 years, respectively. The restenosis rate was 25% at 8 years. Clinical benefit, as defined by either improved or cured hypertension, was found in 79% of patients overall, with two thirds of patients having maintained this benefit at 8 years. The authors concluded that balloon angioplasty is highly effective in symptomatic FMD with excellent durable functional benefits.⁹³

The utility of balloon angioplasty alone in the treatment of renovascular hypertension appears to be limited. Van Jaarsveld and associates performed a prospective study in which patients with renal artery stenosis were randomized to either drug therapy or balloon angioplasty treatment.⁹⁴ A total of 106 patients with 50% diameter stenosis or greater plus hypertension or renal insufficiency were randomized in the study. At 3 months, there was no difference in the degree to which BP was controlled between the two groups. However, the degree and dose of antihypertensive medications was slightly lowered in the balloon angioplasty group. The above advantage of the angioplasty group completely disappeared at 12 months, making the authors conclude that, in the treatment of patients with hypertension and renal artery stenosis, percutaneous transluminal balloon angioplasty alone offers minimal advantage over antihypertensive drug therapy.

RENAL ARTERY STENTING

Endovascular stent placement is the treatment of choice for patients with symptomatic or high-grade renal artery occlusive disease (Fig. 23-48). This is due in part to the high incidence of restenosis with balloon angioplasty alone, particularly in the setting of ostial stenosis. Renal artery stenting is also indicated for renal artery dissection caused by balloon angioplasty or other catheter-based interventions. Numerous studies have clearly demonstrated the clinical efficacy of renal artery stenting when compared to balloon angioplasty alone in patients with high-grade renal artery stenosis.

Renal artery stenting. **A.** Focal lesion in the renal artery (*arrow*). **B.** Poststenting angiogram reveals a satisfactory result following a renal artery stenting placement (*arrow*).

White and colleagues conducted a study to evaluate the role of renal artery stenting in patients with poorly controlled hypertension and renal artery lesions that did not respond well to balloon angioplasty alone.⁹⁵ The technical success of the procedure was 99%. The mean BP values were $173 \pm 25/88 \pm 17$ mmHg before stent implantation and $146 \pm 20/77 \pm 12$ mmHg 6 months after renal artery stenting ($P < .01$). Angiographic follow-up with 67 patients (mean 8.7 ± 5 months) demonstrated restenosis, as defined by 50% or greater luminal narrowing, occurred in 15 patients (19%). The study concluded that renal artery stenting is a highly effective treatment for renovascular hypertension, with a low angiographic restenosis rate. In another similar study, Blum and colleagues prospectively performed renal artery stenting in 68 patients (74 lesions) with ostial renal artery stenosis and suboptimal balloon angioplasty.⁹⁶ Patients were followed for a mean of 27 months with measurements of BP and serum creatinine (Scr), duplex sonography, and intra-arterial angiography. Five-year patency was 84.5% (mean follow-up was 27 months). Restenosis occurred in eight of 74 arteries (11%), but, after reintervention, the secondary, 5-year patency rate was 92.4%. BP was cured or improved in 78% of patients. The authors concluded that primary stent placement is an effective treatment for renal artery stenosis involving the ostium.

The clinical utility of renal artery stenting in renal function preservation was analyzed by several studies, which measured serial Scr levels to determine the response of renal function following endovascular intervention.⁹⁷ In a study reported by Harden and colleagues, who performed 33 renal artery stentings in 32 patients with renal insufficiency, they noted that renal function improved or stabilized in 22 patients (69%).⁹⁸ In a similar study, Watson and associates evaluated the effect of renal artery stenting on renal function by comparing the slopes of the regression lines derived from the reciprocal of Scr vs.

time.⁹⁷ With a total of 61 renal stentings performed in 33 patients, the authors found that after stent placement, the slopes of the reciprocal of the serum creatinine (1/Scr) were positive in 18 patients and less negative in seven patients. The study concludes that in patients with chronic renal insufficiency due to obstructive renal artery stenosis, renal artery stenting is effective in improving or stabilizing renal function.

The clinical outcome of several large clinical studies of renal artery stenting in the treatment of renovascular hypertension or chronic renal insufficiency is shown in Table 23-13.^{95,96,98-104} These studies uniformly demonstrated an excellent technical success rate with low incidence of restenosis or procedural-related complications. A similar analysis was reported by Leertouwer and colleagues who performed a meta-analysis of 14 studies comparing patients with renal arterial stent placement to those who underwent balloon angioplasty alone for renal arterial stenosis.¹⁰⁵ The study found that stent placement proved highly successful, with an initial technical success of 98%. The overall cure rate for hypertension was 20%, whereas hypertension was improved in 49%. Renal function improved in 30% and stabilized in 38% of patients. The restenosis rate at follow-up of 6 to 29 months was 17%. Renal stenting resulted in a higher technical success rate and a lower restenosis rate when compared to balloon angioplasty alone.

AORTOILIAC OCCLUSIVE DISEASE

The distal abdominal aorta and the iliac arteries are common sites affected by atherosclerosis. The symptoms and natural history of the atherosclerotic process affecting the aortoiliac arterial segment are influenced by the disease distribution and extent. Atherosclerotic plaques may cause clinical symptoms by restricting blood flow due to luminal obstruction or by embolizing atherosclerotic debris to the LE circulation. If the aortoiliac plaques reach sufficient mass that impinge on the arterial lumen, obstruction of blood flow to lower extremities occurs. Various risk factors exist that can lead to the development of aortoiliac occlusive disease. Recognition of these factors and understanding this disease entity will enable physicians to prescribe the appropriate treatment strategy that may alleviate symptoms and improve quality of life.

Diagnostic Evaluation

On clinical examination, patients often have weakened femoral pulses and a reduced ABI. Verification of iliac occlusive disease is usually made by color duplex scanning that reveals either a peak systolic velocity ratio of 2.5 or greater at the site of stenosis and/or a monophasic waveform. Noninvasive tests such as pulse volume recording (PVR) of the LE with estimation of the thigh-brachial pressure index may be suggestive of aortoiliac disease. MRA and multidetector CTA are increasingly being used to determine the extent and type of obstruction. DSA offers the interventionalist the benefit of making a diagnosis and the option of performing an endovascular treatment in a single session. Angiography provides important information regarding distal arterial runoff vessels as well as the patency of the profunda femoris artery (PFA). Presence of pelvic and groin collaterals is important in providing crucial collateral flow in maintaining lower limb viability. It must be emphasized, however, that patients should be subjected to angiography only if their symptoms warrant surgical intervention.

Differential Diagnosis

Degenerative hip or spine disease, lumbar disc herniation, spinal stenosis, diabetic neuropathy, and other neuromuscular problems can produce symptoms that may be mistaken for vascular claudication. Such cases can be distinguished from true claudication by the fact that the discomfort from neuromuscular problems often is relieved by sitting or lying down, as opposed to cessation of ambulation. In addition, complaints that are experienced upon standing suggest nonvascular causes. When confusion persists, the use of noninvasive vascular laboratory testing modalities, including treadmill exercise, can help establish the diagnosis.

Collateral Arterial Network

The principal collateral pathways in severe aortoiliac artery occlusive disease or chronic aortic occlusion that may provide blood flow distal to the aortoiliac lesion include: (a) the SMA to the distal IMA via its superior hemorrhoidal branch to the middle and inferior hemorrhoidals to the internal iliac artery (39%); (b) the lumbar arteries to the superior gluteal artery to the internal iliac system (37%); (c) the lumbar arteries to the lateral and deep circumflex arteries to the common femoral artery (CFA) (12%); and (d) Winslow's pathway from the subclavian to the superior epigastric artery to the inferior epigastric artery to the external iliac arteries at the groin (Fig. 23-49). In general, treatment indications for aortoiliac artery occlusive disease include disabling claudication, ischemic rest pain, nonhealing LE tissue wound, and LE microembolization that arise from aortoiliac lesions.

Pertinent collateral pathways are developed in the event of chronic severe aortoiliac occlusive disease. As illustrated in this multidetector computed tomography angiography, these collaterals include epigastric arteries (*large white arrows*), an enlarged inferior mesenteric artery (*white arrowhead*), and enlarged lumbar arteries (*black arrows*).

Disease Classification

Based on the atherosclerotic disease pattern, aortoiliac occlusive disease can be classified into three various types (Fig. 23-50). Type I aortoiliac disease, which occurs in 5 to 10% of patients, is confined to the distal abdominal aorta and common iliac vessels (Fig. 23-51). Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment, limb-threatening symptoms are rare in the absence of more distal disease (Fig. 23-52). This type of aortoiliac occlusive disease occurs in a relatively younger group of patients (aged in their mid-50s), compared with patients who have more femoropopliteal disease. Patients with a type I disease pattern have a lower incidence of hypertension and diabetes, but a significant frequency of abnormal blood lipid levels, particularly type IV hyperlipoproteinemia. Symptoms typically consist of bilateral thigh or buttock claudication and fatigue. Men report diminished penile tumescence and may have complete loss of erectile function. These symptoms in the absence of femoral pulses constitute Leriche's syndrome. Rest pain is unusual with isolated aortoiliac disease unless distal disease coexists. Occasionally patients report a prolonged history of thigh and buttock claudication that recently has become more severe. It is likely that this group has underlying aortoiliac disease that has progressed to acute occlusion of the terminal aorta. Others may present with "trash foot" that represents microembolization into the distal vascular bed (Fig. 23-53).

Fig. 23-50.

Aortoiliac disease can be classified into three types. Type I represents focal disease affecting the distal aorta and proximal common iliac artery. Type II represents diffuse aortoiliac disease above the inguinal ligament. Type III represents multisegment occlusive disease involving aortoiliac and infrainguinal arterial vessels.

Type I aortoiliac disease is confined to the distal abdominal aorta (*long arrow*) or proximal common iliac arteries. Due to the localized nature of this type of aortic obstruction and formation of collateral blood flow around the occluded segment (*short arrows*), limb-threatening symptoms are rare in the absence of more distal disease.

Atherosclerotic disease involving the aortoiliac segment can result in microembolization of the lower leg circulation, resulting in trash foot or digital gangrene of toes.

Type II aortoiliac disease represents a more diffuse atherosclerotic progression that involves predominately the abdominal aorta with disease extension into the CIA. This disease pattern affects approximately 25% of patients with aortoiliac occlusive disease. Type III aortoiliac occlusive disease, which affects approximately 65% of patients with aortoiliac occlusive disease, is widespread disease that is seen above and below the inguinal ligament (Fig. 23-54). Patients with "multilevel" disease are older, more commonly male (with a male-to-female ratio of 6:1), and much more likely to have diabetes, hypertension, and associated atherosclerotic disease involving cerebral, coronary, and visceral arteries. Progression of the occlusive process is more likely in these patients than in those with localized aortoiliac disease. For these reasons, most patients with a type III pattern tend to present with symptoms of advanced ischemia and require revascularization for limb salvage rather than for claudication. These patients have a decreased 10-year life expectancy when compared to patients with localized aortoiliac disease.

Fig. 23-54.

Type III aortoiliac occlusive disease is a multilevel disease pattern that affects the aortoiliac segment as well as infrainguinal femoropopliteal vessels. Most patients with this disease pattern tend to present with symptoms of advanced ischemia and require revascularization for limb salvage rather than for claudication.

The most commonly used classification system of iliac lesions has been set forth by the TASC II group with recommended treatment options. This lesion classification categorizes the extent of atherosclerosis and has suggested a therapeutic

approach based on this classification (Table 23-14 and Fig. 23-55).² According to this consensus document, endovascular therapy is the treatment of choice for type A lesions, and surgery is the treatment of choice for type D lesions. Endovascular treatment is the preferred treatment for type B lesions, and surgery is the preferred treatment for good-risk patients with type C lesions. In comparison to the 2000 TASC II document, the commission has not only made allowances for treatment of more extensive lesions, but also took into account the continuing evolution of endovascular technology and the skills of individual interventionalists when stating that the patient's comorbidities, fully informed patient preference, and the local operator's long-term success rates must be considered when making treatment decisions for type B and type C lesions.^{2,106}

Table 23-14 TASC II Classification of Aortoiliac Occlusive Lesions
Type A lesions
<ul style="list-style-type: none"> • Unilateral or bilateral stenoses of CIA • Unilateral or bilateral single short (≤ 3 cm) stenosis of EIA
Type B lesions
<ul style="list-style-type: none"> • Short (≤ 3 cm) stenosis of infrarenal aorta • Unilateral CIA occlusion • Single or multiple stenosis totaling 3–10 cm involving the EIA not extending into the CFA • Unilateral EIA occlusion not involving the origins of internal iliac or CFA
Type C lesions
<ul style="list-style-type: none"> • Bilateral CIA occlusions • Bilateral EIA stenoses 3–10 cm long not extending into the CFA • Unilateral EIA stenosis extending into the CFA • Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA • Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA
Type D lesions
<ul style="list-style-type: none"> • Infrarenal aortoiliac occlusion • Diffuse disease involving the aorta and both iliac arteries requiring treatment • Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA • Unilateral occlusions of both CIA and EIA • Bilateral occlusions of EIA • Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

AAA = abdominal aortic aneurysm; CFA = common femoral artery; CIA = common iliac artery; EIA = external iliac artery; TASC II = Trans-Atlantic Inter-Society Consensus.

Schematic depiction of Trans-Atlantic Inter-Society Consensus classification of aortoiliac occlusive lesions.

General Treatment Considerations

There is no effective medical therapy for the management of aortoiliac disease, but control of risk factors may help slow progression of atherosclerosis. Patients should have hypertension, hyperlipidemia, and diabetes mellitus controlled. They should be advised to stop smoking. Most patients are empirically placed on antiplatelet therapy. A graduated exercise program may improve walking efficiency, endothelial function, and metabolic adaptations in skeletal muscle, but, there is usually minimal improvement in patients with aortoiliac disease who are treated with these measures. Failure to respond to exercise and/or drug therapy should prompt consideration for limb revascularization. Patients with buttock claudication and reduced or absent femoral pulses who fail to respond to exercise and drug therapy should be considered for revascularization because they are less likely than patients with more distal lesions to improve without concomitant surgical or endovascular intervention.

Surgical Reconstruction of Aortoiliac Occlusive Disease

AORTOBIFEMORAL BYPASS

Surgical options for treatment of aortoiliac occlusive diseases consist of various configurations of aortobifemoral bypass (ABF) grafting, various types of extra-anatomic bypass grafts, and aortoiliac endarterectomy. The procedure performed is determined by several factors, including anatomic distribution of the disease, clinical condition of the patient, and personal preference of the surgeon.

In most cases, ABF is performed because patients usually have disease in both iliac systems. Although one side may be more severely affected than the other, progression does occur, and bilateral bypass does not complicate the procedure or add to the physiologic stress of the operation. ABF reliably relieves symptoms, has excellent long-term patency (approximately 70 to 75% at 10 years), and can be completed with a tolerable perioperative mortality (2 to 3%).¹⁰⁷

TECHNICAL CONSIDERATIONS FOR AORTOBIFEMORAL BYPASS

Both femoral arteries are initially exposed to ensure that they are adequate for the distal anastomoses. The abdomen is then opened in the midline, the small intestine is retracted to the right, and the posterior peritoneum overlying the aorta is incised. A retroperitoneal approach may be selected as an alternative in certain situations. This approach involves making a left flank incision and displacing the peritoneum and its contents to the right. Such an approach is contraindicated if the right renal artery is acutely occluded, because visualization from the left flank is very poor. Tunneling of a graft to the right femoral artery also is more difficult from a retroperitoneal approach, but can be achieved. The retroperitoneal approach has been reputed to be better tolerated than midline laparotomy for patients with multiple previous abdominal operations and with severe pulmonary disease. Further proposed advantages of the retroperitoneal approach include less GI disturbance, decreased third-space fluid losses, and ease with which the pararenal aorta can be accessed. There are randomized reports, however, that support and refute the superiority of this approach. A collagen-impregnated, knitted Dacron graft is used to perform the proximal aortic anastomosis, which can then be made in either an end-to-end or end-to-side fashion using 3-0 polypropylene suture. The proximal anastomosis should be made as close as possible to the renal arteries to decrease the incidence of restenosis from progression of the atherosclerotic occlusive process in the future.

An end-to-end proximal aortic anastomosis is necessary in those patients with an aortic aneurysm or complete aortic occlusion extending up to the renal arteries (Fig. 23-56). Although in theory, the end-to-end configuration allows for less turbulence and less chance of competitive flow with still patent host iliac vessels, there have not been consistent results to substantiate differences in patency between end-to-end and end-to-side grafts. Relative indications for an end-to-side proximal aortic anastomosis include the presence of large aberrant renal arteries, an unusually large IMA with poor back-bleeding, suggesting inadequate collateralization, and/or occlusive disease involving bilateral external iliac arteries. Under such circumstances, end-to-end bypass from the proximal aorta to the femoral level devascularizes the pelvic region because there is no antegrade or retrograde flow in the occluded external iliac arteries to supply the hypogastric arteries. As a result of the pelvic devascularization, there is an increased incidence of impotence, postoperative colon ischemia, buttock ischemia, and paraplegia secondary to spinal cord ischemia, despite the presence of excellent femoral and distal pulses.

Fig. 23-56.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>

In an end-to-end proximal aortic anastomosis, the aorta is divided in half. The proximal end of the aorta is anastomosed to the end of a prosthetic graft while the distal divided aortic stump is oversewn.

An end-to-side proximal aortic anastomosis can be associated with certain disadvantages, which include the potential for distal embolization when applying a partially occlusive aortic clamp (Fig. 23-57). Furthermore, the distal aorta often proceeds to total occlusion after an end-to-side anastomosis. There may also be a higher incidence of aortoenteric fistula following construction of end-to-side proximal anastomoses because the anterior projection makes subsequent tissue coverage and reperitonealization of the graft more difficult. The limbs of the graft are tunneled through the retroperitoneum to the groin, where an end-to-side anastomosis is fashioned between the graft and the bifurcation of the CFA using 5-0 polypropylene suture. Endarterectomy or patch angioplasty of the profunda femoris may be required concurrently. Once the anastomoses have been fashioned and the graft thoroughly flushed, the clamps are removed and the surgeon carefully controls the degree of aortic occlusion until full flow is re-established. During this period the patient must be carefully monitored for hypotension. Declamping hypotension is a complication of sudden restoration of aortic flow, particularly following prolonged occlusion. Once flow has been re-established, the peritoneum is carefully reapproximated over the prosthesis to prevent fistulization into the intestine.

Fig. 23-57.

In an end-to-side aortic anastomosis, the end of a prosthetic graft is connected to the side of an aortic incision.

Despite the presence of multilevel disease in most patients, a properly performed aortobifemoral operation can provide arterial inflow and alleviate claudication symptoms in 70 to 80% of patients; however, 10 to 15% of patients will require simultaneous outflow reconstruction to address distal ischemia and facilitate limb salvage. The advantage of concomitant distal revascularization is avoidance of reoperation in a scarred groin. As a rule, if the profunda femoris can accept a 4-mm probe and if a No. 3 Fogarty embolectomy catheter can be passed distally for 20 cm or more, the PFA will be sufficient for outflow and concomitant distal revascularization is not necessary.

AORTIC ENDARTERECTOMY

Aortoiliac endarterectomy is rarely performed, as it is associated with greater blood loss, greater sexual dysfunction, and is more difficult to perform. Long-term patency is comparable with aortobifemoral grafting, and thus it remains a reasonable option in cases in which the risk of infection of a graft is excessive, because it involves no prosthetic tissue. Aortoiliac endarterectomy was useful when disease was localized to either the aorta or CIAs; however, at present, aortoiliac PTA, stents, and other catheter-based therapies have become first-line treatments in this scenario. Endarterectomy should not be performed if the aorta is aneurysmal because of continued aneurysmal degeneration of the endarterectomized segment. If there is total occlusion of the aorta to the level of the renal arteries, aortic transection several centimeters below the renal arteries with thrombectomy of the aortic cuff followed by graft insertion is easier and more expeditious when compared to endarterectomy. Involvement of the EIA makes aortic endarterectomy more difficult to complete because of decreased vessel diameter, increased length, and exposure issues. The ability to establish an appropriate endarterectomy plane is compromised due to the muscular and inherently adherent nature of the media in this location. There is a higher incidence of early thrombosis and late failure with extended aortoiliac endarterectomy when compared to bypass grafting as a result of recurrent stenosis.

AXILLOFEMORAL BYPASS

An axillofemoral bypass is an extra-anatomic reconstruction that derives arterial inflow from the axillary artery to the femoral artery. This is a treatment option for those patients with medical comorbidities that prohibit an abdominal vascular reconstruction. It may be performed under local anesthesia and is used for limb salvage. Extra-anatomic bypasses have lower patency when compared to aortobifemoral, and therefore, are seldom recommended for claudication. Before performing this operation, the surgeon should check pulses and BP in both arms to ensure that there is no obvious disease

affecting flow through the axillary system. Angiography of the axillosubclavian vasculature is not necessary, but can be helpful if performed at the time of aortography. The axillary artery is exposed below the clavicle, and a 6- to 8-mm externally reinforced PTFE graft is tunneled subcutaneously down the lateral chest wall and lateral abdomen to the groin. It is anastomosed to the ipsilateral distal at the CFA bifurcation into the superficial femoral and profunda femoris arteries. A femorofemoral crossover graft using a 6- to 8-mm externally reinforced PTFE graft is then used to revascularize the opposite extremity if necessary. Reported patency rates over 5 years vary from 30 to 80%.¹⁰⁸ Paradoxically, although it is a less complex procedure than aortofemoral grafting, the mortality rate is higher (10%), reflecting the compromised medical status of these patients.¹⁰⁸

ILIOFEMORAL BYPASS

One option for patients with unilateral occlusion of the distal common iliac or external iliac arteries is iliofemoral grafting (Fig. 23-58). Long-term patency is comparable to aortounifemoral bypass and because the procedure can be performed using a retroperitoneal approach without clamping the aorta, the perioperative mortality is less.¹⁰⁸

Fig. 23-58.

A. Skin markings showing the incisions of an iliofemoral bypass. **B.** A prosthetic bypass graft is used for an iliofemoral artery bypass in which the proximal anastomosis is connected to the common iliac artery (*long arrow*) while the distal anastomosis is connected to the common femoral artery (*short arrow*).

FEMOROFEMORAL BYPASS

A femorofemoral bypass is another option for patients with unilateral stenosis or occlusion of the common or EIA who have rest pain, tissue loss, or intractable claudication. The primary (assisted) patency at 5 years is reported to be 60 to 70%, and, although this is inferior when compared to aortofemoral bypass, there are physiologic benefits, especially for patients with multiple comorbidities, because it is not necessary to cross-clamp the aorta.¹⁰⁹ There are no studies supporting the superiority of unsupported or externally supported PTFE over Dacron for choice of conduit. The fear of the recipient extremity stealing blood from the extremity ipsilateral to the donor limb is not realized unless the donor iliac artery and donor outflow arteries are diseased.¹⁰⁹ Depending on the skills of the interventionalist/surgeon, many iliac lesions classified as TASC II B, C, or D can now be addressed using an endovascular approach, thus obviating the need to perform a femorofemoral bypass. Additionally, femorofemoral bypass can be used as an adjuvant procedure after iliac inflow has been optimized with endovascular methods.

OBTURATOR BYPASS

An obturator bypass is used to reconstruct arterial anatomy in patients with groin sepsis resulting from prior prosthetic grafting, intra-arterial drug abuse, groin neoplasm, or damage from prior groin irradiation. This bypass can originate from the CIA, EIA, or uninvolved limb of an ABF. A conduit of Dacron, PTFE, or autologous vein is tunneled through the

anteromedial portion of the obturator membrane to the distal superficial femoral or popliteal artery. The obturator membrane must be divided sharply so as to avoid injury to adjacent structures, and care must be taken to identify the obturator artery and nerve that pass posterolaterally. After the bypass is completed and the wounds isolated, the infected area is entered, the involved arteries are débrided to healthy tissue, and vascularized muscle flaps are mobilized to cover the ligated ends.¹¹⁰ There have been varied results in terms of patency and limb salvage for obturator bypass. Some authors have reported 57% 5-year patency and 77% 5-year limb salvage rates, whereas others have shown a high rate of reinfection and low patency requiring reintervention.^{110,111}

THORACOFEMORAL BYPASS

The indications for thoracofemoral bypass are (a) multiple prior surgeries with a failed infrarenal aortic reconstruction and (b) infected aortic prosthesis. This procedure is more physiologically demanding than other extra-anatomic reconstructions because the patient must not only tolerate clamping the descending thoracic aorta but also performance of a left thoracotomy. The graft is tunneled to the left CFA from the left thorax posterior to the left kidney in the anterior axillary line using a small incision in the periphery of the diaphragm and an incision in the left inguinal ligament to gain access to the extraperitoneal space from below. The right limb is tunneled in the space of Retzius in an attempt to decrease kinking that is more likely to occur with subcutaneous, suprapubic tunneling. Thoracofemoral bypass has long-term patency comparable to aortofemoral bypass.

Complications of Surgical Aortoiliac Reconstruction

With current surgical techniques and conduits, early postoperative hemorrhage is unusual and occurs in 1 to 2% of cases. It is usually the result of technical oversight or coagulation abnormality.¹¹² Acute limb ischemia (ALI) occurring after aortoiliac surgery may be the result of acute thrombosis or distal thromboembolism. The surgeon can prevent thromboembolic events by (a) avoiding excessive manipulation of the aorta, (b) ensuring adequate systemic heparinization, (c) judicious placement of vascular clamps, and (d) thorough flushing before restoring blood flow. Acute thrombosis of an aortofemoral graft limb in the early perioperative period occurs in 1 to 3% of patients.¹¹² Thrombectomy of the graft limb is performed through a transverse opening in the hood of the graft at the femoral anastomosis. With this approach, it is possible to inspect the interior of the anastomosis and pass embolectomy catheters distally to clear the superficial femoral and profunda arteries. Various complications may be encountered following aortoiliac or aortobifemoral reconstruction (Table 23-15).

Table 23-15 Perioperative Complications of Aortobifemoral Bypass Grafting
Medical complications
• Perioperative myocardial infarction
• Respiratory failure
• Ischemia-induced renal failure
• Bleeding from IV heparinization
• Stroke
Procedure-related complications
Early
• Declamping shock
• Graft thrombosis
• Retroperitoneal bleeding

• Groin hematoma
• Bowel ischemia/infarction
• Peripheral embolization
• Erectile dysfunction
• Lymphatic leak
• Chylous ascites
• Paraplegia
Late
• Graft infection
• Anastomotic pseudoaneurysm
• Aortoenteric fistula
• Aortourinary fistula
• Graft thrombosis

Intestinal ischemia following aortic reconstruction occurs in approximately 2% of cases; however, with colonoscopy, mucosal ischemia, which is a milder form, is seen more frequently. The surgeon can identify patients who require concomitant revascularization of the IMA, hypogastric arteries, or mesenteric arteries by examining the preoperative arteriogram for the presence of associated occlusive lesions in the celiac axis, the superior mesenteric arteries, or both. Likewise patients with patent and enlarged IMA or a history of prior colonic resections will benefit from IMA reimplantation.

In a comprehensive review of 747 patients who had aortoiliac operations for occlusive disease, secondary operations for late complications such as reocclusion, pseudoaneurysms, and infection were necessary in 21% of cases over a 22-year period.¹¹³ The most frequent late complication is graft thrombosis. Limb occlusion occurs in 5 to 10% of patients within 5 years of the index operation and in 15 to 30% of patients 10 years or more after the index operation.^{112,113} Anastomotic pseudoaneurysms occur in 1 to 5% of femoral anastomoses in patients with aortofemoral grafts.¹¹⁴ Predisposing factors to pseudoaneurysm formation include progression of degenerative changes within the host artery, excessive tension at the anastomosis, and infection.¹¹⁴ Due to the associated risks of thrombosis, distal embolization, infection, and rupture, anastomotic aneurysms should be repaired expeditiously.

Infection following aortoiliac reconstruction is a devastating complication that occurs in 1% of cases. Femoral anastomoses of aortofemoral reconstructions and axillofemoral bypasses are prone to infection.^{113,114} Use of prophylactic antibiotics and meticulous surgical technique are vital in preventing contamination of the graft at the time of implantation. If infection appears to be localized to a single groin, one may consider the treatment strategies of graft preservation, aggressive local wound débridement, antibiotic solution irrigation, and soft tissue coverage with rotational muscle flaps. This nonexcisional treatment approach may be useful in selective cases of localized femoral graft infection. Most patients with infected aortoiliofemoral reconstructions usually require graft excision and revascularization via remote uncontaminated routes or the use of in situ replacement to clear the infective process and maintain limb viability. Aortoenteric fistula and associated GI hemorrhage are devastating complications, with a 50% incidence of death or limb loss. The incidence of aortoenteric fistula formation appears to be higher after an end-to-side proximal anastomosis, because it is more difficult to cover the prosthesis with viable tissue and avoid contact with the GI tract with this configuration.^{113,114} Treatment of aortoenteric fistula requires resection of all prosthetic material, closure of the infrarenal abdominal aorta, repair of the GI tract, and revascularization by means of an extra-anatomic graft.

Endovascular Treatment for Aortic Disease

Although aortofemoral bypass surgery has excellent long-term patency and can be performed with low mortality rates, there are patients who are unable to withstand the physiologic stress of longer open procedures performed under general anesthesia, which require aortic cross-clamping, and which are associated with greater blood loss. These patients are more suited to endovascular interventions despite the decreased durability and requirement for more frequent reinterventions.

FOCAL AORTIC STENOSIS

The endovascular technique used to treat infrarenal aortic stenoses is similar to that used for iliac artery disease. Bilateral CFA access is established followed by insertion of a 10F sheath. The lesion is crossed using a hydrophilic wire and a supporting selective catheter and then changed for a stiffer guidewire. A self-expanding nitinol stent or a balloon-expandable stent mounted on a larger caliber angioplasty balloon is implanted followed by adequate postdilation. At the physician's discretion, "kissing" stents, simultaneous bilateral proximal iliac stents, are deployed if the lesion is in the distal aorta in the proximity of the aortic bifurcation. The role of covered stents such as cuffs made for endoluminal abdominal aortic aneurysm (AAA) repair has not been rigorously studied. The aortic diameter should be sized with a calibrated catheter during the angiography or by preintervention CT scanning to avoid undersizing. Balloon size will range from 12 to 18 mm in most cases. A single stent generally is sufficient in most cases. Large Palmaz-type stents mounted on XXL balloons (Meditech, Westwood, Mass) have been successfully used and may be inflated up to 25 mm in diameter if needed. Newer self-expanding stents also have been used. Concentric aortic stenosis may encroach upon the IMA and coverage of this vessel may be unavoidable. Care should be taken to use low inflation pressures (5 mmHg) to minimize the risk of aortic rupture. Patient complaints of back or abdominal pain during balloon inflation should be taken seriously, as they may suggest impending rupture. In case of a calcified small caliber, hypoplastic aorta (≤ 12 mm, typically in female patients), it is recommended to use smaller diameter stents. To achieve clinical improvement, these patients can be recanalized to an aortic diameter of 8 or 9 mm. Distal embolization is one of the potential complications of endovascular treatment for aortic stenoses. Full heparinization, meticulous technique during wire and catheter manipulations, and primary stenting reduce the risk of this complication. Because calcified aortic stenoses are prone to rupture during dilation, it is recommended that the extent of the calcification should be determined beforehand with preoperative CT scans. In case of aortic rupture, as long as wire access has been maintained, an occlusion balloon can be inflated proximal to the disrupted segment to achieve hemostasis and the rupture can be covered with a stent graft or repaired with open surgery.

OCCLUSIVE LESIONS OF THE AORTIC BIFURCATION

Occlusive lesions are treated with the kissing balloon technique to avoid dislodging aortic plaque. Two angioplasty balloons of equal size are positioned across the ostia of the CIAs, using a retrograde approach, and inflated. Simultaneous balloon dilatation at the origins of both CIAs is advocated, even in the presence of a unilateral lesion, to protect the contralateral CIA from dissection or plaque embolization. Calcified lesions, which typically occur at the aortic bifurcation, are not amenable to balloon dilatation, and frequently require that a distal aortic reconstruction be performed using "kissing stents." Fears that the proximal ends of the stents that extend into the distal aorta will become a nidus for thrombus formation, or cause hemolysis have not been realized. The results are difficult to interpret because these bifurcation lesions are usually included in studies with iliac artery lesions. Patency rates for aortic bifurcation PTA range from 76 to 92% at 3 years.¹¹⁵ The largest series reported to date includes 79 patients with aortic bifurcation lesions. The cumulative clinical success rate at a mean of 4 years was 93%.¹¹⁶ In more recent years, stents have been used to reconstruct the aortic bifurcation.¹¹⁷ The kissing stent

technique is well suited for orificial lesions. Technical success with kissing stents at the aortic bifurcation has been reported to be 95 to 100%.¹¹⁷ In the largest series reported, the primary patency at 3 years was 79%.¹¹⁸

Endovascular Treatment for Iliac Artery Disease

PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

PTA is most useful in the treatment of isolated iliac stenoses of <4 cm in length. When used for stenoses rather than occlusion, a 2-year patency of 86% can be achieved.¹¹⁹ The complication rate is approximately 2%, consisting of distal embolization, medial dissection, and acute thrombosis.

Technical Considerations for Iliac Interventions

Crossing a high-grade stenosis or occlusion can be challenging in the iliac arteries. It is vital to image the lesion well because multiple views and use of the image intensifier will frequently uncover the anatomic reason for the difficulty. Frequently, the difficulty is the result of vessel tortuosity that cannot be appreciated on the original view. Use of an angled hydrophilic guidewire and an angled catheter can provide steering and add extra support for the wire trying to cross the lesion. Patience, persistence, and periodic reimaging will facilitate the crossing of a lesion in the great majority of cases. Guidewire traversal must be achieved for performance of endovascular iliac intervention. Over 90% of iliac occlusions can be passed with simple guidewire techniques.

The preferred approach for recanalizing a CIA occlusion is retrograde passage of devices from an ipsilateral CFA puncture because, in this manner, distance to the lesion is short and access is straighter. A stenosis is normally crossed using a combination of a soft-tip 0.035-in guidewire (i.e., Bentson type wire) or hydrophilic wire and a 5 F straight or selective catheter. One of the hazards of retrograde recanalization is that the guidewire stays in a subintimal location, and cannot be redirected into the true lumen at the aortic bifurcation. There are several approaches that can be used to achieve re-entry of total chronic occlusions. Specialized catheters allow passage of a needle and guidewire across the intima distal to the occlusion. Intravascular ultrasound can be used for true lumen re-entry under fluoroscopic guidance. Another method of achieving true lumen re-entry involves performing the recanalization from an antegrade contralateral CFA approach. A 4 F Berenstein catheter (Cordis Corp., Miami Lakes, FL) is used to probe the occlusion. The lesion can be crossed in most instances (5 to 20% failure rate) with a hydrophilic guidewire or, occasionally, with its stiffer back end. As soon as the guidewire crosses the obstruction and lies within the ipsilateral EIA lumen, it is snared and partially pulled out of the ipsilateral CFA. A short catheter is then inserted in a retrograde fashion over the wire end into the abdominal aorta proximal to the lesion. The hydrophilic guidewire is then exchanged for a stiffer Amplatz (Boston Scientific, Natick, MA) guidewire to facilitate iliac stenting.

Obtaining arterial access when there are absent femoral pulsations is aided by the use of ultrasound guidance and "road-map" imaging software that is available on modern angiographic equipment. When the lesion is successfully crossed, balloons of an appropriate size and length are selected for the angioplasty. Most CIAs will accommodate 8- to 10-mm diameter balloons, while most EIAs will accommodate 6- to 8-mm diameter balloons. Inflation is performed with caution, especially if there is heavy calcification, and should be guided by patient discomfort, pressure gauge readings, and changes in balloon outline.

If guidewire traversal is straightforward, consideration should be given to the presence of an acute thrombosis that may benefit from CDT. If guidewire traversal is challenging, it is unlikely that CDT will be beneficial. Investigators have found that

routine thrombolysis and balloon dilation of occluded arteries before stent placement is associated with an increased incidence of distal embolic events.¹²⁰ Stents should be placed after inadequate angioplasty. Stents are warranted when there is a greater than 30% residual stenosis, when there is a flow-limiting dissection, or when there is a pressure gradient of 5 mmHg or greater across the treated segment.¹²¹ Placement of stents can precipitate distal embolization in up to 10%, especially if lesions are friable and vulnerable to manipulation. Routine primary stent placement is not recommended because it has not been found to be superior to selective stenting in terms of outcomes or cost.¹²²

PRIMARY STENTING VS. SELECTIVE STENTING IN ILIAC ARTERIES

Primary stenting rather than selective stenting should be considered for longer iliac lesions and for all TASC II C and D lesions. The primary patency rates at 1, 2, and 3 years were 96%, 90%, and 72% for longer lesions (>5 cm) that were primarily stented vs. 46%, 46%, and 28% with selective stenting.¹²² Primary stenting generally is advocated for chronic iliac artery occlusions, recurrent stenosis after previous iliac PTA, and for complex stenoses with eccentric, calcified, ulcerated plaques, or plaques with spontaneous dissection. All these lesions are prone to distal embolization during manipulation of wires and angioplasty balloons. Distal embolization with isolated PTA is not common for uncomplicated lesions, but can occur in up to 24% of cases, when treating ulcerated plaques, aortoiliac bifurcation lesions, or iliac occlusions.¹²² It is believed that direct stent placement without predilation significantly reduces the risk of distal embolization by trapping potentially emboligenic material between the arterial wall and the stent mesh. Although PTA has demonstrated excellent results in focal stenoses of the abdominal aorta and iliacs, primary stenting in these locations is safe, improves patency rates, reduces the degree of restenosis when compared with PTA alone, and also decreases the risk of distal embolization. Additional potential advantages of direct stenting include shorter procedural time and less radiation exposure. The Dutch Iliac Stent Trial has provided evidence that refutes the superiority of primary stenting over angioplasty alone.¹²³ Most interventionalists continue to perform angioplasty first and stent selectively for inadequate results. The approach to aortoiliac stenting is intuitive. Individual judgment and experience are important in the decision-making process, and there are lesions with unstable morphology such as long occlusions, ulceration, and dissection that warrant primary stenting.

STENT GRAFT PLACEMENT FOR AORTOILIAC INTERVENTIONS

Stent grafts have been used to treat complex iliac lesions in an attempt to exclude these sources of embolization. A recent report suggested that the use of stent grafts was beneficial for TASC II C and D lesions.¹²⁴ Bosiers and colleagues published a series involving 91 limbs with diseased iliacs that they treated with 107 stent grafts. They reported successful deployment in all patients without distal embolization or vessel rupture and a primary patency rate of 91.1% at 1-year follow-up.¹²⁵ The authors commented about their concerns of causing embolization during placement of the stent grafts and recommended that, once an occlusion was traversed with the guidewire, to gently predilate with a 5-mm balloon, followed by smooth stent graft insertion into the newly created channel. The role of stent grafts in aortoiliac occlusive disease has not been fully elucidated yet.

Complications of Endovascular Aortoiliac Interventions

Iliac artery angioplasty is associated with a 2 to 4% major complication rate and 4 to 15% minor complication rate. Many of these minor complications are related to the arterial puncture site. The most frequent complications relate to access site cannulation. Hemorrhage can range from the more common access site hematoma to the rarer retroperitoneal and intraperitoneal hemorrhage. Distal embolization occurs in 2 to 10% of iliac PTA and stenting procedures.¹¹² Percutaneous catheter aspiration should be the initial treatment for calf vessel embolization, but, for larger emboli such as those that lodge

in the profunda femoris or common femoral arteries, surgical embolectomy may be required because the embolic material contains atherosclerotic plaque, which is not amenable to transcatheter aspiration or CDT. The incidence of pseudoaneurysm formation at the puncture site is 0.5%. The treatment of choice for pseudoaneurysms >2 cm in diameter is percutaneous thrombin injection under ultrasound guidance. Arterial rupture may complicate the procedure in 0.3% of cases. Tamponade of the ruptured artery with an occlusion balloon should be performed, and a covered stent should be placed. In case of failure, surgical treatment is required.

Clinical Results Comparing Surgical and Endovascular Treatment of Aortoiliac Disease

The mortality risk for ABF in patients with isolated, localized aortoiliac disease is relatively low, whereas, for patients with concomitant atherosclerosis in coronary, carotid, and visceral vessels, mortality and morbidity are higher. For this reason, the cumulative long-term survival rate for patients having aortoiliac reconstruction remains 10 to 15 years less than anticipated for a normal age- and sex-matched population. Twenty-five to 30% of patients with concomitant atherosclerosis in other vascular distributions are dead within 5 years, and 50 to 60% will have died by 10 years.¹¹⁴

Compared with conventional ABF, common iliac angioplasty was shown to have a 10 to 20% lower overall patency rate. It should be noted that these results were reported in early trials that used older generations of endovascular equipment. With continued progress and newer angioplasty balloons and stenting practices, more comparable outcomes are being reported. Review of the literature confirms that there is an 85 to 90% graft patency rate at 5 years and 70 to 75% at 10 years after aortobifemoral reconstruction.¹²⁶ Due in part to factors including continued refinements in anesthetic management, intraoperative monitoring, and postoperative intensive care, low perioperative mortality rates for ABF can be achieved commonly in today's clinical practice.

Despite its lower long-term success, common iliac angioplasty is a useful procedure in patients with focal disease and mild symptoms in whom a major surgical revascularization is not justified. Angioplasty of the iliac vessels can be a useful adjunct to distal surgical bypass as well, increasing the success of distal revascularization and eliminating the risks associated with aortoiliac bypass. Thus, with long-term patency less than, but comparable to, open surgical bypass, and with more favorable morbidity rates, iliac angioplasty has become a well-accepted modality of treatment for iliac occlusive disease. Ideal iliac angioplasty lesions are nonocclusive and short. Patency after intervention is better when lesions occur in larger diameter vessels, when stenoses rather than occlusions are treated, when runoff vessels are patent, and when the indication for intervention is lifestyle-limiting claudication rather than critical limb ischemia.

Becker and associates estimated a 5-year patency rate of 72% in an analysis of 2697 cases of iliac angioplasty and noted a better patency (79%) in claudicants.¹²⁷ Less favorable results are obtained with long stenoses, external iliac stenoses, and tandem lesions. The reported technical and initial clinical success of balloon angioplasty in iliac artery stenoses exceeds 90% in most series and the 5-year patency rates range between 54 and 92%.¹²⁸ The reported technical and initial clinical success of balloon angioplasty in iliac artery occlusions ranges between 78 and 98% and the 3-year patency rates range between 48 and 85%.¹²⁸

Factors reported to affect the patency of aortoiliac endovascular interventions adversely include quality of runoff vessels, severity of ischemia, and length of diseased segments treated. Likewise, as vessel diameter and flow rates change, so do success rates after angioplasty. It was reported in the literature that location of the lesion at the EIA adversely affects both primary and assisted-primary patency. Following angioplasty of the CIA, patency rates were 81 and 52% at 1 and 6 years,

whereas, after EIA angioplasty, they were 74 and 48% at 1 and 4 years. Although there is literature that supports location of the lesion in the EIA as a factor that adversely affects both primary and assisted-primary patency, this has not been a universal finding.¹²⁹ Female patients are also reported to have lower patency rates than males following iliac PTA, with or without stent placement in the EIA.¹³⁰

Stenting of the iliac arteries provides a durable and curative treatment, with a 3-year patency rate of 41 to 92% for stenoses and a 3-year patency rate of 64 to 85% and 4-year patency rate of 54 to 78% for occlusions.¹²⁸ A meta-analysis of 2116 patients by Bosch and Hunink showed that aortoiliac PTA resulted in a 39% improvement in long-term patency compared to balloon angioplasty, despite the fact that complication rates and 30-day mortality rates did not differ significantly.¹³¹ Park and colleagues presented long-term follow-up results in a cohort of patients with all four TASC II types of iliac lesions. The authors presented primary patency rates of 87%, 83%, 61%, and 49% at 3, 5, 7, and 10 years, respectively, after the index intervention.¹³² Leville and associates achieved primary and secondary patency rates of 76 and 90%, respectively, after 3 years, in a cohort of patients that they stented for iliac occlusions. The authors postulated that endovascular treatment for iliac occlusive disease should be extended to type C and D lesions, because they observed no detectable differences between the four TASC II classifications in terms of primary and secondary patency rates.¹³³ They concluded that presence of TASC II C and D lesions should not preclude endovascular treatment and believe that endovascular attempts should be exhausted before open surgical repair of iliac occlusions is attempted because of the decreased perioperative morbidity and good midterm durability.

Not all results have been in favor of stenting, and, at present, universal primary stenting cannot be recommended. Although stents are often used to improve the outcome of PTA, there is no general consensus that stenting should be mandatory in all iliac lesions. Complex, ulcerated iliac lesions with high emboligenic potential or recanalized chronic iliac occlusions may be an exception. In the Dutch Iliac Trial, primary stenting did not prove to be superior to iliac angioplasty and selective stenting. The researchers in this prospective, randomized, multicenter study concluded that balloon angioplasty with selective stenting had comparable 2-year patency rates with primary stenting; 77 and 78%, respectively. It must be noted, however, that it was necessary to stent 43% of the patients in the PTA treatment group due to unsatisfactory angioplasty results.¹²³ The 5-year outcomes between the two groups were also similar, with 82 and 80% of the treated iliac segments remaining free of the need for new revascularization procedures after a mean follow-up of 5.6 ± 1.3 years.¹²³

LOWER EXTREMITY ARTERIAL OCCLUSIVE DISEASE

The symptoms of LE occlusive disease are classified into two large categories: ALI and chronic limb ischemia (CLI). Ninety percent (90%) of acute ischemias are either thrombotic or embolic. Frequently, sudden onset of limb-threatening ischemia may be the result of acute exacerbation of the pre-existing atherosclerotic disease. Chronic ischemia is largely due to atherosclerotic changes of the LE that manifest from asymptomatic to limb-threatening gangrene. As the population ages, the prevalence of chronic occlusive disease of the LE is increasing and it significantly influences lifestyle, morbidity, and mortality. In addition, multiple comorbid conditions increase risks of surgical procedures. Endovascular interventions become an important alternative in treating LE occlusive disease. However, despite rapid evolving endovascular technology, LE endovascular intervention continues to be one of the most controversial areas of endovascular therapy.

Epidemiology

In a detailed review of the literature, McDaniel and Cronenwett concluded that claudication occurred in 1.8% of patients under 60 years of age, 3.7% of patients between 60 and 70 years of age, and 5.2% of patients over 70 years of age.¹³⁴

Leng and his colleagues scanned 784 subjects using ultrasound in a random sample of men and women ages 56 to 77 years. Of the subjects that were scanned, 64% demonstrated atherosclerotic plaque.¹³⁵ However, a large number of patients had occlusive disease without significant symptoms. In a study by Schroll and Munck, only 19% of the patients with peripheral vascular disease were symptomatic.¹³⁶ Using ankle-brachial indices (ABIs), Stoffers and colleagues scanned 3171 individuals between the ages of 45 and 75 and identified 6.9% of patients who had ABIs <0.95, only 22% of whom had symptoms.¹³⁷ In addition, they demonstrate that the concomitant cardiovascular and cerebrovascular diseases were three to four times higher among the group with asymptomatic peripheral vascular diseases than those without peripheral vascular disease. Furthermore, they confirm that 68% of all peripheral arterial obstructive diseases were unknown to the primary care physician and this group mainly represented less advanced cases of atherosclerosis. However, among patients with an ABI ratio <0.75, 42% were unknown to the primary physicians.

Diagnostic Evaluation

The diagnosis of LE occlusive disease often is made based upon a focused history and physical examination, and confirmed by the imaging studies. A well-performed physical examination often reveals the site of lesions by detecting changes in pulses, temperature, and appearances. The bedside ABIs using BP cuff also aid in diagnosis. Various clinical signs and symptoms are useful to differentiate conditions of viable, threatened, and irreversible limb ischemia caused by arterial insufficiency (Table 23-16).

Table 23-16 Signs and Symptoms of Acute Limb Ischemia			
	Category		
Description	Viable	Threatened	Irreversible
Clinical description	Not immediately threatened	Salvageable if promptly treated	Major tissue loss, amputation unavoidable
Capillary return	Intact	Intact, slow	Absent (marbling)
Muscle weakness	None	Mild, partial	Profound, paralysis (rigor)
Sensory loss	None	Mild, incomplete	Profound anesthetic
Arteriovenous Doppler finding	Audible	Inaudible or audible	Inaudible

Noninvasive studies are important in documenting the severity of occlusive disease objectively. Ultrasound Dopplers measuring ABIs and segmental pressures are widely used in North America and Europe. Normal ABI is >1.0. In patients with claudication, ABIs decrease to 0.5 to 0.9 and to even lower levels in patients with rest pain or tissue loss.¹³⁸ Segmental pressures are helpful in identifying the level of involvement. Decrease in segmental pressure between two segments indicates significant disease. Ultrasound duplex scans are used to identify the site of lesion by revealing flow disturbance and velocity changes. A meta-analysis of 71 studies by Koelemay and associates confirmed that duplex scanning is accurate for assessing arterial occlusive disease in patients suffering from claudication or critical ischemia, with an accumulative sensitivity of 80% and specificity of over 95%.¹³⁹ Adding an ultrasound contrast agent further increases sensitivity and specificity to ultrasound technology.¹⁴⁰ Other noninvasive imaging technologies such as MRA and CTA are rapidly evolving and gaining popularity in the diagnosis of LE occlusive disease (Figs. 23-59 and 23-60).

A. A multidetector computed tomographic angiography of a patient with an infrapopliteal arterial circulation. **B.** Pedal arterial circulation. The high spatial resolution and image quality of these images show three patent infrapopliteal runoff vessels and patent pedal vessels at the foot level.

Contrast angiography remains the gold standard in imaging study. Using contrast angiography, interventionists can locate and size the anatomic significant lesions and measure the pressure gradient across the lesion, as well as plan for potential intervention. Angiography is, however, semi-invasive and should be confined to patients for whom surgical or percutaneous intervention is contemplated. Patients with borderline renal function may need to have alternate contrast agents such as gadolinium or carbon dioxide to avoid contrast-induced nephrotoxicity.

Differential Diagnosis

Arterial insufficiency frequently leads to muscle ischemic pain involving the LE muscularly, particularly during exercise. Intermittent claudication is pain affecting the calf, and, less commonly, the thigh and buttock, which is induced by exercise and relieved by rest. Symptom severity varies from mild to severe. Intermittent claudication occurs as a result of muscle ischemia during exercise caused by obstruction to arterial flow. For differential diagnosis of intermittent claudication, there are a variety of neurologic, musculoskeletal, and venous conditions that may produce symptoms of calf pain (Table 23-17). Additionally, various non-atherosclerotic conditions also can cause symptoms consistent with intermittent LE claudication (Table 23-18). Nocturnal calf muscle spasms or night cramps are not indicative of arterial disease. They are common but are difficult to diagnose with certainty. Foot ulceration is not always the result of arterial insufficiency. Ischemic ulcers occur on the toes or lateral side of the foot and are painful. By comparison, venous ulcers, which also are common, occur above the medial malleolus. These venous stasis ulcers are typically surrounded by a peripheral area of darkened skin discoloration that

is also known as *lipodermatosclerosis*. Neuropathic ulcers usually are found on weight-bearing surfaces, have thick calluses, and are pain free. Ulcers may be the result of more than one etiology. Rest pain must be distinguished from peripheral neuropathy, which is prevalent in diabetic patients. Patients with diabetic neuropathy tend to have decreased vibration and position sense and decreased reflexes. Spinal stenosis causes pain that is exacerbated with standing and back extension.

Table 23-17 Differential Diagnosis of Intermittent Claudication

Condition	Location of Pain or Discomfort	Characteristic Discomfort	Onset Relative to Exercise	Effect of Rest	Effect of Body Position	Other Characteristics
Intermittent claudication (calf)	Calf muscles	Cramping pain	After same degree of exercise	Quickly relieved	None	Reproducible
Chronic compartment syndrome	Calf muscles	Tight, bursting pain	After much exercise (e.g., jogging)	Subsides very slowly	Relief speeded by elevation	Typically heavy-muscled athletes
Venous claudication	Entire leg, but usually worse in thigh and groin	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep venous thrombosis, signs of venous congestion, edema
Nerve root compression (e.g., herniated disk)	Radiates down leg, usually posteriorly	Sharp lancinating pain	Soon, if not immediately after onset	Not quickly relieved (also often present at rest)	Relief may be aided by adjusting back position	History of back problems
Symptomatic Baker's cyst	Behind knee, down calf	Swelling, soreness, tenderness	With exercise	Present at rest	None	Not intermittent
Intermittent claudication (hip, thigh, buttock)	Hip, thigh, buttocks	Aching discomfort, weakness	After same degree of exercise	Quickly relieved	None	Reproducible
Hip arthritis	Hip, thigh, buttocks	Aching discomfort	After variable degree of exercise	Not quickly relieved (and may be present at rest)	More comfortable sitting, weight taken off legs	Variable, may relate to activity level, weather changes
Spinal cord compression	Hip, thigh, buttocks (follows dermatome)	Weakness more than pain	After walking or standing for same length of time	Relieved by stopping only if position changed	Relief by lumbar spine flexion (sitting or stooping forward) pressure	Frequent history of back problems, provoked by increased intra-abdominal pressure
Intermittent claudication (foot)	Foot, arch	Severe deep pain and numbness	After same degree of exercise	Quickly relieved	None	Reproducible
Arthritic, inflammatory process	Foot, arch	Aching pain	After variable degree of exercise	Not quickly relieved (and may be present at rest)	May be relieved by not bearing weight	Variable, may relate to activity level

• Takayasu's disease
• Thromboangiitis obliterans

Lower Extremity Occlusive Disease Classification

LE occlusive disease may range from exhibiting no symptoms to limb-threatening gangrene. There are two major classifications based on the clinical presentations.

The Fontaine classification uses four stages: Fontaine I is the stage when patients are asymptomatic; Fontaine II is when they have mild (IIa) or severe (IIb) claudication; Fontaine III is when they have ischemic rest pain; and Fontaine IV is when patients suffer tissue loss such as ulceration or gangrene (Table 23-19).¹⁴¹

Table 23-19 Classification of Peripheral Arterial Disease Based on the Fontaine and Rutherford Classifications				
Fontaine Classification		Rutherford Classification		
Stage	Clinical	Grade	Category	Clinical
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication	I	1	Mild claudication
IIb	Moderate to severe claudication	I	2	Moderate claudication
		I	3	Severe claudication
III	Ischemic rest pain	II	4	Ischemic rest pain
IV	Ulceration or gangrene	III	5	Minor tissue loss
		III	6	Major tissue loss

The Rutherford classification has four grades (0–III) and seven categories (0–6). Asymptomatic patients are classified into category 0; claudicants are stratified into grade I and divided into three categories based on the severity of the symptoms; patients with rest pain belong to grade II and category 4; patients with tissue loss are classified into grade III and categories 5 and 6, based on the significance of the tissue loss.² These clinical classifications help to establish uniform standards in evaluating and reporting the results of diagnostic measurements and therapeutic interventions (see Table 23-19).

The most clinically useful classification of LE atherosclerotic disease should be based on morphologic characters of the

lesions. The TASC II task force published a guideline separating LE arterial diseases into femoropopliteal and infrapopliteal lesions (Table 23-20). This guideline is particularly useful in determining intervention strategies based on the disease classifications. Based on the guideline, femoropopliteal lesions are divided into four types: A, B, C, and D. Type A lesions are single focal lesions <3 cm in length that did not involve the origins of the superficial femoral artery (SFA) or the distal popliteal artery; Type B lesions are single lesions 3 to 5 cm in length not involving the distal popliteal artery or multiple or heavily calcified lesions <3 cm in length; Type C lesions are multiple stenoses or occlusions >15 cm in length, or recurrent stenoses or occlusions that need treatment after two endovascular interventions. Type D lesions were those with complete occlusion of CFA, SFA, or popliteal artery.²

Table 23-20 TASC II Classification of Femoral Popliteal Occlusive Lesions
Type A lesions
<ul style="list-style-type: none"> • Single stenosis ≤10 cm in length • Single occlusion ≤5 cm in length
Type B lesions
<ul style="list-style-type: none"> • Multiple lesions (stenoses or occlusions), each ≤5 cm • Single stenosis or occlusion ≤15 cm not involving the infra geniculate popliteal artery • Single or multiple lesions in the absence of continuous tibial vessels to improve inflow for a distal bypass • Heavily calcified occlusion ≤5 cm in length • Single popliteal stenosis
Type C lesions
<ul style="list-style-type: none"> • Multiple stenoses or occlusions totaling >15 cm with or without heavy calcification • Recurrent stenoses or occlusions that need treatment after two endovascular interventions
Type D lesions
<ul style="list-style-type: none"> • Chronic total occlusions of CFA or SFA (>20 cm, involving the popliteal artery) • Chronic total occlusion of popliteal artery and proximal trifurcation vessels

CFA = common femoral artery; SFA = superficial femoral artery; TASC II = Trans-Atlantic Inter-Society Consensus.

In a similar fashion, infrapopliteal arterial diseases are classified into four types based on TASC II guideline (Fig. 23-61). Type A lesions are single lesions <1 cm in length not involving the trifurcation; Type B lesions are multiple lesions <1 cm in length or single lesions shorter than 1 cm involving the trifurcation; Type C lesions are those lesions extensively involving trifurcation or those that are 1- to 4-cm stenotic or 1- to 2-cm occlusive lesions; Type D lesions are occlusions longer than 2 cm or diffuse diseases.²

Schematic depiction of Trans-Atlantic Inter-Society Consensus classification of femoral popliteal occlusive lesions.

Etiology of Acute Limb Ischemia

ALI is defined as *sudden loss of limb perfusion* and the term is applicable up to 2 weeks after an initiating event. Although the instances of acute leg ischemia caused by emboli have decreased due to more effective treatment of rheumatic fever and atrial fibrillation, the incidence of thrombotic acute leg ischemia has increased. Even with the extensive use of newer endovascular techniques including thrombolysis, most published series report a 10 to 30% 30-day amputation rate.² The short-term mortality of patients presenting with acute ischemia is 15 to 20%. The most common etiologies of ALI include embolism, native vessel thrombosis, reconstruction thrombosis, trauma, and complications of peripheral aneurysm. Most cases of acute LE ischemia are the result of thrombosis of a prosthetic conduit. This stems from increased use of prosthetic conduits to address CLI.

Presenting symptoms in ALI are pain and loss of sensory or motor function. The abruptness and time of onset of the pain, its location and intensity, as well as change in severity over time, should all be taken into consideration. The duration and intensity of the pain and presence of motor or sensory changes are very important in clinical decision making and urgency of revascularization. Thrombolysis may be less effective for thrombosis of a 2-week or longer duration compared with acute thrombosis.¹⁴²

ARTERIAL EMBOLISM

The heart is the most common source of distal emboli, which account for more than 90% of peripheral arterial embolic events. Atrial fibrillation is the most common source. Sudden cardioversion results in the dilated noncontractile atrial appendage regaining contractile activity, which can dislodge the contained thrombus. Other cardiac sources include mural thrombus overlying a myocardial infarction, or thrombus forming within a dilated left ventricular aneurysm. Mural thrombi also can develop within a ventricle dilated by cardiomyopathy. Emboli that arise from a ventricular aneurysm or from a

dilated cardiomyopathy can be very large and can lodge at the aortic bifurcation (saddle embolus), thus rendering both legs ischemic. Diseased valves are another source of distal embolization. Historically, this occurred as a result of rheumatic heart disease. Currently, subacute and acute bacterial endocarditis are the more common causes. Infected emboli can seed the recipient vessel wall, creating mycotic aneurysms.

An electrocardiogram will diagnose atrial fibrillation. A transthoracic or transesophageal echocardiogram should be performed to look for a cardiac source. It is important to seek other sources of the embolus using CT scanning of the descending thoracic and abdominal aorta. More unusual sources include mural thrombus from an aortic aneurysm and, occasionally, idiopathic arterial-to-arterial thrombus occurs, usually from a thrombus that has formed in an atherosclerotic aortic arch or descending thoracic aorta. The presence of mobile plaque on transesophageal echocardiography is suggestive of this source.

Paradoxical embolus occurs when a patient has a patent foramen ovale and an embolus from a deep venous thrombosis which embolizes across the atrial defect into the left side of the heart and passes into the peripheral circulation. This is diagnosed using a bubble echocardiography, in which air bubbles introduced into the venous circulation can be seen traversing the septal defect.

ARTERIAL THROMBOSIS

Thrombosis can occur in native arteries and in arterial reconstructions. Patients with thrombosed arterial segments often have an underlying atherosclerotic lesion at the site of thrombosis, or aneurysmal degeneration with mural thrombosis. It is important to obtain a history, determine risk factors for atherosclerosis and hypercoagulable status, and examine the contralateral extremity for circulatory problems. Patients with thrombosis of prior arterial reconstructions have limb incisions from previous surgery, and graft occlusion can be confirmed with duplex imaging.

Clinical Manifestations of Acute Limb Ischemia

Acute LE ischemia manifests with the "five Ps": *pain*, *pallor*, *paresthesias*, *paralysis*, and *pulselessness*, to which some add a sixth "P"—*poikilothermia* or "*perishing cold*." Pain is the usual symptom that causes a patient to present to the emergency room. The most common location for an embolus to lodge in the leg is at the common femoral bifurcation. Typically a patient will complain of foot and calf pain. Pulses are absent and there may be diminution of sensation. Inability to move the affected muscle group is a sign of very severe ischemia and necessitates urgent revascularization. During evaluation of the affected extremity, it is important to compare findings with the contralateral limb. Clinical evaluation is extremely important in determining the etiology and location of the obstruction. One of the most important pieces of information to obtain is whether the patient has had prior vascular procedures or if there is a history of LE claudication. Either of these features suggests pre-existing vascular disease, renders revascularization more complicated, and usually mandates angiography to permit surgical planning. On the contrary, in a patient with no history suggestive of prior vascular disease, the etiology is most likely embolic and simple thrombectomy is more likely to be successful.

Absent bilateral femoral pulses in a patient with bilateral LE ischemia are most likely due to saddle embolus to the aortic bifurcation. A palpable femoral pulse and absent popliteal and distal pulses may either be due to distal common femoral embolus (the pulse being palpable above the level of occlusion) or embolus to the superficial femoral or popliteal arteries. Typically, emboli lodge at arterial bifurcations where they are trapped due to sudden reductions in arterial diameter. A popliteal trifurcation embolus will present with calf ischemia and absent pedal pulses, possibly with a popliteal pulse present. The finding of palpable contralateral pulses and the absence of ipsilateral pulses in the acutely ischemic leg is suggestive of an embolus, irrespective of presence of Doppler signals. Arteriography is not mandatory in patients without antecedent

history suggestive of vascular disease; nevertheless, all patients should be positioned on the OR table in such a way that fluoroscopic access to the entire inflow and outflow tract is possible, if necessary.

The main question to be answered by the history and physical examination is the severity of the ALI, which is the major consideration in early management decisions. Patients with ALI should be evaluated in a fashion that takes into consideration the severity and duration of ischemia at the time of presentation. Ideally, all patients with acute ischemia should be investigated with imaging, especially if there is an antecedent vascular reconstruction; however, the clinical condition and access to resources must guide further investigations.² Unnecessary delays can result in amputation. Arteriography, if it can be performed in a timely fashion, is an excellent modality for localizing obstructions and deciding which type of intervention (endovascular, embolectomy, or bypass) patients will benefit more from. One of the goals of treatment for ALI is to prevent thrombus propagation; therefore, expedient anticoagulation with heparin is indicated as soon as the diagnosis is suspected.

Treatment Considerations for Acute Limb Ischemia

In the absence of any significant contraindication, the patient with an ischemic LE should be immediately anticoagulated. This will prevent propagation of the clot into unaffected vascular beds. IV fluid should be started and a Foley catheter inserted to monitor urine output. Baseline labs should be obtained and creatinine levels noted. A hypercoagulable work-up should be performed before initiation of heparin if there is sufficient suspicion. According to results from randomized trials, there is no clear superiority for thrombolysis over surgery in terms of 30-day limb salvage or mortality. Access to each treatment option is a major issue in the decision-making process, as time is often critical. National registry data from the United States reveal that surgery is used three- to fivefold more frequently than thrombolysis. Three randomized studies have investigated the role of catheter-directed thrombolytic therapy in the treatment of ALI.¹⁴³

Endovascular Treatment

The potential to reduce mortality and morbidity while achieving limb salvage is the impetus that makes thrombolysis preferable to open surgery as first-line treatment in patients with ALI (class I and IIa). Advantages of thrombolytic therapy over balloon embolectomy include the reduced endothelial trauma and potential for more gradual and complete clot lysis in branch vessels usually too small to access by embolectomy balloons. It is hoped that the more gradual clot dissolution with thrombolysis may decrease the incidence of reperfusion injury that is encountered after open surgical procedures where rapid return of blood flow may precipitate compartment syndrome. Skeletal muscle tissue appears to be most vulnerable to ischemia. Pathophysiologic studies reveal that irreversible damage to muscle tissue starts after 3 hours of ischemia and is nearly complete at 6 hours. Progressive microvascular damage appears to follow rather than precede skeletal muscle tissue damage. The more severe the cellular damage, the greater the microvascular changes. When the musculature and microvasculature are severely damaged, amputation rather than attempts at revascularization may be the most prudent course to prevent washout of toxic by-product from the ischemic limb into the systemic circulation. The mortality rate associated with reperfusion syndrome is high, because of the development of concomitant adult respiratory distress syndrome, shock, disseminated intravascular coagulation, and renal failure.

Patients with small-vessel occlusion are poor candidates for surgery because they lack distal target vessels to use for bypass. These patients should be offered a trial of thrombolysis unless they have contraindications to thrombolysis or their ischemia is so severe that the time needed to achieve adequate lysis is considered too long. The major contraindications of thrombolysis are recent stroke, intracranial primary malignancy, brain metastases, or intracranial surgical intervention. Relative contraindications for performance of thrombolysis include renal insufficiency, allergy to contrast material, cardiac

thrombus, diabetic retinopathy, coagulopathy, and recent arterial puncture or surgery (Table 23-21).

Table 23-21 Contraindications to Thrombolytic Therapy
Absolute contraindications
Established cerebrovascular events (including transient ischemic attack) within last 2 mo
Active bleeding diathesis
Recent (<10 d) GI bleeding
Neurosurgery (intracranial or spinal) within last 3 mo
Intracranial trauma within last 3 mo
Intracranial malignancy or metastasis
Relative major contraindications
Cardiopulmonary resuscitation within last 10 d
Major nonvascular surgery or trauma within last 10 d
Uncontrolled hypertension (>180 mmHg systolic or >110 mmHg diastolic)
Puncture of noncompressible vessel
Intracranial tumor
Recent eye surgery
Minor contraindications
Hepatic failure, particularly with coagulopathy
Bacterial endocarditis
Pregnancy
Diabetic hemorrhagic retinopathy

Advances in clot removal techniques with percutaneous mechanical thrombectomy and thromboaspiration may extend the applicability of this intervention to patients with more advanced degrees of ALI (class IIb) and contraindications to thrombolysis. Several thrombectomy devices have received FDA approval for acute LE arterial thrombosis. The utility of these thrombectomy devices is that they can be used as stand-alone therapy when there are contraindications for thrombolytic therapy. Additionally, these thrombectomy devices can be used in conjunction with thrombolytic agents, for pharmacomechanical thrombectomy, to enhance clot lysis, and to limit the doses and time required for thrombolysis.^{144,145}

Surgical Treatment

EMBOLECTOMY

When a decision is made to proceed with open surgical intervention, the abdomen, contralateral groin, and entire LE are prepped in the field. The groin is opened through a vertical incision, exposing the CFA and its bifurcation. Frequently, the location of the embolus at the femoral bifurcation is readily apparent by the presence of a palpable proximal femoral pulse, which disappears distally. The artery is clamped and opened transversely over the bifurcation. Thrombus is extracted by passing a Fogarty balloon embolectomy catheter. Good back-bleeding and antegrade bleeding suggest that the entire clot has been removed. Embolic material often forms a cast of the vessel and is sent for culture and histologic examination. Completion angiography is advisable to ascertain the adequacy of clot removal. The artery is then closed and the patient fully anticoagulated.

When an embolus lodges in the popliteal artery, in most cases it can be extracted via a femoral incision using a balloon embolectomy catheter approach. A femoral approach is preferred because the larger diameter of the femoral artery results in decreased likelihood of arterial compromise when the arteriotomy is closed. The disadvantage with using the femoral approach for embolectomy is the greater difficulty involved in directing the embolectomy catheter into each of the infrapopliteal arteries. Use of fluoroscopic imaging and an over-the-wire thrombectomy catheter can overcome this problem. Alternatively, use of a separate incision to expose the popliteal bifurcation may be necessary to achieve a complete thrombectomy.

A more complex situation arises when a patient has antecedent peripheral vascular disease and in situ thrombosis develops on top of pre-existing atheroma because, frequently, embolectomy catheters will not pass through these occlusions. Similarly, when a bypass graft fails, it is usually due to progression of atheroma proximal or distal to the graft anastomoses, or to intrinsic stenoses that develop within a vein graft. In these scenarios, expeditious angiography is useful, to determine the extent of the occlusion, to search for inflow and distal outflow vessels, and to decide whether thrombolysis or surgery will be the better intervention. Although the surgeon's preference tends to dictate the approach selected, the decision is based on the presence or absence of good target vessels and availability of a suitable bypass conduit. If there are good distal vessels and the saphenous vein is suitable, surgical bypass is recommended, as it is fast, durable, and reliable. In the absence of a good distal target and saphenous vein, or in a patient at high risk for surgery, lysis is recommended.

BYPASS GRAFT THROMBECTOMY

Bypass thrombectomy is more likely to succeed with prosthetic bypasses. Bypass graft revision or replacement is more appropriate for acute vein graft failures as they are less likely to respond to thrombolysis and require some type of revision such as valve lysis, interposition, or extension. Thrombectomy of autogenous grafts is prone to failure unless an anatomic cause for failure such as a retained valve or unligated side branch is found and corrected. The performance of a fasciotomy to circumvent reperfusion injury/compartment syndrome is an important consideration.

Complications Related to Treatment for Acute Limb Ischemia

Adverse events related to CDT are primarily related to bleeding complications. The overall risk of hemorrhagic stroke from a thrombolysis procedure has been reported to be 1 to 2.3%, with 50% of hemorrhagic complications occurring during the thrombolytic procedure.¹⁴⁶ Hematoma at the vascular puncture site has been reported in 12 to 17% of cases. GI bleeding is reported in 5 to 10% of cases. Hematuria following thrombolysis is uncommon and should prompt a search for urinary tumors. Hemorrhage requiring transfusion can occur in approximately 25% of patients undergoing thrombolysis.^{138,143} Lytic agents are absolutely contraindicated in patients with intracranial surgery, intracranial hemorrhage within the last 3 months, or in the presence of any active bleeding. Most bleeding complications occur at the arterial puncture sites, but concealed retroperitoneal bleeding is possible. The most feared complication that patients can sustain is intracerebral hemorrhage. Older patients may be more susceptible to this complication and thus many interventionalists are extremely reticent to use thrombolysis in patients older than 80 years of age.

Patients who are treated for acute ischemia are susceptible to two major complications following revascularization, which include reperfusion and compartment syndromes. Other procedure-related complications can include arterial rethrombosis, recurrent embolization, and arterial injuries secondary to the balloon catheter manipulations.

Reperfusion of the ischemic limb is variable in its physiologic effects and directly relates to the severity and extent of the ischemia. Patients with a saddle embolus of the aortic bifurcation and severely ischemic limbs may develop the full-blown

"reperfusion syndrome," whereas patients with minimal muscle ischemia who are reperfused in a timely fashion essentially develop no effects. Many patients with ALI have severe underlying cardiac disease and are unable to tolerate even short ischemic periods. Complications occurring after revascularization of the LE and causes of recurrent thrombosis are listed in Table 23-22.

Table 23-22 Complications of Arterial Revascularization
Compartment syndrome
Ischemic neuropathy
Muscle necrosis
Recurrent thrombosis
Lower leg swelling
Reperfusion syndrome
Hypotension
Hyperkalemia
Myoglobinuria
Renal failure

Compartment syndrome occurs after prolonged ischemia is followed by reperfusion. The capillaries leak fluid into the interstitial space in the muscles, which are enclosed within a nondistensible fascial envelope. When the pressure inside the compartment exceeds the capillary perfusion pressure, nutrient flow ceases and progressive ischemia occurs, even in the presence of peripheral pulses. Consequently, every patient who has sustained an ischemic event and is reperfused is monitored for compartment syndrome, which is characterized by excessive pain in the compartment, pain on passive stretching of the compartment, and sensory loss due to nerve compression of the nerves coursing though the compartment (Table 23-23 and Fig. 23-62). The most commonly affected compartment is the anterior compartment in the leg. Numbness in the web space between the first and second toes is diagnostic due to compression of the deep peroneal nerve. Compartment pressure is measured by inserting an arterial line into the compartment and recording the pressure. Although controversial, pressures >20 mmHg are an indication for fasciotomy. Compartment pressures are relieved in the leg by medial and lateral incisions. Through the medial incision, long openings are then made in the fascia of the superficial and deep posterior compartments. Through the lateral incision, the anterior and peroneal compartments are opened. Both skin and fascial incisions should be of adequate length to ensure full compartment decompression. Laboratory evidence of rhabdomyolysis is seen in 20%. The myoglobin from damaged muscle precipitates in kidney tubules and causes acute tubular necrosis. Alkalinization of urine increases the solubility of myoglobin, thus preventing it from crystallizing in the tubules. In addition to alkalinization, therapy consists of forced saline diuresis and removal of the source of dead muscle that is releasing the myoglobin.

Table 23-23 Fascial Compartments of the Lower Leg				
	Anterior Compartment	Lateral Compartment	Superficial Posterior Compartment	Deep Posterior Compartment
Muscles	Tibialis anterior	Peroneus longus	Gastrocnemius	Tibialis posterior
	Extensor digitorum longus	Peroneus brevis	Plantaris	Flexor digitorum longus

	Peroneus tertius		Soleus	Flexor hallucis longus
	Extensor hallucis longus			
	Extensor digitorum brevis			
	Extensor hallucis brevis			
Artery	Anterior tibial artery	Anterior and posterior tibial branches of the popliteal artery	—	Posterior tibial artery
				Peroneal artery
Nerve	Deep peroneal nerve	Superficial peroneal nerve	—	Tibial nerve

Schematic illustration of fascial compartments of the lower extremity.

Clinical Manifestations of Chronic Limb Ischemia

The term *chronic limb ischemia* is reserved for patients with objectively proven arterial occlusive disease and symptoms lasting for more than 2 weeks. Symptoms include rest pain and tissue loss such as ulceration or gangrene (Table 23-24).

The diagnosis should be corroborated with noninvasive diagnostic tests such as the ABI, toe pressures, and transcutaneous oxygen measurements. Ischemic rest pain most commonly occurs below an ankle pressure of 50 mmHg or a toe pressure <30 mmHg.² Ulcers are not always of an ischemic etiology (Table 23-25). In many instances, there are other etiologic factors (traumatic, venous, or neuropathic) that are contributory, but it is underlying peripheral arterial disease (PAD) that may be responsible for delayed or absent healing (Fig. 23-63). Healing of ulcers requires an inflammatory response and greater perfusion than is required to support intact skin and underlying tissues. As a result, the ankle and toe pressure levels needed for healing are higher than the pressures seen with ischemic rest pain. For patients with ulcers or gangrene, the presence of CLI is suggested by an ankle pressure <70 mmHg or a toe systolic pressure <50 mmHg.² It is important to understand that there is no definite consensus regarding the vascular hemodynamic parameters required to make the diagnosis of CLI.

Table 23-24 Clinical Categories of Chronic Limb Ischemia			
Grade	Category	Clinical Description	Objective Criteria
0	0	Asymptomatic—no hemodynamically significant occlusive disease	Normal treadmill or reactive hyperemia test
	1	Mild claudication	Able to complete treadmill exercise ^a ; AP after exercise >50 mmHg but at least 20 mmHg lower than resting value
I	2	Moderate claudication	Between categories 1 and 3
	3	Severe claudication	Cannot complete standard treadmill exercise ^a and AP after exercise <50 mmHg
II ^b	4	Ischemic rest pain	Resting AP <40 mmHg, flat or barely pulsatile ankle or metatarsal PVR; TP <30 mmHg
III ^b	5	Minor tissue loss—nonhealing ulcer, focal gangrene with diffuse pedal ischemia	Resting AP <60 mmHg, ankle or metatarsal PVR flat or barely pulsatile; TP <40 mmHg
	6	Major tissue loss—extending above TM level, functional foot no longer salvageable	Same as category 5

^a 5 minutes at 2 miles per hour on a 12% incline of treadmill exercise.

^b Grades II and III, categories 4, 5, and 6, are encompassed by the term *chronic critical ischemia*.

AP = ankle pressure; PVR = pulse volume recording; TM = transmetatarsal; TP = toe pressure.

Table 23-25 Symptoms and Signs of Neuropathic Ulcer versus Ischemic Ulcer	
Neuropathic Ulcer	Ischemic Ulcer
Painless	Painful
Normal pulses	Absent pulses
Regular margins, typically punched-out appearance	Irregular margin
Often located on plantar surface of foot	Commonly located on toes, glabrous margins
Presence of calluses	Calluses absent or infrequent
Loss of sensation, reflexes, and vibration	Variable sensory findings
Increased in blood flow (atrioventricular shunting)	Decreased in blood flow

	Collapsed veins
Dilated veins	Cold foot
Dry, warm foot	No bony deformities
Bony deformities	Pale and cyanotic in appearance
Red or hyperemic in appearance	

Fig. 23-63.

A. A neuropathic ulcer is characterized by a punched-out appearance with loss of sensation in the surrounding skin. The foot may be warm to touch, and pulses may be present in the distal pedal arteries. **B.** An ischemic ulcer is characterized by a gangrenous skin change in the foot or toes. The foot is usually cold to touch with absent pedal pulses. The foot is painful to touch with decreased distal capillary refills.

One of the most common sites for occlusive disease is in the distal SFA as it passes deep through the adductor canal. It may be that the entrapment by the adductor hiatus prevents the compensatory dilation that occurs in atherosclerotic vessels. Stenoses, which develop here, progress to occlusion of the distal third of the SFA (Fig. 23-64). When distal SFA occlusion develops slowly, it may be totally asymptomatic because of development of collaterals from the proximal SFA or the profunda femoris artery (PFA) can bypass the occlusion and reconstitute the popliteal artery. Symptom development is a function of the extent of occlusion, adequacy of collaterals, and also the activity level of the patients.

Computed tomography angiogram of a patient with an occluded left superficial femoral artery (*single long arrow*) with reconstituted superficial femoral artery at the level of midthigh. Diffuse arterial calcifications (*double small arrows*) are noted in the mid and distal left superficial femoral arteries.

Presenting symptoms of femoropopliteal occlusive disease are broadly classified into two types: limb-threatening and non-limb-threatening ischemia. Claudication is non-limb-threatening, while rest pain, ulceration, and gangrene are limb-threatening and warrant urgent intervention. Occlusive disease of the femoral artery may be isolated or occur in conjunction with multilevel disease that involves both the aortoiliac segment and the tibial vessels. Symptoms in patients with multilevel

disease are more severe than in those with single-level disease. Pain from isolated SFA and popliteal occlusion typically manifests as calf claudication. Cramping pain develops in the calf on ambulation, occurs at a reproducible distance, and is relieved by rest. Activities such as climbing stairs or going uphill also exacerbate the pain. Many patients report worsening symptoms during cold weather. It is important to evaluate whether the symptoms are progressive or static. In >70% of patients, the disease is stable, particularly with risk factor modification.

Progression of the underlying atherosclerotic process is more likely to occur in patients with diabetes, those who continue to smoke, and those who fail to modify their atherosclerotic risk factors. In comparison, rest pain is constant, and usually occurs in the forefoot across the metatarsophalangeal joint. It is worse at night and requires placing the foot in a dependent position to improve symptoms. Patients may report that they either sleep in a chair or hang the foot off the side of the bed. The pain is severe and relentless, even with narcotics. Ischemic ulceration most commonly involves the toes. Any toe can be affected. Occasionally, ulcers develop on the dorsum of the foot. Ulceration can occur in atypical positions in an ischemic foot from trauma such as friction from poorly fitting shoes. Injury to a foot with borderline ischemia can convert an otherwise stable situation into one that is limb-threatening. The initial development of gangrene commonly involves the digits. As with all vascular patients, it is important to evaluate their risk factors, intercurrent cardiac diseases, and any prior vascular interventions.

Treatment Considerations for Chronic Limb Ischemia

Patients with vascular diseases frequently have complicated medical comorbidities. Careful patient evaluation and selection should be performed for any peripheral arterial vascular procedure. The fundamental principle is to assess not only the surgical risk from the peripheral arterial system but also the global nature of the atherosclerotic process. Full cardiac evaluations are often necessary due to the high incidence of concomitant atherosclerotic coronary arteries disease, resulting in a high risk for ischemic events. Hertzner and associates reviewed coronary angiographies on 1000 patients undergoing elective vascular procedures and identified 25% of concomitant correctable CAD, including 21% in patients undergoing elective peripheral vascular intervention.⁸ Conte and associates analyzed their 20-year experience in a tertiary practice setting in 1642 open LE reconstructive surgeries and concluded that patients requiring LE reconstruction presented an increasingly complex medical and surgical challenge compared with the previous decade.¹⁴⁷ With aging of the population, there are a growing number of vascular patients who have prohibitive medical comorbidities that are deemed high-risk for open surgical repair. Endovascular intervention provides an attractive alternative.

As for open surgical repair, the clinical indications for endovascular intervention of LE PADs include lifestyle-limiting claudication, ischemic rest pain, and tissue loss or gangrene. Importantly, endovascular procedures should be performed by a competent vascular interventionist who understands the vascular disease process and is familiar with a variety of endovascular techniques. In addition, certain lesions such as long segment occlusion, heavily calcified lesion, orifice lesion, or lesions that can be not be traversed by a guidewire may not be amendable to endovascular treatment or may be associated with poor outcomes. A proper selection of patients and techniques is critical in achieving a good long-term outcome.

Endovascular intervention for LE occlusive disease is continuously evolving. Success and patency rates of endovascular intervention are closely related to the anatomic and morphologic characters of the treated lesions. The TASC II work group made recommendations on the intervention strategies of LE arterial diseases based on the morphologic characters. Based on the TASC II guidelines, endovascular treatment is recommended for type A lesions, open surgery is recommended for Type D lesions, and no recommendations were made for Types B and C lesions. However, with rapid advancement in endovascular

technologies, there are increased numbers of lesions amenable to endovascular interventions.

There is less literature support on infrapopliteal endovascular intervention due to higher complication and lower success rates. The treatment is restricted to patients with limb-threatening ischemia who lack surgical alternatives. However, with further advancement of endovascular technology and the development of new devices, endovascular intervention will become an integral part of treatment (Table 23-26). By itself or combined with open technique, percutaneous intervention plays an important role in therapeutic options for LE occlusive disease. As described by the TASC II guidelines, four criteria should be measured to evaluate the clinical success of the treatment: improvement in walking distance, symptomatic improvement, quality of life, and overall graft patency. These criteria should all be carefully weighed and evaluated for each individual before endovascular therapy.

Table 23-26 Summary of Endovascular Treatment Strategies Using Device-Based Infrapopliteal Intervention		
Intervention	Advantages	Disadvantages
Angioplasty	<ul style="list-style-type: none"> • Easy to use • Broad range of applications 	<ul style="list-style-type: none"> • Failure in long lesions, calcified lesions, and disease at multiple levels
Balloon-expandable stent	<ul style="list-style-type: none"> • Overcomes arterial recoil from angioplasty 	<ul style="list-style-type: none"> • Crushability can lead to restenosis
	<ul style="list-style-type: none"> • Useful in treatment of flow-limiting dissection 	<ul style="list-style-type: none"> • Poor distal runoff can result in stent thrombosis; limited data
Self-expanding stent	<ul style="list-style-type: none"> • Vessel conformability and wall apposition prevents kinking and crushing of stent 	<ul style="list-style-type: none"> • Limited sizes; limited data; multicenter trials under way
Bioabsorbable stent	<ul style="list-style-type: none"> • Overcomes arterial recoil from angioplasty 	<ul style="list-style-type: none"> • Limited data; multicenter trials under way
	<ul style="list-style-type: none"> • Absorbed long-term to prevent risk of stent thrombosis 	
Cryoplasty	<ul style="list-style-type: none"> • Reduces the risk of flow-limiting dissection, therefore reducing the need for stent implantation 	<ul style="list-style-type: none"> • Short-term results of a multicenter trial are promising; however, long-term data are limited
Cutting balloon	<ul style="list-style-type: none"> • Useful in anastomotic segments of bypass grafts and instent restenosis where "watermelon seeding" can prevent adequate expansion of plaque 	<ul style="list-style-type: none"> • Limited data
Mechanical atherectomy	<ul style="list-style-type: none"> • Allows for debulking of plaque without the need for stent implantation in most cases 	<ul style="list-style-type: none"> • Limited use in areas of heavy calcification
	<ul style="list-style-type: none"> • Allows for removal of plaque for histologic analysis 	<ul style="list-style-type: none"> • No large, randomized, prospective trial comparing this technique to angioplasty and stenting
Laser	<ul style="list-style-type: none"> • Useful in acute thrombotic and chronic total occlusions 	<ul style="list-style-type: none"> • Minimal data in infrapopliteal arteries
		<ul style="list-style-type: none"> • Need adjunctive treatment with angioplasty, stenting, or atherectomy

Endovascular Treatment

TECHNICAL CONSIDERATIONS

A sterile field is required in either an OR or an angiography suite with image capability. The most common and safest access site is the CFA via either a retrograde or antegrade approach. For diagnostic angiography, arterial access should be contralateral to the symptomatic sides. For therapeutic procedures, location of the lesion and the anatomic structures of the

arterial tree determine the puncture site. To avoid puncturing the iliac artery or SFA, the femoral head is located under the fluoroscopy and used as the guide for the level of needle entry. In addition, there are several useful techniques in helping access a pulseless CFA, including puncturing guided by ultrasound, using a micropuncture kit, and targeting calcification in a calcified vessel. An antegrade approach may be challenging, particularly in obese patients. Meticulous technique is crucial in preventing complications, and a bony landmark can be used as guidance to ensure CFA puncture.

Traversing the lesion with a wire is the most critical part of the procedure. Typically, 0.035-in guidewires are used for femoropopliteal lesions and 0.014- or 0.018-in guidewires are used for infrapopliteal access. Hydrophilic-coated wires, such as Glide wires, are useful in navigating through tight stenosis or occlusion. An angled-tip wire with a torque device may be helpful in crossing an eccentric lesion, and a shaped selective catheter is frequently used in helping manipulate the wire across the lesion. The soft and floppy end of the wire is carefully advanced, crossing the lesion under fluoroscopy, and gentle force is applied while manipulating the wire. Once the lesion has been traversed, one needs to pay particular attention to the tip of the wire to ensure a secure wire access and avoid vessel wall perforation or dissection.

Once the access to the diseased vessel is secured and the wire has successfully traversed the lesion, several treatment modalities can be used either used alone or in conjunction with others, including angioplasty, stent or stent graft placement, and atherectomy. The available angioplasty techniques are balloon angioplasty, cryoplasty, subintimal angioplasty (SA), and cutting balloon. The most commonly used atherectomy techniques include percutaneous atherectomy catheter and laser atherectomy device.

Systemic anticoagulation should be maintained routinely during LE arterial interventions to minimize the risk of pericatheter thrombosis. Unfractionated heparin is the most commonly used agent, given on a weight-based formula. It is a common clinical practice to use a 80 to 100 mg/kg initial bolus for a therapeutic procedure to achieve the activated clotting time above 250 seconds on the catheter insertion and subsequently 1000 units for each additional hour of the procedure. Newer agents such as low molecular weight heparin, platelet IIb/IIIa inhibitor, direct thrombin inhibitor, or recombinant hirudin have been available and can be used either alone or in conjunction with heparin, particularly in patients sensitive to unfractionated heparin. After procedures, all patients are placed on antiplatelet therapy such as aspirin. Additional antiplatelet agents such as clopidogrel (Plavix) are given to selected patients with stent placement for at least 6 weeks after LE interventions, unless otherwise contraindicated.

Percutaneous Transluminal Balloon Angioplasty

After the lesion is crossed with a wire, an appropriate balloon angioplasty catheter is selected and tracked along the wire to traverse the lesion. The length of the selected catheter should be slightly longer than the lesion and the diameter should be equal to the adjacent normal vessel. The balloon tends to be approximately 10 to 20% oversized. The radiopaque markers of the balloon catheter are placed so that they will straddle the lesion. Then, the balloon is inflated with saline and contrast mixture to allow visualization of the insufflation process under the fluoroscopy (Fig. 23-65). The patient may experience mild pain, which is not uncommon. However, severe pain can be indicative of vessel rupture, dissection, or other complications. An angiography is crucial in confirming the intraluminal location of the catheter and absence of contrast extravasation. The inflation is continued until the waist of the atherosclerotic lesion disappears and the balloon is at full profile. Frequently, several inflations are required to achieve full profile of the balloon (Fig. 23-66). Occasionally, a lower profile balloon is needed to predilate the tight stenosis so that the selected balloon catheter can cross the lesion.

A. Angiogram demonstrating a segmental occlusion in the distal superficial femoral artery (*single arrow*). **B.** This lesion was treated with cryoplasty, which lowered the balloon catheter temperature to a temporary freezing state during the balloon angioplasty procedure (*double arrows*). **C.** Completion angiogram demonstrated satisfactory result with no evidence of vessel dissection.

Besides length and diameter, the operators need to be familiar with several balloon characters. Noncompliant and low-compliant balloons tend to be inflated to their preset diameter and offer greater dilating force at the site of stenosis. Low-compliant balloons are the mainstay for peripheral intervention. A balloon with a low profile is used to minimize complication at the entry site and for crossing the tight lesions. Upon inflation, most balloons do not rewrap to their preinflation diameter and assume a larger profile. Furthermore, trackability, pushability, and crossability of the balloon should be considered when choosing a particular type. Lastly, shoulder length is an important characteristic when performing PTA to avoid injury to the adjacent arterial segments. After PTA, a completion angiogram is performed while the wire is still in place. Leaving the wire in place provides access for repeating the procedure if the result is unsatisfactory.

PTA is an established and effective therapy for select patients with LE occlusive diseases. Studies have shown that PTA of the femoropopliteal segment achieved over a 90% technical success rate and a 38 to 58% 5-year primary patency rate.^{148–150} However, efficacy of PTA is highly dependent upon anatomic selection and patient condition.¹⁰⁶ PTA of lesions longer than 7 to 10 cm offer limited patency, while PTA of shorter lesions, such as those that are <3 cm, have fairly good results. Lofberg and associates performed 127 femoropopliteal PTA procedures and reported a primary 5-year success rate of 12% in limbs with an occlusion longer than 5 cm vs. 32% in limbs with an occlusion <5 cm in length.¹⁵¹ Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions,

and heavy calcifications have a negative impact on success rates. A meta-analysis by Hunink and associates showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal lesions varied from 12 to 68%, the best results being for patients with claudication and stenotic lesions.¹⁵⁰ Distal runoff is another powerful predictor of long-term success. Johnston analyzed 254 consecutive patients who underwent femoral and popliteal PTA and reported that 5-year patency rates of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoffs vs. a 5-year patency of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff.¹⁴⁹ Literature reviews showed that 5-year patency rates varied from 27 to 67% based on the runoff statuses.¹⁵⁰

Due to limited success with infrapopliteal PTA, the indication for infrapopliteal artery PTA is stringent, reserved for limb salvage. Current patency rates from infrapopliteal PTA can be improved further by proper patient selection, ensuring straight-line flow to the foot in at least one tibial vessel, and close patient surveillance for early reintervention. Possible future advances including the use of drug-eluting stents (DES), cutting balloons, and atherectomy devices are being investigated to improve clinical outcomes following endovascular interventions on the tibial arteries. Varty and associates reported a 1-year limb salvage rate of 77% in patients with critical ischemia who underwent infrapopliteal PTA.¹⁵² In patients with favorable anatomies, a 2-year limb salvage rate after infrapopliteal artery PTA is expected to exceed 80%.

SUBINTIMAL ANGIOPLASTY

The technique of SA was first described in 1987 when successful establishment of flow was made by accidental creation of a subintimal channel during treatment of a long popliteal artery occlusion. SA is recommended for chronic occlusion, long segments of lesion, and heavily calcified lesions. In addition, this technique is applicable for vessels with diffuse diseases and for vessels that had previously failed an intraluminal approach because it is difficult to negotiate the wire across the entire diseased segment without dissection.

The principle of this technique is to bypass the occlusion by deliberately creating a subintimal dissection plan commencing proximal to the lesion and continuing in the subintimal space before breaking back into the true lumen distal to the lesion. The occluded lumen is recanalized through the subintimal plan. SA can be performed through either ipsilateral antegrade or contralateral retrograde using the CFA approach. If selecting contralateral CFA puncture, a long guiding sheath is placed across the aortic bifurcation to provide access for the femoropopliteal and infrapopliteal vessels. The subintimal dissection is initiated at the origin of an occlusion by directing the tip of an angled guidewire, usually an angled hydrophilic wire such as Glidewire. A supporting catheter is used to guide the tip of the guidewire away from the important collaterals. When the wire is advanced, a loop is naturally formed at the tip of the guidewire. Once the subintimal plan is entered, the wire tends to move freely in the dissection space. Subintimal location of the wire and the catheter can be confirmed by injecting a small amount of diluted contrast. At this point, the wire and the catheter are then advanced along the subintimal plan until the occlusion segment is passed. A loss of resistance is often encountered as the guidewire re-enters the true lumen distal to the occlusion. Recanalization is confirmed by advancing the catheter over the guidewire beyond the point of re-entry and obtaining an angiogram. This is followed by a balloon angioplasty. To confirm the patency following balloon dilatation, a completion angiogram is performed before withdrawing the catheter and wire. If flow is impaired, repeat balloon dilatation may be necessary. Frequently, a stent is required to maintain a patent lumen and treat residual stenosis if more than a 30% luminal reduction is confirmed on completion angiogram.

Multiple studies have demonstrated the efficacy of SA. Bolia and his colleagues and London and his colleagues reported their extensive experiences on SA for treating long segment occlusions of infrainguinal vessels.^{153,154} They achieved a technical success rate of over 80% for both femoropopliteal and tibial arteries. One-year patency rates varied from 53% for

infrapopliteal vessels to 71% for femoropopliteal segments. Limb salvage rates reached over 80% at 12 months. They also reported that the factors influencing patency are smoking, number of runoff vessels, and occlusion length. Studies by other groups showed similar results.^{155,156} Treiman and colleagues treated 25 patients with 6- to 18-cm femoropopliteal occlusion and achieved a technical success rate of 92% and a 12-month primary patency rate of 92%,¹⁵⁶ while Lipsitz and associates reported a technical success rate of 87% in treating 39 patients and achieved a 12-month cumulative patency rate of 74%.¹⁵⁵ Additionally, Ingle and associates reported a technical success rate of 87% on 67 patients with femoropopliteal lesions and a 36-month limb salvage rate of 94%.¹⁵⁷ As demonstrated herein, although technical success rates are similar in most series, the patency rates vary widely in different studies. Patient selection, anatomic character, and lesion locations may account for the wide range of outcomes.

STENT PLACEMENT

Although suggested by Dotter during the late 1960s, the use of an endoluminal stent was not pursued until the limitations of PTA were widely recognized. There are several situations where stent placement is appealing. The primary indication is the potential salvage of an unacceptable angioplasty result. Stent placement is typically used when residual stenosis after PTA is 30% or greater. An endoluminal stent is also used for dissection, perforation, and other PTA complications. Primary stent placement has become a viable alternative for treating ulcerative lesions that may potentially be the source for embolization. Primary stent is also used to treat occlusive lesions that have a tendency of reocclusion and distal embolization after PTA. In addition, an endoluminal stent is potentially beneficial for early restenosis post-PTA. DESs are currently under investigation in the United States and may be promising in decreasing restenotic rates.

Even though technical success rates are high, a published series on femoropopliteal artery stents show that patency rates are comparable to PTA alone with primary patency rates varying from 18 to 72% at 3 years.^{106,158} Gray and associates stented 58 limbs after suboptimal PTA for long SFA lesions and demonstrated a 1-year primary patency rate of 22%.¹⁵⁹ However, Mewissen treated 137 limbs using self-expanding SMART nitinol stents in patients with TASC II A, B, and C femoropopliteal lesions and reported a 1-year primary patency rate of 76% and a 24-month primary patency rate of 60%.¹⁶⁰ Appropriate patient selection and the anatomic characteristics of the lesions are crucial in the success of treatment outcomes. Additionally, stent characteristics may contribute to the patency rate.

Several clinical studies have demonstrated the significant improvements of the new generation of nitinol stents for the SFA lesions: the German Multicenter Experience, the Mewissen trial, the BLASTER Trial, and the SIROCCO trials.¹⁶¹ The German Multicenter Experience was a retrospective review of 111 SFA stenting procedures and found the 6-month patency rates for Smart stents and Wall stents were 82% and 37%, respectively. The BLASTER (Bilateral Lower Arterial Stenting Employing Reopro) Trial evaluated the feasibility of using nitinol stents with and without IV abciximab for the treatment of femoral artery disease. Preliminary results showed a 1-year clinical patency rate of 83%.¹⁶²

Furthermore, DESs, which proved effective at decreasing restenosis in coronary intervention, may offer another promising alternative in LE diseases. The drug, released over a period of time, interferes with smooth muscle cell proliferation, the main cellular element and source of extracellular-matrix-producing restenosis. The first DES clinical trial used Cordis Cypher SMART stents coated with sirolimus (SIROCCO trial).¹⁶³ The SIROCCO results showed binary inlesion restenosis rates of 0% in the sirolimus-eluting group vs. 23.5% in the noneluting group at 6-month follow-up angiography.

STENT GRAFT

The concept of endobypass using stent graft in treating atherosclerotic SFA disease has been entertained. A stent graft is

placed percutaneously across a long segment or multiple segments of lesions and is used to create a femoropopliteal bypass. Theoretically, endobypass has the potential of being as successful as surgical bypass graft by relining the vessel wall in its anatomical position without the negative impact of anastomosis. Stent grafts can be divided into two categories: unsupported and fully supported. The unsupported grafts consist of segments of bypass graft, such as PTFE, with an expandable stent at one or both ends. The unsupported grafts are flexible with a low profile, but prone to external compression. The supported stent grafts consist of a metallic skeleton covered with graft fabric. The presence of a dense metal skeleton promotes an extensive inflammatory response and increases the risk of thrombosis. There is no FDA-approved stent graft for peripheral intervention. However, Viabahn (WL Gore, Calif) is the most commonly used device in the United States, composed of an ultrathin PTFE graft externally supported by a self-expanding nitinol meshwork. The Viabahn device has a specific delivery mechanism—pulling back the attached string—which results in a proximal-to-distal delivery of the endoprosthesis.

Although it is an intriguing concept, data on endobypass results are limited and the graft thrombosis rate is high. Additionally, covering major collateral vessels can potentially jeopardize the viability of the limb if stent graft occlusion occurs. Bauermeister treated 35 patients with Hemobahn and reported a 28.6% occlusion rate on an average 7-month follow-up.¹⁶⁴ Kedora and colleagues recently conducted a prospective, randomized study comparing covered PTFE/nitinol self-expanding stent grafts with prosthetic above-the-knee femoropopliteal bypass. Fifty limbs were randomized into each group. Primary patency at 1-year was approximately 74% for both cohorts, with a mean follow-up of 18 months. The covered nitinol PTFE stent graft in the SFA had a 1-year patency rate comparable to surgical bypass, with a significantly shorter hospital stay (0.9 vs. 3.1 days).¹⁶⁵

ATHERECTOMY

The basic principle of atherectomy is to remove the atheroma from obstructed arterial vessels. There are currently five atherectomy devices approved by the FDA: Simpson AtheroCath (DVI, Redwood City, Calif), Transluminal Extraction Catheter (Interventional Technologies, San Diego, Calif), Theratec recanalization arterial catheter (Trac-Wright), Auth Rotablator (Heart Technologies, Redmond, Wash), and SilverHawk system (FoxHollow Technologies, Redwood City, Calif). These devices either cut and remove or pulverize the atheroma plaques.

The Simpson AtheroCath has a directional cutting element that is exposed to one third of the circumference of the arterial wall. The atheroma protruding into the window is excised and pushed into the collection chamber. The Transluminal Extraction Catheter has an over-the-wire, nondirectional cutter mounted on the distal end of a torque tube. The excised atheroma is simultaneously removed by aspiration through the torque tube. The Theratec recanalization arterial catheter is a nondirectional, noncoaxial, atheroablative device. The rotating cam tip pulverizes the atheromatous lesion into minute particles. The Auth Rotablator is a nondirectional, coaxial, atheroablative device with a metal burr embedded with fine diamond chips. Lastly, the SilverHawk device, approved by the FDA for peripheral use in 2003, is a monorail catheter designed to overcome the drawback of direction atherectomy catheter, such as the Simpson AtheroCath. The working end consists of a hinged housing unit containing a carbide cutting blade. The blade is activated from the motor drive unit and the catheter is then advanced through the length of the lesion. Once each pass is completed, the cutter then packs the tissue into the distal end of the nosecone to maximize collection capacity. The SilverHawk can then either be removed or torqued to treat a different quadrant in the same lesion or other lesions.

Despite the promising early technical and clinical success, the mid- and long-term results have been disappointing due to a high incidence of restenosis. However, a multicenter clinical registry of plaque atherectomy in patients with femoropopliteal occlusive disease showed potential clinical efficacy of this technology as the 6- and 12-month rates of survival free of target

lesion revascularization were 90 and 80%, respectively.¹⁶⁶ Importantly, nearly three fourths (73%) of patients treated with plaque excision modality did not require adjunctive endovascular therapy as infrainguinal stenting was necessary in only 6.3% of lesions. Results from the TALON registry support the role of plaque excision in selective patients with LE arterial disease.¹⁶⁶

Laser Atherectomy

Since laser atherectomy was reported in the 1960s, a variety of innovative approaches have been developed in an effort to overcome the limitation of laser angioplasty. Recent developments in excimer laser technology have led to increased optimism regarding the ability to safely deliver laser energy. Excimer laser atherectomy approved by the FDA for peripheral artery intervention uses precision laser energy control (shallow tissue penetration) and safer wavelengths (ultraviolet as opposed to the infrared spectra in older laser technology), which decreases perforation and thermal injury to the treated vessels.

A laser atherectomy catheter, with diameters varying from 0.9 mm to 2.5 mm, is tracked over the guidewire to the desired target. Once activated, the excimer laser uses ultraviolet energy to ablate the lesion and create a nonthrombogenic arterial lumen. This lumen is further dilated by an angioplasty balloon. Because the excimer laser can potentially reduce the rate of distal embolization by evaporating the lesion, it may be used as an adjunct tool for ostial lesions and lesions that can be traversed by a wire but not an angioplasty balloon catheter.

Several studies regarding the use of excimer laser atherectomy combined with balloon angioplasty on LE occlusive disease have shown promising clinical outcomes.^{167,168} Peripheral excimer laser angioplasty trials involved 318 patients with chronic SFA occlusion. They achieved a technical success rate of 83.2%, a 1-year primary patency rate of 33.6%, and an assisted primary patency rate of 65%.¹⁶⁸ Steinkamp and his colleagues treated 127 patients with long-segment of popliteal artery occlusion using laser atherectomy followed by balloon angioplasty and reported a 3-year primary patency rate of 22%.¹⁶⁹ The multicenter clinical trial evaluating the use of laser angioplasty for critical limb ischemia supports the efficacy of this treatment modality in selective patients as the 6-month primary patency rate and clinical improvement were 33 and 89%, respectively.¹⁶⁷

Complications of Endovascular Interventions

ANGIOPLASTY-RELATED COMPLICATIONS

Complications related to PTA vary widely, including dissection, rupture, embolization, pseudoaneurysms, restenosis, hematoma, and acute occlusion secondary to thrombosis, vasospasm, or intimal injury. Clark and associates analyzed the data from 205 patients in the SCVIR Transluminal Angioplasty and Revascularization registry and reported a complication rate of 7.3% for patients undergoing femoropopliteal angioplasty.¹⁷⁰ Minor complications accounted for 75% of the cases, including distal emboli (41.7%), puncture site hematomas (41.7%), contained vessel rupture (8.3%), and vagal reactions (8.3%). In another study, Axisa and colleagues reported an overall rate of significant complications for patients undergoing PTA of the lower extremities as 4.2%, including retroperitoneal bleeding (0.2%), false aneurysm (0.2%), ALI (1.5%), and vessel perforation (1.7%).¹⁷¹

Complications limiting the application of SA are parallel to those of PTA. A study investigating the use of SA in 65 patients with SFA occlusion found that complications developed in 15% of patients.¹⁷² These complications included significant stenosis (44%), SFA rupture (6%), distal embolization (3%), retroperitoneal hemorrhage (1.5%), and pseudoaneurysm

(1.5%). Additional complications reported consist of perforation, thrombosis, dissection, and extensions beyond the planned re-entry site.¹⁷³ Importantly, damage to significant collateral vessels may occur in 1 to 1.5% of patient who undergo SA. If a successful channel is not achieved in this situation, the patient may have a compromised distal circulation that necessitates distal bypass. Cryoplasty is a modified form of angioplasty, and long-term results on LE intervention are not yet available. Fava and associates treated 15 patients with femoropopliteal disease and had a 13% complication rate involving guidewire dissection and PTA-induced dissection of a tandem lesion remote to the cryoplasty zone.¹⁷⁴

ENDOLUMINAL STENT AND STENT GRAFT–RELATED COMPLICATIONS

In addition to the aforementioned complications with angioplasty, endoluminal stents are associated with the risk of stent fracture and deformity. The adductor canal has nonlaminar flow dynamics, especially with walking. The forces exerted on the SFA include torsion, compression, extension, and flexion. These forces exert significant stress on the SFA and stents. In addition, the LE is subject to external trauma, which further increases the risk of stent deformity and fracture (Fig. 23-67). The SIROCCO study showed that stent fracture, although not associated with clinical symptoms, occurs in 18.2% of the procedures involving both the DES and control stent.¹⁶³

Fig. 23-67.

Source: Brunicardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*; <http://www.accessmedicine.com>

Due to various geometric forces, including torsion, compression, extension, and flexion, which exert on the superficial femoral artery, stent fracture (*arrows*) is a known complication following superficial femoral artery stent placement.

Stent grafts may present an additional complication of covering important collaterals, which results in compromised distal

circulation. A prospective study evaluating Hemobahn stent grafts in the treatment of femoropopliteal arterial occlusions demonstrated a 23% immediate complication rate, including distal embolization (7.7%), groin hematoma (13.5%), and arteriovenous fistula (1.9%).¹⁷⁵

ATHERECTOMY-RELATED COMPLICATIONS

Overall complication rates associated with atherectomy range from 15.4 to 42.8% and include spasm, thrombosis, dissection, perforation, distal emboli, no reflow, and hematoma.^{176,177} Jahnke and associates conducted a prospective study evaluating high-speed, rotational atherectomy in 15 patients with infrapopliteal occlusive disease. They yielded a 94% technical success rate, which was complicated by vessel rupture (5%), distal embolization (5%), and arterial spasm (5%).¹⁷⁵ Although the excimer laser atherectomy reduces embolic events by evaporating the lesion, embolization still remains a problematic complication. Studies show that distal embolic events occur in 3 to 4% of procedures, and perforation in 2.2 to 4.3% of cases.^{168,169} Other complications compromising laser atherectomy therapy include acute reocclusion, vasospasm, direct vessel injury, and dissection.

Surgical Treatment for Chronic Limb Ischemia Due to Femoropopliteal Disease

ENDARTERECTOMY

Endarterectomy has a limited, albeit important, role in LE occlusive disease. It is most frequently used when there is disease in the CFA or involving the PFA. In this procedure, the surgeon opens the diseased segment longitudinally and develops a cleavage plane within the media that is developed proximally and distally. This permits the inner layer containing the atheroma to be excised. Great care must be taken at the distal end of the endarterectomy to ensure either a smooth transition or to tack down the distal endpoint to prevent the flow from elevating a potentially occlusive atheromatous flap. Currently, there is essentially no role for long open endarterectomy in the treatment of SFA stenoses or occlusions. The high incidence of restenosis is what limits use of endarterectomy in this location. Short-segment stenoses are more appropriately treated with balloon angioplasty. Endarterectomy using a catheter-based approach (e.g., Moll endarterectomy device) supplemented with stent grafting or stenting across the endpoint of the endarterectomy is currently being re-evaluated; however, no long-term data are available.

BYPASS GRAFTING

Bypass grafting remains the primary intervention for LE occlusive disease. The type of bypass and conduit are important variables to consider. Patients with occlusive disease limited to the SFA, who have at least 4 cm (ideally 10 cm) of normal popliteal artery reconstituted above the knee joint and at least one continuous vessel to the foot, can be treated with an above-knee (AK) femoropopliteal bypass graft. Despite the fact that in this above-knee location, the differential patencies between prosthetic (PTFE) and vein graft are comparable; undoubtedly, it remains ideal to use a saphenous vein as the bypass conduit, if possible. Saving the vein for future coronary artery bypass or distal leg bypass grafting has been shown to be a flawed argument. One must also take into consideration that the consequences to the vascular outflow after a thrombosed prosthetic are worse than after a thrombosed vein graft.

When the disease extends to involve the popliteal artery or the tibial vessels, the surgeon must select an appropriate outflow vessel to perform a bypass. Suitable outflow vessels are defined as uninterrupted flow channels beyond the anastomosis into the foot. In order of descending preference, they are: AK popliteal artery, below-knee (BK) popliteal artery, posterior tibial artery, anterior tibial artery, and peroneal artery. In patients with diabetes, it is frequently the peroneal artery that is

spared. Although the peroneal artery has no direct flow into the foot, collateralization to the posterior tibial and anterior tibial arteries makes it an appropriate outflow vessel. There is no objective evidence to preferentially select tibial over peroneal arteries if they are vessels of equal caliber and quality. The dorsalis pedis, which is the continuation of the anterior tibial in the foot, is frequently spared from atherosclerotic disease and can be used as a target for distal bypasses. Patency is affected by the length of the bypass (longer bypasses have reduced patency), quality of the recipient artery, extent of runoff to the foot, and quality of the conduit (saphenous vein/graft). Five-year assisted patency rates for infrapopliteal venous bypasses are 60%. Venous conduits also have been shown to be suitable for bypasses to plantar arteries. In this location, venous conduits have a 3-year limb salvage of 84% and a 3-year secondary patency of 74%.² A meta-analysis suggests unsatisfactory results when PTFE-coated grafts are used to bypass to infrapopliteal arteries. In this location, prosthetic grafts have a 5-year primary patency rate of 30.5%.¹⁷⁸ Additionally, due to distal embolization and compromise of outflow vessels, prosthetic graft occlusion may have more severe consequences than vein graft occlusion.¹⁷⁸

Two techniques are used for distal bypass grafting: reversed saphenous vein grafting and in situ saphenous vein grafting. There is no difference in outcomes (patency or limb salvage) between these techniques.² In the former, the vein is excised in its entirety from the leg using open or endoscopic vein harvest, reversed to render the valves nonfunctional, and tunneled from the CFA inflow to the distal target vessels. End-to-side anastomoses are then created.

Several adjunctive techniques have been tried to improve the patency of bypass grafts to tibial arteries. Creation of an arteriovenous fistula at the distal anastomosis is one option, but it has not been shown to improve patency.¹⁷⁹ Another method involves creating various configurations of vein cuffs or patches at the distal anastomosis in an attempt to streamline the flow and to reduce the likelihood of neointimal hyperplasia. Results with this approach are more promising, especially when done to improve patency of a below-the-knee prosthetic; however, there are no definitive comparative trials that support the superiority of one configuration over another.

AMPUTATION

Primary amputation is defined as an amputation that is performed without a prior attempt at surgical or endovascular revascularization. It is rarely necessary in patients who, as a result of neglect, present with class III ALI. Primary amputation may play a role in patients with critical limb ischemia who are deemed nonambulatory because of knee contractures, debilitating strokes, or dementia.

Complications of Surgical Reconstruction

VEIN GRAFT STENOSES

Fifteen percent of vein grafts will develop intrinsic stenoses within the first 18 months following implantation. Consequently, patients with a vein graft were entered into duplex surveillance protocols (scans every 3 months) to detect elevated (>300 cm/s) or abnormally low (<45 cm/s) graft velocities early. Stenoses greater than 50%, especially if associated with changes in ABI, should be repaired to prevent graft thrombosis. Repair usually entails patch angioplasty or short-segment venous interposition, but PTA/stenting is an option for short, focal lesions. Grafts with stenoses that are identified and repaired before thrombosis have assisted primary patency identical to primary patency, whereas a thrombosed autogenous bypass has limited longevity, resulting from ischemic injury to the vein wall. Secondary patency is markedly inferior to primary assisted patency. The recommendation for routine duplex ultrasound surveillance of autogenous infrainguinal bypasses was recently brought into question by a randomized, controlled trial that demonstrated no cost benefit or quality-of-life

improvement after 18 months in patients with femoropopliteal venous bypasses. Many surgeons continue with programs of vein graft surveillance, as has been suggested in older trials, awaiting further confirmation of the findings from the more recent study. When intervening on a failing infrainguinal bypass, the original indication for surgery is an important consideration. Limb salvage rates for occluded grafts are better if the indication for the original bypass was claudication rather than rest pain or tissue loss. An acutely occluded infrainguinal graft (≤ 30 postoperative days) has a 25% limb salvage rate.¹⁸¹

LIMB SWELLING

Limb swelling is common following revascularization and usually returns to baseline within 2 to 3 months. The etiology is multifactorial, with lymphatic interruption, interstitial edema, and disruption of venous drainage all contributing. Limb swelling tends to worsen with repeat revascularization (see Table 23-22).

WOUND INFECTION

Because the most common inflow vessel for distal bypass is the CFA, groin infection is common and occurs in 7% of cases.¹⁸² When an autogenous conduit such as a saphenous vein is used, most infection can be managed with local wound care because it involves the subcutaneous tissue or skin rather than infection of the actual vein. When a prosthetic graft has been used, management of graft infection is a major undertaking. Infection of a LE prosthetic bypass graft is associated with a significant amputation rate because of the tendency for graft thrombosis and anastomotic disruption. Prosthetic graft infections cannot be eradicated with antibiotics, and they mandate graft excision and complex revascularization using a vein, if available.

Choice of Conduit for Infrainguinal Bypass Grafting

AUTOGENOUS VEIN

Autogenous vein is superior to prosthetic conduits for all infrainguinal bypasses, even in the AK position. This preference is applicable not only for the initial bypass but also for reoperative cases. For long bypasses, ipsilateral great saphenous vein (GSV), contralateral GSV, small saphenous vein, arm vein, and spliced vein are used, in decreasing order of preference. If only a short segment of vein is missing, the SFA can be endarterectomized and the proximal anastomosis performed distally to decrease the length of the conduit and to avoid harvesting and splicing additional vein. When GSV is not available and a relatively short bypass is necessary, arm vein or small saphenous vein is effective. Small saphenous vein is of particular use when a posterior approach is used. If a longer bypass with vein is necessary, arm vein is preferable because it is less awkward to harvest. Another conduit alternative is to harvest the upper arm basilic, median cubital, and cephalic veins in continuity, while incising valves in the basilic segment and using the cephalic segment in reversed configuration to provide a relatively long, unspliced autogenous conduit.¹⁸³

CRYOPRESERVED GRAFTS

Cryopreserved grafts are usually cadaveric arteries or veins that have been subjected to rate-controlled freezing with dimethyl sulfoxide and other cryopreservants. Cryopreserved vein grafts are more expensive than prosthetic grafts and are more prone to failure. The endothelial lining is lost as part of the freezing process, making these grafts prone to early thrombosis. Cryopreserved grafts also are prone to aneurysmal degeneration. Despite the fact that these grafts have not performed as well as prosthetic bypasses and autogenous vein in clinical practice, they can still play a role when revascularization is required following removal of infected prosthetic bypass grafts, especially when autogenous vein is

unavailable to create a new bypass through clean tissue planes.¹⁸⁴

HUMAN UMBILICAL VEIN

Human umbilical vein (HUV) is less commonly used than PTFE, because it is thicker and more cumbersome to handle and because of concerns about aneurysmal degeneration. HUV allografts are stabilized with glutaraldehyde and do not have viable cells or antigenic reactivity. These grafts have poor handling characteristics and require extra care when suturing because of an outer Dacron mesh wrapping, which is used to decrease aneurysmal degeneration. Dardik and colleagues have reported favorable results after using HUV and an adjunctive distal arteriovenous fistula.¹⁸⁵ One trial comparing HUV with PTFE and saphenous vein showed that HUV was better than PTFE but worse than saphenous vein in terms of 5-year patency in the AK location.¹⁸⁶ In a systematic review, HUV appears to perform better than cryopreserved veins.¹⁸⁷

PROSTHETIC CONDUITS AND ADJUNCTIVE MODIFICATIONS

If vein is truly unavailable, PTFE or Dacron is the best option for AK bypass. The addition of rings to PTFE did not confer benefit in a single prospective, randomized clinical trial.¹⁸⁸ For infrageniculate prosthetic bypasses, use of a vein patch, cuff, or other venous anastomotic modification can improve patency (52% patency at 2 years for PTFE with vein cuff vs. 29% for PTFE with no cuff) and also improve limb salvage (84% vs. 62%).¹⁸⁹

Although prosthetic grafts are readily available, easy to handle, and do not require extensive dissection to harvest, their propensity to undergo thrombosis and develop neointimal hyperplasia makes them a less favorable alternative when compared to vein. In a recent review of vein and prosthetic AK femoropopliteal bypasses, the 5-year primary patency rates were reported to be 74 and 39%, respectively.¹⁹⁰ Outcomes were even worse for BK prosthetic bypasses. Unfortunately, the use of autologous venous conduits is not possible in as many as 30% of patients. The GSV may be unsuitable because of small size and poor quality or unavailable due to prior harvest.

Methods to improve prosthetic graft performance have consisted of altering the geometry at the distal anastomosis to get the benefit obtained with vein cuffs (Distaflo, Bard Peripheral Vascular, Tempe, Ariz) and covalently bonding agents onto the luminal surface with anticoagulant, anti-inflammatory and antiproliferative characteristics (Propaten, Gore, Flagstaff, Ariz). One randomized trial that compared precuffed PTFE and PTFE with a vein cuff enrolled 104 patients at 10 centers. Eighty-nine patients were randomized to 47 precuffed PTFE bypasses and 44 bypasses with a vein cuff. At 1 and 2 years, primary patency rates were 52 and 49% for the precuffed group and 62 and 44% for the vein cuffed group, respectively. At 1 year and 2 years, the limb salvage rate was 72 and 65% for the precuffed group and 75 and 62% in the vein cuffed group, respectively. Although numbers are small and follow-up short, the midterm analysis revealed that Distaflo precuffed grafts and PTFE grafts with vein cuff had similar results. The authors concluded that a precuffed graft was a reasonable alternative for infragenicular reconstruction in the absence of saphenous vein.¹⁹¹ Other authors have been less optimistic and question if there is any benefit derived from geometrically altering prosthetic conduits.¹⁹²

Another approach for improving outcomes when using prosthetic for bypass grafts involves bonding anticoagulants to the conduit. The Gore Propaten graft has heparin bonded onto the luminal surface of the PTFE graft using Carmeda BioActive Surface technology, which immobilizes the heparin molecule with a single covalent bond that does not alter its anticoagulant properties.¹⁹³ The heparin binding does not alter the microstructure and handling characteristics of the PTFE. A prospective, randomized trial by Devine and associates suggested that heparin-bonded Dacron or PTFE was superior to plain PTFE for AK popliteal bypasses. The 3-year primary patency for the heparin-bonded grafts was 55% compared with 42% for PTFE ($P < .044$). Both of these patency rates are inferior to GSV; however, if the improved results with heparin bonding continue to

be substantiated, then heparin-bonded prosthetic grafts will become the preferred conduit for AK bypass in the absence of suitable vein.¹⁹⁴ A recent review of available studies with this graft showed an 80% 1-year patency for BK bypasses.¹⁹⁵ Randomized, controlled clinical trials with more patients and longer follow-up are necessary to validate whether the PROPATEN vascular graft is superior to other prosthetics, and if, indeed, it is comparable to autogenous vein for BK interventions.

Clinical Results of Surgical and Endovascular Interventions for Femoropopliteal Occlusive Disease

Balloon angioplasty of the femoropopliteal vessels has not enjoyed the degree of success seen with iliac angioplasty. Patency in this region is dependent upon whether the patient presents with claudication vs. limb-threatening ischemia, the status of the distal runoff vessels, and lesion morphology.² Initial technical success for femoropopliteal angioplasty is seen in 80 to 90% of cases, with failures to cross a lesion occurring in 7% of stenoses and 18% of occlusive lesions. Studies have shown that PTA of the femoropopliteal segment achieved greater than a 90% technical success rate and had a 59% primary patency rate at 5-years.^{148,149} PTA of lesions longer than 7 to 10 cm results in compromised patency, while PTA of shorter lesions (<3 cm) gives fairly good results. Lofberg and associates performed 127 femoropopliteal PTA procedures and reported a primary patency rate at 5-year follow-up of 12% in limbs with occlusion longer than 5 cm vs. 32% in limbs with occlusion <5 cm in length.¹⁵¹ Occlusive lesions have much worse initial technical success rates than stenotic lesions. Concentric lesions respond better to PTA than eccentric lesions, and heavy calcifications have a negative impact on success rates. Distal runoff is another powerful predictor of long-term success.

Johnston and associates analyzed 254 consecutive patients who underwent femoropopliteal PTA and reported a 5-year patency rate of 53% for stenotic lesions and 36% for occlusive lesions in patients with good runoff vs. 5-year patency of 31% for stenotic lesions and 16% for occlusive lesions in patients with poor runoff.¹⁴⁹ A meta-analysis by Hunink and colleagues showed that adjusted 5-year primary patencies after angioplasty of femoropopliteal lesions varied from 12 to 68%, the best results occurring in patients with claudication and stenotic lesions.¹⁵⁰ Although the initial technical success is better for stenoses than occlusions, long-term patency rates for stenoses and short occlusions have been variable and there have been conflicting results regarding the efficacy of stent use. Early published series that examined efficacy of femoropopliteal artery stents showed patency rates that were comparable to stand-alone PTA with primary patency rates varying from 18 to 72% at 3 years.¹⁵⁸ Patient selection and the anatomic character of the lesions may play important roles in the outcomes. Additionally, stent characteristics may contribute to the patency rate. Several clinical studies have demonstrated significant improvements in patency when the newer generations of nitinol stents are used to treat SFA lesions.^{160,196}

Mewissen treated 137 lower limbs in 122 patients with CLI, secondary to TASC II A ($n = 12$) or TASC II B or C ($n = 125$) lesions in the SFA. Patients were treated with Cordis SMART self-expanding nitinol stents. Binary restenosis (>50%) was measured by standard duplex velocity criteria at various postintervention intervals. Primary stent patency, defined as absence of binary restenosis in this study, was calculated by life table methods from the time of intervention. The mean lesion length was 12.2 cm (range, 4 to 28 cm). The technical success was 98%. Mean follow-up was 302 days. The primary stent patency rates were 92%, 76%, 66%, and 60% at 6, 12, 18, and 24-months, respectively.¹⁶⁰ Ferreira and associates treated 59 patients who had 74 femoropopliteal lesions (60% TASC II D) with Zilver nitinol self-expanding stents (COOK, Bloomington, Ind). Mean recanalization length was 19 cm (range 3 to 53 cm). Mean follow-up time was 2.4 years (range 3 days to 4.8 years). Kaplan-Meier estimates for primary patency rates were 90%, 78%, 74%, 69%, and 69% at 1, 2, 3, 4,

and 4.8 years, respectively.¹⁹⁷

There is general agreement that for suboptimal PTA of an SFA lesion, stent placement is indicated, but a recent randomized trial by Schillinger and associates suggests that primary stenting results in lower restenosis rates than PTA and selective stenting. Restenosis rates at 2 years were 45.7% vs. 69.2% in favor of primary stenting compared with PTA and optional secondary stenting using an intention-to-treat analysis ($P = .031$). Consistently, stenting, both primary and selective, was superior to stand-alone PTA with respect to the occurrence of restenosis (49.2% vs. 74.3%; $P = .028$) by a treatment-received analysis.¹⁹⁸

Nitinol bare metal stents that are designed specifically for BK interventions are showing very encouraging results. Bosiers and colleagues reported their 12-month results using the commercially available non-drug-eluting Xpert (Abbott Vascular, Santa Clara, Calif) nitinol stent system in BK arterial interventions.¹⁹⁹ They had a 12-month primary patency rate of 76.3%, and a limb salvage rate of 95.9%. They followed patients to 12 months and performed angiography with quantitative vessel analysis on the 73% of patients available. Angiography revealed a binary restenosis rate (>50%) of only 20.5%, which is comparable to well-accepted coronary DES study outcomes. The authors attributed this optimal performance to the maintenance of flow dynamics because the stent was specifically designed for use in small vessels.¹⁹⁹ Kickuth and colleagues also have obtained good results using the Xpert stent. After stent placement, the primary cumulative patency rate at 6 months for the study group of 35 patients was 82%. The sustained clinical improvement rate as evidenced by improved ABI was 80%, and freedom from major amputation was 100% at the 6-month follow-up. The rate of major complications was 17%.²⁰⁰

Wolf and associates published a multicenter, prospective randomized trial comparing PTA with bypass in 263 men who had iliac, femoral, or popliteal artery obstruction.²⁰¹ In 56 patients, cumulative 1-year primary patency after PTA was 43% and, after bypass surgery, was 82%, demonstrating that for long SFA stenoses or occlusions, surgery is better than PTA. Another recent randomized study (BASIL trial) of 452 patients with CLI demonstrated no difference in amputation-free survival at 6 months between surgery and PTA/stenting. The authors commented that surgery was somewhat more expensive and recommended that endovascular intervention should be used as first-line therapy, especially in medically unfit patients. They did conclude that at 2-year follow-up, healthy patients without medical comorbidities derived greater benefit from surgery because it was associated with decreased need for reintervention and had a decreased hazard ratio in terms of all-cause mortality.²⁰² Using the 2000 TASC II definitions and a Markov state transition model decision analysis, Nolan and colleagues showed that PTA/stenting surpasses bypass efficacy for TASC II C lesions if PTA/stenting primary patency is greater than 32% at 5 years, patient age is >80 years, and/or GSV bypass operative mortality is greater than 6%.^{106,203}

NON-ATHEROSCLEROTIC DISORDERS OF BLOOD VESSELS

The majority of cases of peripheral vascular disease that are seen by vascular surgeons are attributable to underlying atherosclerosis. Non-atherosclerotic disease states that result in arterial pathology are less commonly encountered, but are nonetheless important, as they are potentially treatable lesions that may mimic atherosclerotic lesions and result in vascular insufficiency (see Table 23-18). A thorough knowledge of these rare disease states is important for the practicing vascular surgeon to make medical recommendations and provide appropriate surgical treatment.

Giant Cell Arteritis (Temporal Arteritis)

Giant cell arteritis is also known as *temporal arteritis*, which is a systemic chronic inflammatory vascular disease with many characteristics similar to those of Takayasu's disease. The histologic and pathologic changes as well as laboratory findings

are similar. Patients tend to be white women over the age of 50 years old, with a high incidence in Scandinavia and among women of Northern European descent. Genetic factors may play a role in disease pathogenesis, with a human leukocyte antigen (HLA) variant having been identified. Differences exist between Takayasu's and giant cell arteritis in terms of presentation, disease location, and therapeutic efficacy. The inflammatory process typically involves the aorta and its extracranial branches, of which the superficial temporal artery is specifically affected.

The clinical syndrome begins with a prodromal phase of constitutional symptoms, including headache, fever, malaise, and myalgia. The patients may be initially diagnosed with coexisting polymyalgia rheumatica; an HLA-related association may exist between the two diseases. As a result of vascular narrowing and end-organ ischemia, complications may occur such as visual alterations, including blindness and mural weakness, resulting in acute aortic dissection that may be devastating. Ischemic optic neuritis resulting in partial or complete blindness occurs in up to 40% of patients and is considered a medical emergency. Cerebral symptoms occur when the disease process extends to the carotid arteries. Jaw claudication and temporal artery tenderness may be experienced. Aortic lesions usually are asymptomatic until later stages and consist of thoracic aneurysms and aortic dissections.

The diagnostic gold standard is a temporal artery biopsy, which will show the classic histologic findings of multinucleated giant cells with a dense perivascular inflammatory infiltrate. Treatment regimens are centered on corticosteroids, and giant cell arteritis tends to rapidly respond. Remission rates are high, and treatment tends to have a beneficial and preventative effect on the development of subsequent vascular complications.

Takayasu's Arteritis

Takayasu's arteritis is a rare but well-recognized chronic inflammatory arteritis affecting large vessels, predominantly the aorta and its main branches (Table 23-27).²⁰⁴ Chronic vessel inflammation leads to wall thickening, fibrosis, stenosis, and thrombus formation. Symptoms are related to end-organ ischemia. The acute inflammation can destroy the arterial media and lead to aneurysm formation. This rare autoimmune disease occurs predominantly in women between the ages of 10 and 40 years old who are of Asian descent. Genetic studies have demonstrated a high frequency of HLA haplotypes in patients from Japan and Mexico, suggesting increased susceptibility to developing the disease in patients with certain alleles. However, these associations have not been seen in North America. Vascular inflammation leads to arterial wall thickening, stenosis, and eventually, fibrosis and thrombus formation. The pathologic changes produce stenosis, dilation, aneurysm formation, and/or occlusion.

Table 23-27 Angiographic Classification of Takayasu's Arteritis	
Type	Vessel Involvement
I	Branches from the aortic arch
IIa	Ascending aorta, aortic arch and its branches
IIb	Ascending aorta, aortic arch and its branches, thoracic descending aorta
III	Thoracic descending aorta, abdominal aorta, and/or renal arteries
IV	Abdominal aorta and/or renal arteries
V	Combined features of types IIb and IV

Involvement of the coronary or pulmonary arteries are designated as C (+) or P (+), respectively.

The clinical course of Takayasu's arteritis begins with a "prepulseless" phase in which the patient demonstrates constitutional

symptoms. These include fever, anorexia, weight loss, general malaise, arthralgias, and malnutrition. As the inflammation progresses and stenoses develop, more characteristic features of the disease become evident. During the chronic phase, the disease is inactive or "burned out." It is during this latter stage that patients most frequently present with bruits and vascular insufficiency according to the arterial bed involved. Laboratory data may show elevations in erythrocyte sedimentation rate, C-reactive protein, white blood cell count, or conversely, anemia may predominate. Characteristic clinical features during the second phase vary according to the involved vascular bed and include hypertension reflecting renal artery stenosis, retinopathy, aortic regurgitation, cerebrovascular symptoms, angina and congestive heart failure, abdominal pain or GI bleeding, pulmonary hypertension, or extremity claudication.

The gold standard for diagnosis remains angiography showing narrowing or occlusion of the entire aorta or its primary branches, or focal or segmental changes in large arteries in the upper or lower extremities. Six types of Takayasu's arteritis exist and are graded in terms of severity: type I, affecting the aorta and arch vessels; type IIa, affecting the ascending aorta, aortic arch, and branches; type IIb, affecting the ascending aorta, aortic arch and branches, and thoracic descending aorta; type III, affecting the thoracic descending aorta, abdominal aorta, and/or renal arteries; type IV, affecting the abdominal aorta and/or renal arteries; and type V, with combined features of types IIb and IV.²⁰⁴

Treatment consists of steroid therapy initially, with cytotoxic agents used in patients who do not achieve remission. Surgical treatment is performed only in advanced stages, and bypass needs to be delayed during active phases of inflammation. There is no role for endarterectomy, and synthetic or autogenous bypass grafts need to be placed onto disease-free segments of vessels. For focal lesions, there have been reports of success with angioplasty.^{205–207}

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is one of the more significant inheritable disorders affecting the connective tissue, along with Marfan syndrome. This syndrome represents a heterogeneous group of connective tissue disorders (types I through IV) that were first described in 1682 by van Meekeren.²⁰⁸ It is an autosomal dominant disorder affecting approximately one in 5000 persons that is characterized by skin elasticity, joint hypermobility, tissue fragility, multiple ecchymoses, and subcutaneous pseudotumors. Ehlers-Danlos syndrome is a disorder of fibrillar collagen metabolism with identifiable, specific defects that have been found in the collagen biosynthetic pathway that produce clinically distinct forms of this disease. Ten different phenotypes have been described, each with variable modes of inheritance and biochemical defects. Of the four basic types of collagen found in the body, the predominant type in blood vessels is type III. Within the vessel wall, type III collagen contributes to structural integrity and tensile strength, as well as playing a role in platelet aggregation and thrombus formation.

Of the three types of Ehlers-Danlos syndrome that have arterial complications, type IV represents 5% of cases and is the one most likely to be seen by a vascular surgeon. These patients synthesize abnormal type III collagen (mutation COL3A1), and represent 5% of all cases.²⁰⁸ Affected individuals do not show the typical skin and joint manifestations, and thus typically present for diagnosis when a major vascular catastrophe occurs. In a review of 36 patients with this disorder, Cikrit and colleagues reported a 44% mortality rate from major hemorrhage before any surgical intervention.²⁰⁹ In the 20 patients who underwent 29 vascular procedures, there was a 29% mortality rate. Arterial rupture, aneurysm formation, and acute aortic dissection may occur in any major artery, with the most frequent site of rupture being the abdominal cavity. Repair is problematic, as the vessel wall is soft and sutures pull through the fragile tissue. Ligation may be the only option in many circumstances.

Marfan Syndrome

Another heterogeneous heritable disorder of connective tissue, Marfan syndrome is characterized by abnormal musculoskeletal, ocular, and cardiovascular features first described by Antoine Marfan in 1896.²¹⁰ The inborn error of metabolism in this syndrome has been localized to the long arm of chromosome 15 (15q21.3). Defects occur in fibrillin, a basic protein in the microfibrillar apparatus that serves as a backbone for elastin, which is one of the main extracellular structural proteins in blood vessels. This is an autosomal dominant gene with high penetrance; however, approximately 15 to 20% of cases are secondary to new spontaneous mutations.²¹⁰

Classic recognizable features of Marfan syndrome include tall stature, long limbs (dolichostenomelia), long fingers (arachnodactyly), joint hyperextensibility, chest wall deformities, and scoliosis. Ocular manifestations are flattened corneas, lens subluxation, and myopia. Ninety-five percent of patients have cardiovascular involvement, which may include ascending aortic dilatation, mitral valve prolapse, valvular regurgitation, and aortic dissection. Skin, central nervous system, and pulmonary features may be present as well. Aortic root dilatation will generally occur in all patients. This may not be evident on standard chest radiograph until dilatation has resulted in an ascending aortic aneurysm, aortic valve regurgitation, or dissection. Left untreated, the cardiovascular complications are devastating and reduce the life expectancy to about 40 years for men and slightly higher for women. Death is usually attributable to life-threatening complications of aortic regurgitation, dissection, and rupture after the ascending aorta has dilated to 6 cm or more.

Aggressive medical management with beta-adrenergic blocking agents and other BP lowering regimens is crucial to treatment. Surgical intervention entails replacement of the aortic root with a composite valve graft (e.g., Bentall procedure).²⁰⁵ Prophylactic operative repair is indicated for an aneurysm >5.5 cm, with an acceptable perioperative mortality of less than 5%.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is a rare inherited disorder of connective tissue that is characterized by an unbalanced elastic fiber metabolism and synthesis, resulting in fragmentation and calcification of the fibers. Clinical manifestations occur in the skin, ocular, GI, and cardiovascular systems.²⁰⁶ Characteristic skin lesions are seen in the axilla, antecubital and popliteal fossae, and groin. The yellow, xanthoma-like papules occur in redundant folds of skin and are said to resemble plucked chicken skin. The inheritance pattern includes both autosomal dominant and recessive types and has a prevalence of one in 160,000 individuals.¹⁸³ The ATP-binding cassette subfamily C member 6 (ABCC6) gene has been demonstrated to be responsible, and 43 mutations have been identified, all of which lead to calcification of the internal elastic laminae of medium-sized vessel walls.²⁰⁶

Cardiovascular features are common and include premature CAD, cerebrovascular disease, renovascular hypertension, diminished peripheral pulses, and restrictive cardiomyopathy. Symptom onset typically occurs in the second decade of life, with onset at an average age of 13 years. Patients should be counseled to reduce potential contributing factors for atherosclerosis such as tobacco use and high cholesterol levels. Calcium intake should be restricted in adolescents, as a positive correlation has been found between disease severity and calcium intake.²⁰⁶ Surgical management involves standard vascular techniques, with the exception that arterial conduits should not be used in cardiac bypass.

Kawasaki Disease

Kawasaki disease was first described in 1967, as a mucocutaneous lymph node syndrome occurring in young children. In

most studies, more than one half of the patients are younger than 2 years of age, with a higher prevalence in boys.²⁰⁷ Although originally described in Japan, the disease is found worldwide. An infectious agent may be causative; however, no specific agent has been identified. Immune activation with the contribution of cytokines, elastases, growth factors, and metalloproteinases is believed to be a mechanism for inflammation and aneurysm formation. Coronary artery aneurysms, the hallmark of the disease, histologically demonstrate a panarteritis with fibrinoid necrosis. Coronary arteriography may show occlusions, recanalization, and localized stenosis, in addition to multiple aneurysms. A variety of constitutional symptoms and signs resulting from systemic vasculitis are present in the acute phase of the illness.²⁰⁷

Medical therapy for Kawasaki disease clearly decreases the manifestations of coronary artery involvement. IV gamma globulin and aspirin therapy are most successful if begun within the first 10 days of illness. Up to 20% of untreated patients will develop coronary arterial lesions.²⁰⁷ A long-term, low-dose aspirin therapy regimen usually is recommended.

Inflammatory Arteritis and Vasculitis

Chronic inflammatory arteritis and vasculitis (i.e., inflammatory changes within veins as well as arteries) include a spectrum of disease processes caused by immunologic mechanisms. These terms signify a necrotizing transmural inflammation of the vessel wall associated with antigen-antibody immune complex deposition within the endothelium. These conditions show pronounced cellular infiltration in the adventitia, thickened intimal fibrosis, and organized thrombus.²⁰⁴ These disease processes may clinically mimic atherosclerosis, and most are treated by corticosteroid therapy or chemotherapeutic agents. Even so, it is important to recognize distinguishing characteristics of each disease to establish the course of treatment and long-term prognosis. A classification system of systemic vasculitis by vessel size is shown in Table 23-28.

Table 23-28 Classification of Vasculitis Based on Vessel Involvement
Large vessel vasculitis
Takayasu's arteritis
Giant cell arteritis
Behçet's disease
Medium-sized vessel vasculitis
Polyarteritis nodosa
Kawasaki disease
Buerger's disease
Small vessel vasculitis
Hypersensitivity angiitis

Behçet's Disease

Behçet's disease is a rare syndrome characterized by oral and genital ulcerations and ocular inflammation, affecting males in Japan and the Mediterranean. An HLA linkage has been found, indicating a genetic component to the etiology. Vascular involvement is seen in 7 to 38% of patients, and is localized to the abdominal aorta, femoral artery, and pulmonary artery.²¹¹ Vascular lesions also may include venous complications such as deep venous thrombosis or superficial thrombophlebitis. Arterial aneurysmal degeneration can occur; however, this is an uncommon, albeit potentially devastating, complication. Multiple true aneurysms and pseudoaneurysms may develop, and rupture of an aortic aneurysm is the major cause of death in patients with Behçet's disease.²¹²

Histologically, degeneration of the vasa vasorum with surrounding perivascular lymphocyte infiltration is seen, along with thickening of the elastic laminae around the tunica media.²¹³ Aneurysm formation is believed to be associated with a loss of the nutrient flow and elastic component of the vessels, leading to progressive dilatation. Multiple aneurysms are relatively common, with a reported occurrence of 36% in affected Japanese patients.²¹² Furthermore, pseudoaneurysm formation after surgical bypass is common at anastomotic suture lines due to the vascular wall fragility and medial destruction. Systemic therapy with corticosteroids and immunosuppressive agents may diminish symptoms related to the inflammatory process; however, they have no effect on the rate of disease progression and arterial degeneration.²¹²

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is another systemic inflammatory disease process, which is characterized by a necrotizing inflammation of medium-sized or small arteries that spares the smallest blood vessels (i.e., arterioles and capillaries). This disease predominantly affects men more than women by a 2:1 ratio. PAN develops subacutely, with constitutional symptoms that last for weeks to months. Intermittent, low-grade fever, malaise, weight loss, and myalgia are common presenting symptoms. As medium-sized vessels lie within the deep dermis, cutaneous manifestations occur in the form of livedo reticularis, nodules, ulcerations, and digital ischemia.²¹⁴ Skin biopsies of these lesions may be sufficient for diagnosis. Inflammation may be seen histologically, with pleomorphic cellular infiltrates and segmental transmural necrosis leading to aneurysm formation.

Neuritis from nerve infarction occurs in 60% of patients, and GI complications in up to 50%.²¹⁵ Additionally, renal involvement is found in 40%, and manifests as microaneurysms within the kidney or segmental infarctions. Cardiac disease is a rare finding except at autopsy, where thickened, diseased coronary arteries may be seen, as well as patchy myocardial necrosis. Patients may succumb to renal failure, intestinal hemorrhage, or perforation. End-organ ischemia from vascular occlusion or aneurysm rupture can be disastrous complications with high mortality rates. The mainstay of treatment is steroid and cytotoxic agent therapy. Up to 50% of patients with active PAN will experience remission with high dosing.²¹⁵

Radiation-Induced Arteritis

Radiation-induced arteritis results from progressive stenosis due to endothelial damage that leads to cellular proliferation and fibrosis. These are well-described complications of combined irradiation and chemotherapy for the treatment of head and neck malignancy. Arterial lesions are known complications of radiation and are similar to those found in atherosclerotic occlusive disease. A history of therapeutic irradiation to the neck can complicate the management of carotid artery occlusive disease. Radiation-induced damage to blood vessels has been well studied. The small capillaries and sinusoids are most susceptible to radiation effects, as endothelial cells are the most radiosensitive cells. The radiation effects on the medium and large-sized arteries include myointimal proliferation, with or without lipid deposits, and thrombosis. Characteristically, irregular, spindle-shaped cells are seen replacing the normal endothelial cells in the healing phase. Occlusive lesions develop in the irradiated carotid arteries, and are either the result of vessel wall fibrosis, or, more commonly, due to accelerated atherosclerosis. Neurologic complications related to radiation-induced carotid artery disease are similar to those due to nonirradiated atherosclerotic occlusive disease.

Rupture of the carotid artery has been reported following neck irradiation, and is likely related to local wound complication and superimposed infection. The diagnosis of radiation arteritis is based on the clinical history and confirmation of the occlusive lesion by duplex ultrasound, MRA, CTA, or subtraction angiography. Irradiated lesions can be confined to the

irradiated segment of the ICA with the remaining part of the vessel spared of disease. Characteristically, the radiation-induced atherosclerotic lesion does not involve the carotid bulb, unlike the nonradiated atherosclerotic lesions. The indications for intervention in radiation-induced carotid lesions are the same for atherosclerotic carotid occlusive lesions as previously discussed in the "Treatment of Carotid Occlusive Disease" section. However, asymptomatic irradiated carotid artery lesions should be considered for intervention because they can be more prone to progression and development of neurologic complications. Endovascular treatment with carotid angioplasty/stenting has become the treatment of choice for radiation-induced lesions, although surgical endarterectomy and bypass have been shown to be safe. The rate of recurrent stenosis is higher in radiation-induced carotid lesions, whether stented or surgically treated.

Raynaud's Syndrome

First described in 1862 by Maurice Raynaud, the term *Raynaud's syndrome* applies to a heterogeneous symptom array associated with peripheral vasospasm, more commonly occurring in the upper extremities. The characteristically intermittent vasospasm classically follows exposure to various stimuli, including cold temperatures, tobacco, or emotional stress. Formerly, a distinction was made between Raynaud's "disease" and Raynaud's "phenomenon" for describing a benign disease occurring in isolation or a more severe disease secondary to another underlying disorder, respectively. However, many patients develop collagen vascular disorders at some point after the onset of vasospastic symptoms; progression to a connective tissue disorder ranges from 11 to 65% in reported series.^{211,216} Therefore, the term *Raynaud's syndrome* is now used to encompass both the primary and secondary conditions.

Characteristic color changes occur in response to the arteriolar vasospasm, ranging from intense pallor to cyanosis to redness as the vasospasm occurs. The digital vessels then relax, eventually leading to reactive hyperemia. The majority of patients are young women <40 years of age. Up to 70 to 90% of reported patients are women, although many patients with only mild symptoms may never present for treatment. Geographic regions located in cooler, damp climates such as the Pacific Northwest and Scandinavian countries have a higher reported prevalence of the syndrome. Certain occupational groups, such as those that use vibrating tools, may be more predisposed to Raynaud's syndrome or digital ischemia. The exact pathophysiologic mechanism behind the development of such severe vasospasm remains elusive, and much attention has focused on increased levels of α_2 -adrenergic receptors and their hypersensitivity in patients with Raynaud's syndrome, as well as abnormalities in the thermoregulatory response, which is governed by the sympathetic nervous system.²¹¹

The diagnosis of severe vasospasm may be made using noninvasive measurements in the vascular laboratory. Angiography is usually reserved for those who have digital ulceration and an embolic or obstructive cause is believed to be present and potentially surgically correctable. Different changes in digital BP will occur in patients with Raynaud's syndrome. Normal individuals will show only a slight decrease in digital BP in response to external cold stimuli, whereas those with Raynaud's syndrome will show a similar curve until a critical temperature is reached.²¹¹ It is at this point that arterial closure acutely occurs.

There is no cure for Raynaud's syndrome, thus all treatments mainly palliate symptoms and decrease the severity and, perhaps, frequency of attacks. Conservative measures predominate, including the wearing of gloves, use of electric or chemically activated hand warmers, avoiding occupational exposure to vibratory tools, abstinence from tobacco, or relocating to a warmer, dryer climate. The majority (90%) of patients will respond to avoidance of cold and other stimuli. The remaining 10% of patients with more persistent or severe syndromes can be treated with a variety of vasodilatory drugs, albeit with only a 30 to 60% response rate. Calcium-channel blocking agents such as diltiazem and nifedipine are the drugs

of choice. The selective serotonin reuptake inhibitor fluoxetine has been shown to reduce the frequency and duration of vasospastic episodes.²¹¹ IV infusions of prostaglandins have been reserved for nonresponders with severe symptoms.

Surgical therapy is limited to débridement of digital ulcerations and amputation of gangrenous digits, which are rare complications. Upper extremity sympathectomy may provide relief in 60 to 70% of patients; however, the results are short lived with a gradual recurrence of symptoms in 60% within 10 years.^{211,216}

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a vasculopathy of uncertain etiology that is characterized by segmental arterial involvement. Histologically, fibrous tissue proliferation, smooth muscle cell hyperplasia, and elastic fiber destruction alternate with mural thinning.²¹³ The characteristic beaded appearance of FMD is due to areas of medial thinning alternating with areas of stenosis. Most commonly affected are medium-sized arteries, including the internal carotid, renal, vertebral, subclavian, mesenteric, and iliac arteries. The ICA is the second most common site of involvement after the renal arteries. FMD occurs most frequently in women (90%) and is recognized at approximately 55 years of age. Only 10% of patients with FMD will have complications attributable to the disease.²¹³ Pathologically, FMD is a heterogeneous group of four distinct types of lesions that are subgrouped, based on the predominant site of involvement within the vessel wall. Of the four types (medial fibroplasia, intimal fibroplasia, medial hyperplasia, and perimedial dysplasia), medial fibroplasia is the most common pathologic type, affecting the ICA and the renal artery, and occurring in 85% of reported cases.²¹³

The two main clinical syndromes associated with FMD are transient ischemic attacks from disease in the ICA, and hypertension from renal artery involvement. Symptoms produced by FMD are generally secondary to associated arterial stenosis, and are clinically indistinguishable from those caused by atherosclerotic disease. Often, asymptomatic disease is found incidentally on conventional angiographic studies being performed for other reasons. Within the ICA, FMD lesions tend to be located higher in the extracranial segment than with atherosclerotic lesions, and may not be readily demonstrated by duplex scan.

Clinically, symptoms are due to encroachment on the vessel lumen and a reduction in flow. Additionally, thrombi may form in areas of mural dilatation from a stagnation of flow, leading to distal embolization. Surgical treatment has been favored for symptomatic patients with angiographically proven disease. Owing to the distal location of FMD lesions in the extracranial carotid artery, resection and repair is not usually feasible. Instead, graduated luminal dilatation under direct vision has been used successfully in patients, with antiplatelet therapy continued postoperatively. Percutaneous transluminal angioplasty (PTA) has been used effectively in patients with FMD-induced hypertension. Several series have documented a high technical success rate, with recurrence rates of 8 to 23% at more than 1 year.²¹⁷ However, the therapeutic effect of BP control may continue to be observed despite restenosis. Surgical reconstruction of the renal arteries for FMD has good long-term results and is recommended for recurrent lesions after angioplasty.²¹⁷ Open balloon angioplasty of the ICA has been described, which allows for precise fluoroscopic guidance, rather than blind dilatation with calibrated metal probes, and back-bleeding after dilatation to eliminate cerebral embolization.²¹⁸ Distal neuroprotective devices may allow this procedure to be performed completely percutaneously, by lessening the threat of cerebral emboli.

Non-Atherosclerotic Disease Affecting the Popliteal Artery Disease

There are three distinct non-atherosclerotic disease entities that may result in LE claudication that predominantly occur in 40- to 50-year-old men. Adventitial cystic disease, popliteal artery entrapment syndrome, and Buerger's disease should be

considered in any young patients presenting with intermittent claudication.

ADVENTITIAL CYSTIC DISEASE OF THE POPLITEAL ARTERY

The first successful operative repair of popliteal artery occlusion caused by a cyst arising from the adventitia was reported in 1954 by Ejrup and Hierton.²¹⁸ Adventitial cystic disease is a rare arterial condition occurring at an incidence of 0.1%, usually in the popliteal artery. This disease affects men in a ratio of approximately 5:1 and appears predominantly in the fourth and fifth decades. The incidence is approximately one in 1200 cases of claudication or one in 1000 peripheral arteriograms.²¹⁸ The predominance of reported cases is found in Japan and Europe. However, this disease may affect other vascular sites such as the femoral, external iliac, radial, ulnar, and brachial arteries. Besides claudication as a symptom, this diagnosis should be considered in young patients who have a mass in a nonaxial vessel in proximity to a related joint. These synovial-like, mucin-filled cysts reside in the subadventitial layer of the vessel wall and have a similar macroscopic appearance to ganglion cysts. Despite this similarity and suggestion of a joint origin for these lesions, histochemical markers have failed to link the cystic lining to synovium.

Patients presenting at a young age with bilateral LE claudication and minimal risk factors for atheroma formation should be evaluated for adventitial cystic disease, as well as the other two non-atherosclerotic vascular lesions described herein. Because of luminal encroachment and compression, peripheral pulses may be present in the limb when extended, but then can disappear during knee joint flexion. Noninvasive studies may suggest arterial stenosis with elevated velocities. Color flow duplex scanning followed by T2-weighted MRI now appears to be the best diagnostic choice. Angiography will demonstrate a smooth, well-defined, crescent-shaped filling defect, the classic "scimitar" sign.²¹⁸ There may be associated calcification in the cyst wall and no other evidence of atherosclerotic occlusive disease.

Various therapeutic methods have been described for the treatment of adventitial cystic disease. The recommended treatments are excision of the cyst with the cystic wall, enucleation, or simple aspiration when the artery is stenotic. Retention of the cystic lining leads to continued secretion of the cystic fluid and recurrent lesions. In 30% of patients who have an occluded artery, resection of the affected artery, followed by an interposition graft using autogenous saphenous vein, is recommended.

POPLITEAL ARTERY ENTRAPMENT SYNDROME

Love and colleagues first coined the term *popliteal artery entrapment* in 1965 to describe a syndrome combining muscular involvement with arterial ischemia occurring behind the knee, with the successful surgical repair having taken place 6 years earlier.²¹⁴ This is a rare disorder with an estimated prevalence of 0.16% that occurs with a male-to-female ratio of 15:1. Five types of anatomic entrapment have been defined, according to the position of the medial head of the gastrocnemius muscle, abnormal muscle slips or tendinous bands, or the course of the popliteal artery itself (Table 23-29). Concomitant popliteal vein impingement occurs in up to 30%. Twenty-five percent of cases are bilateral.

Table 23-29 Classification of Popliteal Entrapment Syndrome	
Type	Description
I	Popliteal artery is displaced medially around a normal medial head of the gastrocnemius
II	Medial head of gastrocnemius, which arises lateral to popliteal artery
III	Popliteal artery is compressed by an accessory slip of muscle from medial head of gastrocnemius
IV	Entrapment by a deeper popliteus muscle

V	Any of the above plus popliteal vein
VI	Functional entrapment

The typical patient presents with swelling and claudication of isolated calf muscle groups following vigorous physical activity. Various differential diagnoses must be considered when encountering patients with symptoms and signs suggestive of popliteal artery entrapment syndrome (Table 23-30). In a large series of 240 patients reported by Turnipseed, the median age for surgical treatment was 28.5 years.²¹⁴ Noninvasive studies with ankle-brachial indices should be performed with the knee extended and the foot in a neutral, forced plantar, and dorsiflexed position. A drop in pressure of 50% or greater or dampening of the plethysmographic waveforms in plantar or dorsiflexion is a classic finding. Contraction of the gastrocnemius should compress the entrapped popliteal artery. The sudden onset of signs and symptoms of acute ischemia with absent distal pulses is consistent with popliteal artery occlusion secondary to entrapment. Other conditions resulting from entrapment are thrombus formation with distal emboli or popliteal aneurysmal degeneration. Although CT and MRI have been used, angiography remains the most widely used test. Angiography performed with the foot in a neutral position may demonstrate classical medial deviation of the popliteal artery or normal anatomic positioning. Coexisting abnormalities may include stenosis, luminal irregularity, delayed flow, aneurysm, or complete occlusion. Diagnostic accuracy is increased with the use of ankle stress view—active plantar flexion and passive dorsiflexion.

Table 23-30 Differential Diagnosis for Popliteal Entrapment Syndrome

Vascular etiologies
Atherosclerosis
Buerger's disease
Trauma
Popliteal aneurysm
Adventitial cystic disease
Extrinsic compression
Cardiac embolism
Deep vein thrombosis
Venous entrapment
Musculoskeletal etiologies
Gastrocnemius or soleus strain
Periostitis
Compartment syndrome
Stress fractures
Tibialis posterior tendonitis
Muscular anomalies
General neurologic etiologies
Spinal stenosis

The treatment of popliteal artery entrapment consists of surgical decompression of the impinged artery with possible arterial reconstruction. Division of the anomalous musculotendinous insertion site with or without saphenous vein interposition grafting to bypass the damaged arterial segment has been described to be the procedure of choice. The natural history of

entrapment is progressive arterial degeneration, leading to complete arterial thrombosis. In such instances, thrombolytic therapy is needed with subsequent release of the functional arterial impairment. Lysis will improve distal runoff and may improve limb-salvage and bypass patency rates.

Buerger's Disease (Thromboangiitis Obliterans)

Buerger's disease, also known as *thromboangiitis obliterans*, is a progressive non-atherosclerotic segmental inflammatory disease that most often affects small and medium-sized arteries, veins, and nerves of the upper and lower extremities.²¹⁹ The clinical and pathologic findings of this disease entity were published in 1908 by Leo Buerger in a description of 11 amputated limbs.²¹⁹ The typical age range for occurrence is 20 to 50 years old, and the disorder is more frequently found in males who smoke. The upper extremities may be involved, and a migratory superficial phlebitis may be present in up to 16% of patients, thus indicating a systemic inflammatory response. In young adults presenting to the Mayo Clinic (1953–1981) with lower limb ischemia, Buerger's disease was diagnosed in 24%.²¹⁹ Conversely, the diagnosis was made in 9% of patients with ischemic finger ulcerations. The cause of thromboangiitis obliterans is unknown; however, use of or exposure to tobacco is essential to both the diagnosis and progression of the disease.

Pathologically, thrombosis occurs in small to medium-sized arteries and veins with associated dense polymorphonuclear leukocyte aggregation, microabscesses, and multinucleated giant cells. The chronic phase of the disease shows a decrease in the hypercellularity and frequent recanalization of the vessel lumen. End-stage lesions demonstrate organized thrombus and blood vessel fibrosis. Although the disease is common in Asia, North American males do not appear to have any particular predisposition, as the diagnosis is made in less than 1% of patients with severe limb ischemia.

Buerger's disease typically presents in young male smokers, with symptoms beginning before age 40 years old. Patients initially present with foot, leg, arm, or hand claudication, which may be mistaken for joint or neuromuscular problems. Progression of the disease leads to calf claudication and eventually ischemic rest pain and ulcerations on the toes, feet, or fingers. A complete history should exclude diabetes, hyperlipidemia, or autoimmune disease as possible etiologies for the occlusive lesions. Because it is likely that multiple limbs are involved, angiography should be performed of all four limbs. Even if symptoms are not yet present in a limb, angiographic findings may be demonstrated. Characteristic angiographic findings show disease confinement to the distal circulation, usually infrapopliteal and distal to the brachial artery. The occlusions are segmental and show "skip" lesions with extensive collateralization, the so-called "corkscrew collaterals."

The treatment of thromboangiitis obliterans revolves around strict smoking cessation. In patients who are able to abstain, disease remission is impressive and amputation avoidance is increased. In the experience reported from the Oregon Health Sciences Center, no disease progression with associated tissue loss occurred after discontinuation of tobacco. The role of surgical intervention is minimal in Buerger's disease, as there is often no acceptable target vessel for bypass. Furthermore, autogenous vein conduits are limited secondary to coexisting migratory thrombophlebitis. Mills and associates reported their results of 31% limb loss in 26 patients over 15 years, thus authenticating the virulence of Buerger's disease involving the lower extremities.²¹⁹ In addition, others have described a significant discrepancy in limb loss in patients that continued to smoke vs. those who discontinued tobacco use (35 vs. 67%).

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 24. Venous and Lymphatic Disease >

KEY POINTS

1. Deep vein thrombosis (DVT) and pulmonary embolism are frequent complications after major abdominal and orthopedic procedures. The risk is further increased in patients with malignancy and a history of venous thromboembolism. Options for DVT prophylaxis include intermittent pneumatic compression, use of graduated compression stockings, and administration of low-dose unfractionated heparin, low molecular weight heparin, fondaparinux, and vitamin K antagonists. However, prophylaxis should be stratified based on the patient's level of risk.
2. In patients with established DVT, unfractionated heparin, low molecular weight heparin, and fondaparinux are options for *initial* antithrombotic therapy. The duration and type of *long-term* anticoagulation should be stratified based on the provoked or unprovoked nature of the DVT, the location of the DVT, previous occurrence of DVT, and presence of concomitant malignancy.
3. Thrombolytic therapy, surgical thrombectomy, and placement of inferior vena cava filters are adjunctive treatments that may be indicated in patients with extensive and complicated venous thromboembolism.
4. Saphenous vein stripping, endovenous laser treatment, and radiofrequency ablation are effective therapies for patients with saphenous vein valvular insufficiency. Concomitant varicose veins may be managed with compression therapy, sclerotherapy (for smaller varices), and phlebectomy.
5. The mainstay of treatment for chronic venous insufficiency is compression therapy. Sclerotherapy, perforator vein ligation, and venous reconstruction may be indicated in patients in whom conservative management fails.
6. Lymphedema is categorized as primary (with early or delayed onset) or secondary. The goals of treatment are to minimize edema and prevent infection. Lymphatic massage, sequential pneumatic compression, use of compression garments, and limb elevation are effective forms of therapy.

VENOUS ANATOMY

Veins are part of a dynamic and complex system that returns venous blood to the heart against the force of gravity in an upright individual. Venous blood flow is dependent on multiple factors such as gravity, venous valves, the cardiac and respiratory cycles, blood volume, and the calf muscle pump. Alterations in the intricate balance of these factors can result in venous pathology.

Structure of Veins

Veins are thin-walled, highly distensible, and collapsible structures. Their structure specifically supports their two primary functions of transporting blood toward the heart and serving as a reservoir to prevent intravascular volume overload. The venous intima is composed of a nonthrombogenic endothelium with an underlying basement membrane and an elastic lamina. The endothelium produces endothelium-derived relaxing factor and prostacyclin, which help maintain a

nonthrombogenic surface through inhibition of platelet aggregation and promotion of platelet disaggregation.¹

Circumferential rings of elastic tissue and smooth muscle located in the media of the vein allow for changes in vein caliber with minimal changes in venous pressure. When an individual is upright and standing still, the veins are maximally distended and their diameter may be several times greater than that in the supine position.

Unidirectional blood flow is achieved with multiple venous valves. The number of valves is greatest below the knee and fewest in the more proximal veins. Each valve is made of two thin cusps consisting of a fine connective tissue skeleton covered by endothelium. Venous valves close in response to cephalad-to-caudal blood flow at a velocity of at least 30 cm/s.² The inferior vena cava (IVC), common iliac veins, portal venous system, and cranial sinuses are valveless.

Lower Extremity Veins

The nomenclature relating to venous anatomy recently has been revised. Lower extremity veins are divided into superficial, deep, and perforating veins. The superficial venous system lies above the uppermost fascial layer of the leg and thigh, and consists of the great saphenous vein (GSV) and small saphenous vein (SSV) and their tributaries. The GSV originates from the dorsal pedal venous arch and courses cephalad, anterior to the medial malleolus, entering the common femoral vein approximately 4 cm inferior and lateral to the pubic tubercle. The saphenous nerve accompanies the GSV medially and supplies cutaneous sensation to the medial leg and ankle. The SSV originates laterally from the dorsal pedal venous arch and courses cephalad in the posterior calf. Most often, it penetrates the popliteal fossa, between the medial and lateral heads of the gastrocnemius muscle, to join the popliteal vein. The termination of the SSV may be quite variable, however, with a proximal extension of the SSV (the vein of Giacomini) frequently connecting with the deep femoral vein or GSV. The sural nerve accompanies the SSV laterally along its course and supplies cutaneous sensation to the lateral malleolar region.

The deep veins follow the course of major arteries in the extremities. In the lower leg, paired veins parallel the course of the anterior tibial, posterior tibial, and peroneal arteries, and join behind the knee to form the popliteal vein. Venous bridges connect the paired veins in the lower leg. The popliteal vein continues through the adductor hiatus to become the femoral vein. In the proximal thigh, the femoral vein joins with the deep femoral vein to form the common femoral vein, becoming the external iliac vein at the inguinal ligament.

Multiple perforator veins traverse the deep fascia to connect the superficial and deep venous systems. Clinically important perforator veins are the Cockett and Boyd perforators. The Cockett perforator veins drain the medial lower leg and are relatively constant. They connect the posterior arch vein (a tributary to the GSV) and the posterior tibial vein. They may become varicose or incompetent in venous insufficiency states. The Boyd perforator veins connect the GSV to the deep veins approximately 10 cm below the knee and 1 to 2 cm medial to the tibia.

Venous sinuses are thin-walled, large veins located within the substance of the soleus and gastrocnemius muscles. These sinuses are valveless and are linked by valved, small venous channels that prevent reflux. A large amount of blood can be stored in the venous sinuses. With each contraction of the calf muscle bed, blood is pumped out through the venous channels into the main conduit veins to return to the heart.

Upper Extremity Veins

As in the lower extremity, there are deep and superficial veins in the upper extremity. Deep veins of the upper extremity are paired and follow the named arteries in the arm. Superficial veins of the upper extremity are the cephalic and basilic veins and their tributaries. The cephalic vein originates at the lateral wrist and courses over the ventral surface of the forearm. In

the upper arm, the cephalic vein terminates in the infraclavicular fossa, piercing the clavipectoral fascia to empty into the axillary vein. The basilic vein runs medially along the forearm and penetrates the deep fascia as it courses past the elbow in the upper arm. It then joins with the deep brachial veins to become the axillary vein. The median cubital vein joins the cephalic and the basilic veins on the ventral surface of the elbow.

The axillary vein becomes the subclavian vein at the lateral border of the first rib. At the medial border of the scalenus anterior muscle, the subclavian vein joins with the internal jugular vein to become the brachiocephalic vein, with the subclavian vein coursing anterior to the scalenus anterior muscle. The left and right brachiocephalic veins join to become the superior vena cava, which empties into the right atrium.

EVALUATION OF THE VENOUS SYSTEM

Clinical Evaluation

The evaluation of the venous system begins with a detailed history and physical examination. Risk factors for acute and chronic venous disease are identified. They include increased age, history of venous thromboembolism (VTE), malignancy, trauma and spinal cord injury, hospitalization and immobilization, obesity, nephrotic syndrome, pregnancy and the recently postpartum state, oral contraceptive use or hormone replacement therapy, varicose veins, and hypercoagulable states, as well as the postoperative state. Venous pathology is often, but not always, associated with visible or palpable signs that can be identified during the physical examination. There is variation among individuals in the prominence of superficial veins when the person is standing. The superficial veins of a lean athletic person, even when normal, will appear large and easily visualized, but these veins will be far less obvious in the obese individual. Possible signs of superficial venous abnormalities are listed in Table 24-1. The deep veins cannot be directly assessed clinically, and abnormalities within them can only be inferred indirectly from changes found on clinical examination.

Table 24-1 Possible Signs of Superficial Venous Abnormalities
Tortuosity
Varicosity
Venous saccule
Distended subdermal venules (corona phlebectatica)
Distended intradermal venules (spider angiomas)
Warmth, erythema, tenderness (superficial thrombophlebitis)

Chronic venous insufficiency (CVI) may lead to characteristic changes in the skin and subcutaneous tissues in the affected limb. CVI results from incompetence of venous valves, venous obstruction, or both. Most CVI involves venous reflux, and severe CVI often reflects a combination of reflux and venous obstruction. It is important to remember that although CVI originates with abnormalities of the veins, the target organ of CVI is the skin. A typical leg affected by CVI will be edematous, with edema increasing over the course of the day (Fig. 24-1). The leg may also be indurated and pigmented with eczema and dermatitis. These changes are due to excessive proteinaceous capillary exudate and deposition of a pericapillary fibrin cuff that may limit nutritional exchange. In addition, an increase in white blood cell trapping within the skin microcirculation in CVI patients may lead to microvascular congestion and thrombosis. Subsequently, white blood cells may migrate into the interstitium and release necrotizing lysosomal enzymes, which results in tissue destruction and eventual ulceration.

Edematous left leg of a patient with chronic venous insufficiency.

Fibrosis occurs from impaired nutrition, chronic inflammation, and fat necrosis (lipodermatosclerosis). Hemosiderin deposition due to the exudation of red cells and subsequent lysis in the skin causes the characteristic pigmentation of chronic venous disease (Fig. 24-2). Ulceration can develop with longstanding venous hypertension and is associated with alterations in microcirculatory and cutaneous lymphatic anatomy and function. The most common location of venous ulceration is approximately 3 cm proximal to the medial malleolus (Fig. 24-3).

Venous ulceration located proximal to the medial malleolus.

Trendelenburg's test is a clinical test that can help determine whether incompetent valves are present and in which of the three venous systems (superficial, deep, or perforator) the valves are abnormal. There are two components to this test. First, with the patient supine, the leg is elevated 45 degrees to empty the veins, and the GSV is occluded with the examiner's hand or with a rubber tourniquet. With the GSV still occluded, the patient stands and the superficial veins are observed for blood

filling. Then compression on the GSV is released and the superficial veins are observed for increased filling with blood. A negative result, indicating no clinically evident venous reflux, is the gradual filling of the veins from arterial inflow. A positive result is the sudden filling of veins with standing in the first part of the test or with release of GSV compression in the second part of the test. The perforator veins are thought to be normal with competent valves if the result of the first component of the test is negative. If the result of this part of the test is positive, there are theoretically incompetent valves in both the deep and perforator veins. The GSV valves are competent if the second component of the test gives a negative result, and the GSV valves are incompetent if the second component of the test yields a positive result. Interpretation of the findings of Trendelenburg's test is obviously subjective. The test has therefore been largely supplanted by the more objective noninvasive vascular laboratory tests to localize sites of venous reflux.

NONINVASIVE EVALUATION

Before the development of vascular ultrasound, noninvasive techniques to evaluate the venous system were based on plethysmographic techniques. Although a variety of plethysmographic techniques are used in the evaluation of both acute and chronic venous disease, they are all based on the detection of volume changes in the limb in response to blood flow.

Duplex ultrasonography (DUS) augmented by color flow imaging is now the most important noninvasive diagnostic method in the evaluation of the venous system. DUS has become standard for the detection of infrainguinal deep vein thrombosis (DVT), with near 100% sensitivity and specificity in symptomatic patients.³ It is also the preferred method of evaluation for upper extremity venous thrombosis and is useful in the evaluation of CVI by documenting the presence of valvular reflux and venous obstruction.

INVASIVE EVALUATION

With the improved accuracy of noninvasive techniques for diagnostic purposes, the use of invasive procedures has become more selective. Venography is now primarily used as an adjunct to percutaneous or operative treatment of venous disorders. Because the pelvic veins often cannot be visualized with DUS because of overlying bowel gas or body habitus, venography is often used to evaluate iliofemoral vein thrombosis in preparation for endovascular treatment or open surgical treatment.

Venography is performed by direct venipuncture with injection of contrast material. As with any invasive procedure, there are inherent risks associated with venography. Local effects include pain and local thrombosis at the puncture site and possible formation of a hematoma if larger veins are used for access. Pain is significantly lower with nonionic low-osmolality contrast media than with conventional contrast agents (with 18% vs. 44% of patients experiencing discomfort, respectively).⁴ Systemic effects of iodinated contrast media include allergic reaction and risk of renal failure. Postvenography venous thrombosis occurs distal to the puncture site in 1 to 9% of patients undergoing venography and results from vein intimal damage from the IV contrast agent.⁴

VENOUS THROMBOEMBOLISM

Epidemiology

Despite increased awareness and use of prophylactic modalities, DVT and pulmonary embolism (PE) remain important preventable sources of morbidity and mortality. The incidence of DVT ranges between 5 and 9 per 10,000 person-years in the general population, and the incidence of VTE (DVT and PE combined) is approximately 14 per 10,000 person-years.^{5,6} The resultant number of new cases of VTE may be over 275,000 per year in the United States.⁷ Not only does VTE pose an immediate threat to life, it also can cause long-term impairment due to resultant venous insufficiency. The 20-year

cumulative incidence rates are 26.8 and 3.7% for the development of venous stasis changes and venous ulcers, respectively, after an episode of DVT.⁸

Risk Factors

Three conditions, first described by Rudolf Virchow in 1862, contribute to VTE formation: stasis of blood flow, endothelial damage, and hypercoagulability. Of these risk factors, relative hypercoagulability appears most important in most cases of *spontaneous* DVT, whereas stasis and endothelial damage likely play a greater role in *secondary* DVT after immobilization, surgical procedures, and trauma. Identifiable risk factors for VTE relate to one of the conditions described by Virchow, and often more than one factor is present. Specific risk factors for VTE are listed in Table 24-2.

Table 24-2 Risk Factors for Venous Thromboembolism	
Acquired	Inherited
Advanced age	Factor V Leiden
Hospitalization/immobilization	Prothrombin 20210A
Hormone replacement therapy and oral contraceptive use	Antithrombin deficiency
	Protein C deficiency
Pregnancy and puerperium	Protein S deficiency
Prior venous thromboembolism	Factor XI elevation
Malignancy	Dysfibrinogenemia
Major surgery	Mixed Etiology
Obesity	Homocysteinemia
Nephrotic syndrome	Factor VII, VIII, IX, XI elevation
Trauma or spinal cord injury	Hyperfibrinogenemia
Long-haul travel (>6 h)	Activated protein C resistance without factor V Leiden
Varicose veins	
Antiphospholipid antibody syndrome	
Myeloproliferative disease	
Polycythemia	

The more common acquired risk factors include advanced age, hospitalization and immobilization, hormone replacement and oral contraceptive therapy, pregnancy and the recently postpartum state, prior VTE, malignancy, major surgery, obesity, nephrotic syndrome, trauma and spinal cord injury, long-haul travel (>6 hours), varicose veins, antiphospholipid syndrome, myeloproliferative disorders, and polycythemia. Heritable risk factors include factor V Leiden; prothrombin 20210A gene variant; antithrombin, protein C, and protein S deficiencies; and dysfibrinogenemias. In some patients, the cause of the thrombophilia may have both a heritable and an acquired component. These mixed causes include homocysteinemia; factor VII, VIII, IX, and XI elevation; hyperfibrinogenemia; and activated protein C resistance in the absence of factor V Leiden.⁹

When multiple inherited and acquired risk factors are present in the same patient, a synergistic effect may occur, depending on the thrombophilia in question. For example, patients who are heterozygous for factor V Leiden are at only moderately increased risk for VTE (fourfold to eightfold). However, when this genetic risk is combined with the additional risk of oral contraceptive use, the risk for VTE increases approximately 35-fold, the same order of magnitude as for someone who is

homozygous for factor V Leiden. The interaction between other common risk factors also was demonstrated in the Women's Health Initiative investigation.¹⁰ The concomitant presence of obesity, advancing age, or factor V Leiden increased the thrombosis risk associated with hormone replacement therapy. However, not all risk factors have the same synergistic effect. Hyperhomocysteinemia and the most common genotype associated with elevated homocysteine levels (MTHFR 677TT) do not appear to interact with the presence of factor V Leiden to further increase the risk for venous thrombosis.¹¹

Other factors associated with venous thrombosis include traditional cardiovascular risk factors (obesity, hypertension, diabetes), and there is a racial predilection for whites and African Americans, compared with Asians and Native Americans.^{12,13} Certain gene variants (single nucleotide polymorphisms) are associated with a mildly increased risk for DVT, and their presence may interact with other risk factors to increase the overall risk for venous thrombosis.¹⁴ However, testing for these polymorphisms is not common in clinical practice.

Diagnosis

CLINICAL EVALUATION

Early in the course of DVT development, venous thrombosis is thought to begin in an area of relative stasis, such as a soleal sinus vein or immediately downstream of the cusps of a venous valve in the axial calf veins. Isolated proximal DVT without tibial vein thrombosis is unusual. Early in the course of a DVT, there may be no or few clinical findings such as pain or swelling. Even extensive DVT may sometimes be present without signs or symptoms. History and physical examination are therefore unreliable in the diagnosis of DVT. In addition, symptoms and signs generally associated with DVT, such as extremity pain and/or swelling, are nonspecific. In large studies, DVT has been found by venography or DUS in $\leq 50\%$ of patients in whom it was clinically suspected.^{15,16} Objective studies are therefore required to confirm a diagnosis of DVT or to exclude the presence of DVT.

Clinical symptoms may worsen as DVT propagates and involves the major proximal deep veins. Massive DVT that obliterates the major deep venous channel of the extremity with relative sparing of collateral veins causes a condition called *phlegmasia alba dolens* (Fig. 24-4). This condition is characterized by pain, pitting edema, and blanching. There is no associated cyanosis. When the thrombosis extends to the collateral veins, massive fluid sequestration and more significant edema ensues, resulting in a condition known as *phlegmasia cerulea dolens*.¹⁷ Phlegmasia cerulea dolens is preceded by phlegmasia alba dolens in 50 to 60% of patients. The affected extremity in phlegmasia cerulea dolens is extremely painful, edematous, and cyanotic, and arterial insufficiency or compartment syndrome may be present. If the condition is left untreated, venous gangrene can ensue, leading to amputation.

Phlegmasia alba dolens of the right leg. Note the blanching and edema.

VASCULAR LAB AND RADIOLOGIC EVALUATION

Duplex Ultrasound

DUS is now the most commonly performed test for the detection of infrainguinal DVT, both above and below the knee, and has a sensitivity and specificity of >95% in symptomatic patients.³ DUS combines real-time B-mode ultrasound with pulsed Doppler capability. Color flow imaging is useful in more technically difficult examinations, such as in the evaluation of possible calf vein DVT. This combination offers the ability to noninvasively visualize the venous anatomy, detect occluded and partially occluded venous segments, and demonstrate physiologic flow characteristics using a mobile self-contained device.

In the supine patient, normal lower extremity venous flow is phasic (Fig. 24-5), decreasing with inspiration in response to increased intra-abdominal pressure with the descent of the diaphragm and then increasing with expiration. When the patient is upright, the decrease in intra-abdominal pressure with expiration cannot overcome the hydrostatic column of pressure existing between the right atrium and the calf. Muscular contractions of the calf, along with the one-way venous valves, are then required to promote venous return to the heart. Flow also can be increased by leg elevation or compression and decreased by sudden elevation of intra-abdominal pressure (Valsalva's maneuver). In a venous DUS examination performed with the patient supine, spontaneous flow, variation of flow with respiration, and response of flow to Valsalva's maneuver are all assessed. However, the primary method of detecting DVT with ultrasound is demonstration of the lack of compressibility of the vein with probe pressure on B-mode imaging. Normally, in transverse section, the vein walls should coapt with pressure. Lack of coaptation indicates thrombus.

Fig. 24-5.

Duplex ultrasound scan of a normal femoral vein with phasic flow signals.

The examination begins at the ankle and continues proximally to the groin. Each vein is visualized, and the flow signal is assessed with distal and proximal compression. Lower extremity DVT can be diagnosed by any of the following DUS findings: lack of spontaneous flow (Fig. 24-6), inability to compress the vein (Fig. 24-7), absence of color filling of the lumen by color flow DUS, loss of respiratory flow variation, and venous distention. Again, lack of venous compression on B-mode imaging is the primary diagnostic variable. Several studies comparing B-mode ultrasound to venography for the detection of femoropopliteal DVT in patients clinically suspected to have DVT report sensitivities of >91% and specificities of >97%.^{18,19} The ability of DUS to assess isolated calf vein DVT varies greatly, with sensitivities ranging from 50 to 93% and specificities approaching 100%.^{20,21}

Fig. 24-6.

B-mode ultrasound of the femoral vein in cross-section. The femoral vein does not collapse with external compression.

Impedance Plethysmography

Impedance plethysmography (IPG) was the primary noninvasive method of diagnosing DVT before the widespread use of DUS but is infrequently used today. IPG is based on the principle that resistance to the flow of electricity between two electrodes, or electrical impedance, occurs as the volume of the extremity changes in response to blood flow. Two pairs of electrodes containing aluminum strips are placed circumferentially around the leg approximately 10 cm apart and a low-level current is delivered to the two outer electrodes. A pneumatic cuff is inflated over the thigh for venous outflow obstruction and then rapidly deflated. Changes in electrical resistance resulting from lower extremity blood volume changes are quantified. IPG is less accurate than DUS for the detection of proximal DVT, with an 83% sensitivity in symptomatic patients. It is a poor detector of calf vein DVT.²²

Iodine 125 Fibrinogen Uptake

Iodine 125 fibrinogen uptake (FUT) is a seldom used technique that involves IV administration of radioactive fibrinogen and monitoring for increased uptake in fibrin clots. An increase of 20% or more in one area of a limb indicates an area of thrombus.²³ FUT can detect DVT in the calf, but high background radiation from the pelvis and the urinary tract limits its ability to detect proximal DVT. It also cannot be used in an extremity that has recently undergone surgery or has active inflammation. In a prospective study, FUT had a sensitivity of 73% and specificity of 71% for identification of DVT in a group of symptomatic and asymptomatic patients.²² Currently, FUT is primarily a research tool of historic interest.

Venography

Venography is the most definitive test for the diagnosis of DVT in both symptomatic and asymptomatic patients. It is the gold standard to which other modalities are compared. This procedure involves placement of a small catheter in the dorsum of the foot and injection of a radiopaque contrast agent. Radiographs are obtained in at least two projections. A positive study result is failure to fill the deep system with passage of the contrast medium into the superficial system or demonstration of discrete filling defects (Fig. 24-8). A normal study result virtually excludes the presence of DVT. In a study of 160 patients with a normal venogram followed for 3 months, only two patients (1.3%) subsequently developed DVT and no patients experienced symptoms of PE.²⁴

Venogram showing a filling defect in the popliteal vein (*arrows*).

Venography is not routinely used for the evaluation of lower extremity DVT because of the associated complications discussed previously. Currently, venography is reserved for imaging before operative venous reconstruction and catheter-based therapy. It does, however, remain the procedure of choice in research studies evaluating methods of prophylaxis for DVT.

Treatment

Once the diagnosis of VTE has been made, antithrombotic therapy should be initiated promptly. If clinical suspicion for VTE is high, it may be prudent to start treatment while the diagnosis is being objectively confirmed. The theoretic goals of VTE treatment are the prevention of mortality and morbidity associated with PE and the prevention of the postphlebotic syndrome. However, the only proven benefit of anticoagulant treatment for DVT is the prevention of death from PE. Treatment regimens may include antithrombotic therapy, vena caval interruption, catheter-directed or systemic thrombolytic therapy, and operative thrombectomy.

ANTITHROMBOTIC THERAPY

Antithrombotic therapy may be initiated with IV or SC unfractionated heparin, SC low molecular weight heparin, or SC fondaparinux (a synthetic pentasaccharide). This initial therapy usually is continued for at least 5 days, while oral vitamin K antagonists are being simultaneously administered. The initial therapy typically is discontinued when the international normalized ratio (INR) is ≥ 2.0 for 24 hours.²⁵

Unfractionated heparin (UFH) binds to antithrombin via a specific 18-saccharide sequence, which increases its activity over 1000-fold. This antithrombin-heparin complex primarily inhibits factor IIa (thrombin) and factor Xa and, to a lesser degree, factors IXa, XIa, and XIIa. In addition, UFH also binds to tissue factor pathway inhibitor, which inhibits the conversion of factor X to Xa, and factor IX to IXa. Finally, UFH catalyzes the inhibition of thrombin by heparin cofactor II via a mechanism that is independent of antithrombin.

UFH therapy is most commonly administered with an initial IV bolus of 80 units/kg or 5000 units. Weight-based UFH dosages have been shown to be more effective than standard fixed boluses in rapidly achieving therapeutic levels.²⁶ The initial bolus is followed by a continuous IV drip, initially at 18 units/kg per hour or 1300 units per hour. The half-life of IV UFH ranges from 45 to 90 minutes and is dose dependent. The level of antithrombotic therapy should be monitored every 6 hours using the activated partial thromboplastin time (aPTT), with the goal range of 1.5 to 2.5 times control values. This should correspond with plasma heparin anti-Xa activity levels of 0.3 to 0.7 IU/mL.

Initial anticoagulation with UFH may be administered SC, although this route is less commonly used. Adjusted-dose therapeutic SC UFH is initiated with 17,500 units, followed by 250 units/kg twice daily, and dosing is adjusted to an aPTT goal range similar to that for IV UFH. Fixed-dose unmonitored SC UFH is started with a bolus of 333 units/kg, followed by 250 units/kg twice daily.²⁵

Hemorrhage is the primary complication of UFH therapy. The rate of major hemorrhage (fatal, intracranial, retroperitoneal, or requiring transfusion of >2 units of packed red blood cells) is approximately 5% in hospitalized patients undergoing UFH therapy (1% in medical patients and 8% in surgical patients).²⁷ For patients with UFH-related bleeding complications, cessation of UFH is required, and anticoagulation may be reversed with protamine sulfate. Protamine sulfate binds to UFH and forms an inactive salt compound. Each milligram of protamine neutralizes 90 to 115 units of heparin, and the dosage should not exceed 50 mg IV over any 10-minute period. Side effects of protamine sulfate include hypotension, pulmonary edema, and anaphylaxis. Patients with prior exposure to protamine-containing insulin (NPH) and patients with allergy to fish may have an increased risk of hypersensitivity, although no direct relationship has been established. The protamine infusion should be terminated if any side effects occur.

In addition to hemorrhage, heparin also has unique complications. Heparin-induced thrombocytopenia (HIT) results from heparin-associated antiplatelet antibodies (HAAbs) directed against platelet factor 4 complexed with heparin.²⁸ HIT occurs in 1 to 5% of patients being treated with heparin.^{29,30} In patients with repeat heparin exposure (such as vascular surgery patients), the incidence of HAAb may be as high as 21%.³¹ HIT occurs most frequently in the second week of therapy and may lead to disastrous venous or arterial thrombotic complications. Therefore, platelet counts should be monitored periodically in patients receiving continuous heparin therapy. All forms of heparin should be stopped if there is a high clinical suspicion or confirmation of HIT [usually accompanied by an unexplained thrombocytopenia (<100,000/ μ L) or platelet count decrease of 30 to 50%]. Fortunately, direct thrombin inhibitors (recombinant hirudin, argatroban, bivalirudin) now are available as alternative antithrombotic agents (see later). Another complication of prolonged high-dose heparin therapy is osteopenia, which results from impairment of bone formation and enhancement of bone resorption by heparin.

Low molecular weight heparins (LMWHs) are derived from the depolymerization of porcine UFH. Like UFH, LMWHs bind to antithrombin via a specific pentasaccharide sequence to expose an active site for the neutralization of factor Xa. However, LMWHs lack the sufficient number of additional saccharide units (18 or more), which results in less inactivation of thrombin (factor IIa). In comparison to UFH, LMWHs have increased bioavailability (>90% after SC injection), longer half-lives (approximately 4 to 6 hours), and more predictable elimination rates. Weight-based once- or twice-daily SC LMWH

injections, for which no monitoring is needed, provide a distinct advantage over continuous IV infusions of UFH for treatment of VTE.

Most patients who receive therapeutic LMWH do not require monitoring. Patients who do require monitoring include those with significant renal insufficiency or failure, pediatric patients, obese patients of >120 kg, and patients who are pregnant. Monitoring may be performed using anti-Xa activity assays. However, the therapeutic anti-Xa goal range will depend on the type of LMWH and the frequency of dosing. Numerous LMWHs are commercially available. The various preparations differ in their anti-Xa and anti-IIa activities, and the treatment dosing for one LMWH cannot be extrapolated for use with another. The action of LMWHs may be partially reversed (approximately 60%) with protamine sulfate.

Numerous well-designed trials comparing SC LMWH with IV and SC UFH for the treatment of DVT have been critically evaluated in several meta-analyses.^{32–34} The more recent studies demonstrate a decrease in thrombotic complications, bleeding, and mortality with LMWHs. LMWHs also are associated with a decreased rate of HAAb formation and HIT (<2%) compared with UFH (at least in prophylactic doses).²⁹ However, patients with established HIT should not subsequently receive LMWHs due to significant rates of cross reactivity.³⁵ A major benefit of LMWHs is the ability to treat patients with VTE as outpatients.^{36,37} In a randomized study comparing IV UFH and the LMWH nadroparin calcium,³⁶ there was no significant difference in recurrent thromboembolism (8.6% for UFH vs. 6.9% for LMWH) or major bleeding complications (2.0% for UFH vs. 0.5% for LMWH). There was a 67% reduction in mean days in the hospital for the LMWH group.

A patient with VTE should meet several criteria before receiving outpatient LMWH therapy. First, the patient should not require hospitalization for any associated conditions. The patient should not require monitoring of the LMWH therapy (which is necessary in patients with severe renal insufficiency, pediatric patients, obese patients, and pregnant patients). The patient should be hemodynamically stable with a low suspicion of PE and have a low bleeding risk. An established outpatient system to administer LMWH and warfarin, as well as to monitor for recurrent VTE and bleeding complications, should be present. In addition, the patient's symptoms of pain and edema should be controllable at home.

Fondaparinux currently is the only synthetic pentasaccharide that has been approved by the U.S. Food and Drug Administration (FDA) for the initial treatment of DVT and PE. Its five-polysaccharide sequence binds and activates antithrombin, causing specific inhibition of factor Xa. In two large noninferiority trials, fondaparinux was compared with the LMWH enoxaparin for the initial treatment of DVT and with IV UFH for the initial treatment of PE.^{38,39} The rates of recurrent VTE ranged from 3.8 to 5%, with rates of major bleeding of 2 to 2.6%, for all treatment arms. The drug is administered SC once daily with a weight-based dosing protocol: 5 mg, 7.5 mg, or 10 mg for patients weighing <50 kg, 50 to 100 kg, or >100 kg, respectively. The half-life of fondaparinux is approximately 17 hours in patients with normal renal function. There are rare case reports of fondaparinux-induced thrombocytopenia.⁴⁰

Direct-thrombin inhibitors (DTIs) include recombinant hirudin, argatroban, and bivalirudin. These antithrombotic agents bind to thrombin, inhibiting the conversion of fibrinogen to fibrin as well as thrombin-induced platelet activation. These actions are independent of antithrombin. The direct thrombin inhibitors should be reserved for (a) patients in whom there is a high clinical suspicion or confirmation of HIT, and (b) patients who have a history of HIT or test positive for heparin-associated antibodies. In patients with established HIT, DTIs should be administered for at least 7 days, or until the platelet count normalizes. Warfarin may then be introduced slowly, overlapping therapy with a DTI for at least 5 days.⁴¹ Because bivalirudin is approved primarily for patients with or without HIT who undergo percutaneous coronary intervention, it is not discussed here in further detail.

Commercially available hirudin is manufactured using recombinant DNA technology. It is indicated for the prophylaxis and treatment of patients with HIT. In patients with normal renal function, recombinant hirudin is administered in an IV bolus dose of 0.4 mg/kg, followed by a continuous IV infusion of 0.15 mg/kg per hour. The half-life ranges from 30 to 60 minutes. The aPTT is monitored, starting approximately 4 hours after initiation of therapy, and dosage is adjusted to maintain an aPTT of 1.5 to 2.5 times the laboratory normal value. The less commonly used ecarin clotting time is an alternative method of monitoring. Because recombinant hirudin is eliminated via renal excretion, significant dosage adjustments are required in patients with renal insufficiency.

Argatroban is indicated for the prophylaxis and treatment of thrombosis in HIT. It also is approved for patients with, or at risk for, HIT who undergo percutaneous coronary intervention. Antithrombotic prophylaxis and therapy are initiated with a continuous IV infusion of 2 µg/kg per minute, without the need for a bolus. The half-life ranges from 39 to 51 minutes, and the dosage is adjusted to maintain an aPTT of 1.5 to 3 times normal. Large initial boluses and higher rates of continuous infusion are reserved for patients with coronary artery thrombosis and myocardial infarction. In these patients, therapy is monitored using the activated clotting time. Argatroban is metabolized by the liver, and the majority is excreted via the biliary tract. Significant dosage adjustments are needed in patients with hepatic impairment. There is no reversal agent for argatroban.

Vitamin K antagonists, which include warfarin and other coumarin derivatives, are the mainstay of long-term antithrombotic therapy in patients with VTE. Warfarin inhibits the γ-carboxylation of vitamin K–dependent procoagulants (factors II, VII, IX, X) and anticoagulants (proteins C and S), which results in the formation of less functional proteins. Warfarin usually requires several days to achieve its full effect, because normal circulating coagulation proteins must first undergo their normal degradation. Factors X and II have the longest half-lives, in the range of 36 and 72 hours, respectively. In addition, the steady-state concentration of warfarin is usually not reached for 4 to 5 days.

Warfarin therapy usually is monitored by measuring the INR, calculated using the following equation:

$$\text{INR} = \left(\frac{\text{patient prothrombin time}}{\text{laboratory normal prothrombin time}} \right)^{\text{ISI}}$$

where *ISI* is the international sensitivity index. The ISI describes the strength of the thromboplastin that is added to activate the extrinsic coagulation pathway. The therapeutic target INR range is usually 2.0 to 3.0, but the response to warfarin is variable and depends on liver function, diet, age, and concomitant medications. In patients receiving anticoagulation therapy without concomitant thrombolysis or venous thrombectomy, the vitamin K antagonist may be started on the same day as the initial parenteral anticoagulant, usually at doses ranging from 5 to 10 mg. Smaller initial doses may be needed in older and malnourished patients, in those with liver disease or congestive heart failure, and in those who have recently undergone major surgery.⁴²

The recommended duration of warfarin antithrombotic therapy is increasingly being stratified based on whether the DVT was provoked or unprovoked, whether it was the first or a recurrent episode, where the DVT is located, and whether malignancy is present. Current American College of Chest Physicians (ACCP) recommendations for duration of warfarin therapy are summarized in Table 24-3. In patients with proximal DVT, several randomized clinical trials have demonstrated that shorter-term antithrombotic therapy (4 to 6 weeks) is associated with a higher rate of recurrence than 3 to 6 months of anticoagulation.^{43–45} In these trials, most of the patients with transient risk factors had a low rate of recurrent VTE; most of the recurrences were in patients with continuing risk factors. These studies support the ACCP recommendation that 3 months of anticoagulation is sufficient to prevent recurrent VTE in patients whose DVT occurred around the time of a transient risk

factor (e.g., hospitalization, orthopedic or major general surgery).

Table 24-3 Summary of American College of Chest Physicians Recommendations Regarding Duration of Long-Term Antithrombotic Therapy for Deep Vein Thrombosis (DVT)

Clinical Subgroup	Antithrombotic Treatment Duration
First episode DVT/transient risk	VKA for 3 mo
First episode DVT/unprovoked	VKA for at least 3 mo
	Consider for long-term therapy if:
	• Proximal DVT
	• Minimal bleeding risk
	• Stable coagulation monitoring
Distal DVT/unprovoked	VKA for 3 mo
Second episode DVT/unprovoked	VKA long-term therapy
DVT and cancer	LMWH 3–6 mo
	Then VKA or LMWH indefinitely until cancer resolves

LMWH = low molecular weight heparin; VKA = vitamin K antagonist.

Source: Adapted with permission from Kearon C, Kahn SR, Agnelli G, et al: Antithrombotic therapy for venous thromboembolic disease: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th edition). *Chest* 133:454S, 2008.

In contrast to patients with thrombosis related to transient risk factors, patients with idiopathic VTE are much more likely to develop recurrence (rates as high as 40% at 10 years). In this latter group of patients, numerous clinical trials have compared 3 to 6 months of anticoagulation therapy with extended-duration warfarin therapy, both at low intensity (INR of 1.5 to 2.0) and at conventional intensity (INR of 2.0 to 3.0).^{46–49} In patients with idiopathic DVT, extended-duration antithrombotic therapy is associated with a relative reduction in the rate of recurrent VTE by 75% to >90%. In addition, conventional-intensity warfarin reduces the risk even further compared with low-intensity warfarin (0.7 events per 100 person-years vs. 1.9 events per 100 person-years), but the rate of bleeding complications is no different.⁴⁹

In patients with VTE in association with a hypercoagulable condition, the optimal duration of anticoagulation therapy is influenced more by the clinical circumstances at the time of the VTE (idiopathic vs. secondary) than by the actual presence or absence of the more common thrombophilic conditions. In patients with VTE related to malignancy, increasing evidence suggests that longer-term therapy with LMWH (up to 6 months) is associated with a lower VTE recurrence rate than treatment using conventional vitamin K antagonists.^{50,51}

The primary complication of warfarin therapy is hemorrhage, and the risk is related to the magnitude of INR prolongation. Depending on the INR and the presence of bleeding, warfarin anticoagulation may be reversed by (a) omitting or decreasing subsequent dosages, (b) administering oral or parenteral vitamin K, or (c) administering fresh-frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa.⁴² Warfarin therapy rarely may be associated with the development of skin necrosis and limb gangrene. These conditions occur more commonly in women (4:1), and the most commonly affected areas are the breast, buttocks, and thighs. This complication, which usually occurs in the first days of therapy, is occasionally, but not exclusively, associated with protein C or S deficiency and malignancy. Patients who require continued anticoagulation may restart low-dose warfarin (2 mg) while receiving concomitant therapeutic heparin. The warfarin dosage is then gradually increased over a 1- to 2-week period.⁴²

SYSTEMIC AND CATHETER-DIRECTED THROMBOLYSIS

Patients with extensive proximal DVT may benefit from systemic thrombolysis or catheter-directed thrombolysis, which can potentially reduce acute symptoms more rapidly than anticoagulation alone. These techniques also may decrease the development of postthrombotic syndrome. Several thrombolysis preparations are available, including streptokinase, urokinase, alteplase (recombinant tissue plasminogen activator), reteplase, and tenecteplase. All these agents share the ability to convert plasminogen to plasmin, which leads to the degradation of fibrin. They differ with regard to their half-lives, their potential for inducing fibrinogenolysis (generalized lytic state), their potential for antigenicity, and their FDA-approved indications for use.

Streptokinase is purified from beta-hemolytic *Streptococcus* and is approved for the treatment of acute myocardial infarction, PE, DVT, arterial thromboembolism, and occluded central lines and arteriovenous shunts. It is not specific for fibrin-bound plasminogen, however, and its use is limited by its significant rates of antigenicity. Fevers and shivering occur in 1 to 4% of patients. Urokinase is derived from human neonatal kidney cells, grown in tissue culture. Currently, it is only approved for lysis of massive PE or PE associated with unstable hemodynamics. Alteplase, reteplase, and tenecteplase all are recombinant variants of tissue plasminogen activator. Alteplase is indicated for the treatment of acute myocardial infarction, acute ischemic stroke, and acute massive PE. However, it often is used for catheter-directed thrombolysis of DVT. Reteplase and tenecteplase are indicated only for the treatment of acute myocardial infarction.

Systemic thrombolysis was evaluated in numerous older prospective and randomized clinical trials, and its efficacy was summarized in a recent Cochrane Review.⁵² In 12 studies involving over 700 patients, systemic thrombolysis was associated with significantly more clot lysis [relative risk (RR) 0.24 to 0.37] and significantly less postthrombotic syndrome (RR 0.66). However, venous function was not significantly improved. In addition, more bleeding complications did occur (RR 1.73), but the incidence appears to have decreased in later studies, probably due to improved patient selection.

In an effort to minimize bleeding complications and increase efficacy, catheter-directed thrombolytic techniques have been developed for the treatment of symptomatic DVT. With catheter-directed therapy, venous access may be achieved through percutaneous catheterization of the ipsilateral popliteal vein, retrograde catheterization through the contralateral femoral vein, or retrograde cannulation from the internal jugular vein. Multi-side-hole infusion catheters, with or without infusion wires, are used to deliver the lytic agent directly into the thrombus.

The efficacy of catheter-directed urokinase for the treatment of symptomatic lower extremity DVT has been reported in a large multicenter registry.⁵³ Two hundred twenty-one patients with iliofemoral DVT and 79 patients with femoropopliteal DVT were treated with catheter-directed urokinase for a mean of 53 hours. Complete lysis was seen in 31% of the limbs, 50 to 99% lysis in 52% of the limbs, and <50% lysis in 17%. Overall, 1-year primary patency was 60%. Patency was higher in patients with iliofemoral DVT than in patients with femoropopliteal DVT (64% vs. 47%, $P < .01$). In addition, patients with acute symptoms (≤ 10 days) had a greater likelihood of complete lysis (34%) than patients with chronic symptoms (> 10 days; 19%). Major bleeding occurred in 11%, but neurologic involvement and mortality were rare (both 0.4%). Adjunctive stent placement to treat residual stenosis and/or short segment occlusion was required in 103 limbs.

One small randomized trial and numerous other retrospective studies have demonstrated similar rates of thrombolysis, with some also showing improved valve preservation and quality of life.^{25,54,55} Combining thrombolysis with percutaneous thrombus fragmentation and extraction has the added benefit of decreasing the infusion time, the hospital stay, and the overall cost of treatment.⁵⁶ These studies, as well as the current ACCP guidelines, suggest that catheter-directed

thrombolysis (with adjunctive angioplasty, venous stenting, and pharmacomechanical fragmentation and extraction) may be useful in selected patients with extensive iliofemoral DVT. Patients should have a recent onset of symptoms (<14 days), good functional status, decent life expectancy, and low bleeding risk.

INFERIOR VENA CAVAL FILTERS

Since the introduction of the Kimray-Greenfield filter in the United States in 1973, numerous vena caval filters have been developed. Although the designs are variable, they all prevent pulmonary emboli, while allowing continuation of venous blood flow through the IVC. Early filters were placed surgically through the femoral vein. Currently, less invasive techniques allow percutaneous filter placement through a femoral vein, internal jugular vein, or small peripheral vein under fluoroscopic or ultrasound guidance. Complications associated with IVC filter placement include insertion site thrombosis, filter migration, erosion of the filter into the IVC wall, and IVC thrombosis. The rate of fatal complications is <0.12%.⁵⁷

Placement of an IVC filter is indicated for patients who develop recurrent DVT (significant propagation of the original thrombus or proximal DVT at a new site) or PE despite adequate anticoagulation therapy and for patients with pulmonary hypertension who experience recurrent PE. In patients who receive IVC filters for these indications, therapeutic anticoagulation should be continued. The duration of anticoagulation is determined by the underlying VTE and not by the presence of the IVC filter itself. Practically speaking, however, many patients who require an IVC filter for recurrent VTE are the same ones who would benefit most from indefinite anticoagulation. The other major indication for placement of an IVC filter is a contraindication to, or complication of, anticoagulation therapy in the presence of an acute proximal DVT. In patients who are not able to receive anticoagulants due to recent surgery or trauma, the clinician should continually reassess if antithrombotic agents may be started safely at a later date. Even some patients who develop anticoagulation-associated bleeding complications may be able to restart therapy at a lower intensity of anticoagulation later in the hospital course. As before, the clinical circumstances surrounding the VTE should determine the duration of anticoagulation.

Placement of permanent IVC filters has been evaluated as an adjunct to routine anticoagulation in patients with proximal DVT.⁵⁸ In this study, routine IVC filter placement did not prolong early or late survival in patients with proximal DVT but did decrease the rate of PE (hazard ratio, 0.22; 95% confidence interval, 0.05 to 0.90). An increased rate of recurrent DVT was seen in patients with IVC filters (hazard ratio, 1.87; 95% confidence interval, 1.10 to 3.20). More controversial indications for IVC filter placement include prophylaxis against PE in patients receiving catheter-directed thrombolysis and in high-risk patients without established DVT or PE.

OPERATIVE VENOUS THROMBECTOMY

In patients with acute iliofemoral DVT, surgical therapy is generally reserved for patients who worsen with anticoagulation therapy and those with phlegmasia cerulea dolens and impending venous gangrene. If the patient has phlegmasia cerulea dolens, a fasciotomy of the calf compartments is first performed. In iliofemoral DVT, a longitudinal venotomy is made in the common femoral vein and a venous balloon embolectomy catheter is passed through the thrombus into the IVC and pulled back several times until no further thrombus can be extracted. The distal thrombus in the leg is removed by manual pressure beginning in the foot. This is accomplished by application of a tight rubber elastic wrap beginning at the foot and extending to the thigh. If the thrombus in the femoral vein is old and cannot be extracted, the vein is ligated. For a thrombus that extends into the IVC, the IVC is exposed transperitoneally and the IVC is controlled below the renal veins. The IVC is opened and the thrombus is removed by gentle massage. An intraoperative completion venogram is obtained to determine if any residual thrombus or stenosis is present. If a residual iliac vein stenosis is present, intraoperative angioplasty and stenting

can be performed. In most cases, an arteriovenous fistula is then created by anastomosing the great saphenous vein (GSV) end to side with the superficial femoral artery in an effort to maintain patency of the thrombectomized iliofemoral venous segment. Heparin is administered postoperatively for several days. Warfarin anticoagulation is maintained for at least 6 months after thrombectomy. Complications of iliofemoral thrombectomy include PE in up to 20% of patients⁵⁹ and death in <1% of patients.⁶⁰

One study⁶¹ followed 77 limbs for a mean of 8.5 years after thrombectomy for acute iliofemoral DVT. In limbs with successful thrombectomies, valvular competence in the thrombectomized venous segment was 80% at 5 years and 56% at 10 years. More than 90% of patients had minimal or no symptoms of postthrombotic syndrome. There were 12 (16%) early thrombectomy failures. Patients were required to wear compression stockings for at least 1 year after thrombectomy.

Survival rates for surgical pulmonary embolectomy have improved over the past 20 years with the addition of cardiopulmonary bypass. Emergency pulmonary embolectomy for acute PE is rarely indicated. Patients with preterminal massive PE (Fig. 24-9) for whom thrombolysis has failed or who have contraindications to thrombolytics may be candidates for this procedure. Open pulmonary artery embolectomy is performed through a posterolateral thoracotomy with direct visualization of the pulmonary arteries. Mortality rates range between 20 and 40%.⁶²⁻⁶⁴

Fig. 24-9.

Autopsy specimen showing a massive pulmonary embolism.

Percutaneous catheter-based techniques for removal of a PE involve mechanical thrombus fragmentation or embolectomy using suction devices. Mechanical clot fragmentation is followed by catheter-directed thrombolysis. Results of catheter-based fragmentation are based on small case series. In a study in which a fragmentation device was used in 10 patients with acute massive PE, fragmentation was successful in 7 patients with a mortality rate of 20%.⁶⁵ Transvenous catheter pulmonary suction embolectomy has also been performed for acute massive PE with a reported 76% successful extraction rate and a 30-day survival of 70%.⁶⁶

Prophylaxis

Patients who undergo major general surgical, gynecologic, urologic, and neurosurgical procedures without thromboprophylaxis have a significant incidence of perioperative DVT (15 to 40%). The incidence is even higher with major trauma (40 to 80%), hip and knee replacement surgery (40 to 60%), and spinal cord injury (60 to 80%).⁶⁷ The goal of prophylaxis is to reduce the mortality and morbidity associated with VTE. The first manifestation of VTE may be a life-threatening PE (Fig. 24-10), and as indicated earlier, clinical evaluation to detect DVT before PE is unreliable.

Effective methods of VTE prophylaxis involve the use of one or more pharmacologic or mechanical modalities. Currently available pharmacologic agents include low-dose UFH, LMWH, synthetic pentasaccharides, and vitamin K antagonists. Mechanical methods include intermittent pneumatic compression (IPC) and graduated compression stockings. Aspirin therapy alone is not adequate for DVT prophylaxis. These prophylaxis methods vary with regard to their efficacy, and the 2008 ACCP Clinical Practice Guidelines stratify their uses according to the patient's level of risk (Table 24-4).

Table 24-4 Thromboembolism Risk and Recommended Thromboprophylaxis in Surgical Patients		
Level of Risk	Approximate DVT Risk without Thromboprophylaxis (%)	Suggested Thromboprophylaxis Options
Low risk	<10	No specific thromboprophylaxis

Minor surgery in mobile patients		Early and "aggressive" ambulation
Moderate risk	10–40	LMWH (at recommended doses), LDUH bid or tid, fondaparinux
Most general, open gynecologic, or urologic surgery		Mechanical thromboprophylaxis
Moderate VTE risk plus high bleeding risk		
High risk	40–80	LMWH (at recommended doses), fondaparinux, oral vitamin K antagonist (INR 2–3)
Hip or knee arthroplasty, hip fracture surgery		
Major trauma, spinal cord injury		Mechanical thromboprophylaxis
High VTE risk plus high bleeding risk		

DVT = deep vein thrombosis; INR = International Normalized Ratio; LDUH = low-dose unfractionated heparin; LMWH = low molecular weight heparin; VTE = venous thromboembolism.

Source: Adapted with permission from Geerts WH, Bergqvist D, Pineo GF, et al: Prevention of venous thromboembolism: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th edition). *Chest* 133: 381, 2008.

VENOUS THROMBOEMBOLISM PROPHYLAXIS IN GENERAL SURGERY

The risk for VTE in general surgery depends on the type of operation, the type of anesthesia, the duration of surgery, and other risk factors, including patient age, presence of cancer, prior VTE, obesity, and presence of infection. Patients at low risk who undergo minor procedures do not require pharmacologic or mechanical prophylaxis. Patients at moderate risk who undergo major procedures should receive low-dose UFH, LMWH, or fondaparinux. These prophylactic options also are effective for patients at high risk, but the UFH requires more frequent dosing (5000 units SC, tid) to achieve a similar level of prevention. The patients at highest risk with multiple VTE risk factors benefit from a combination of pharmacologic and mechanical prophylaxis (IPC and/or graduated compression stockings). Thromboprophylaxis should continue until discharge, except in select high-risk patients with malignancy in whom extended-duration prophylaxis (up to 28 days) may be beneficial. Patients with significant risk for bleeding should receive mechanical prophylaxis until this risk subsides.⁶⁷

Overall, low-dose UFH and LMWH reduce the risk for symptomatic and nonsymptomatic VTE by 60 to 70%. The risks for bleeding differ, depending on the dosage. Lower dosages of LMWH appear to be associated with less bleeding risk than low-dose UFH, but the latter produces less bleeding risk than higher prophylactic dosages of LMWH.⁶⁸ Other advantages of LMWH include once-daily dosing protocols and a lower rate of heparin-associated antibody formation.

Fondaparinux has been compared with the LMWH dalteparin in patients who undergo high-risk major abdominal surgery. It also has been compared with IPC alone in patients undergoing non-high-risk abdominal surgery.^{69,70} The pentasaccharide had rates of VTE prevention, bleeding complications, and mortality similar to those of LMWH. It was more beneficial than IPC alone in reducing VTE but at the cost of a higher rate of bleeding (1.6% vs. 0.2%).

Prophylactic insertion of IVC filters has been suggested for VTE prophylaxis in high-risk trauma patients and in some patients with malignancy who have contraindications for LMWH therapy.⁷¹ Trauma patients at a higher risk than the general trauma population include those with severe head injuries, spinal cord injuries, and severe fractures of the pelvis or long bones. A 5-

year study of prophylactic IVC filter placement in 132 trauma patients at high risk of PE reported a 0% incidence of symptomatic PE in patients with a correctly positioned IVC filter.⁷² In 47 patients with a malpositioned IVC filter (strut malposition or filter tilt) there was a 6.3% incidence of symptomatic PE with three deaths. DVT occurred at the insertion site in 3.1% of the patients. IVC patency was 97.1% at 3 years by life table analysis.

Fatal and nonfatal PE can still occur in a patient with prophylactic vena cava interruption. Long-term complications associated with permanent IVC filters include IVC thrombosis and DVT. Currently, the ACCP recommends that IVC filters be placed only if a proximal DVT is present and anticoagulation therapy is contraindicated. IVC filter insertion is not recommended for primary prophylaxis, although this is widely done.

In an attempt to avoid long-term complications associated with permanent IVC filters, retrievable IVC filters have been developed for use in patients with a temporarily increased risk of PE (Fig. 24-11).⁷³ Depending on the device, the filter may be removed at anywhere from 4 weeks to 6 months after insertion, assuming the period of increased PE risk has passed and no significant emboli are trapped by the filter. The best patient groups for retrievable filter placement may include young trauma patients with transient immobility, patients undergoing surgical procedures associated with a high risk of PE, and patients with hypercoagulable states who cannot receive anticoagulation therapy for a short period of time. If the device traps a significant embolus, it may be left in place as a permanent filter.

VENOUS THROMBOEMBOLISM PROPHYLAXIS IN LAPAROSCOPIC SURGERY

There are significant discrepancies in the recommendations regarding the optimal use of thromboprophylaxis around the time of laparoscopic procedures. The ACCP guidelines recommend against routine thromboprophylaxis, other than early and frequent ambulation, in patients at low risk who undergo entirely laparoscopic procedures.⁶⁷ In patients with additional VTE risk factors, the guidelines recommend prophylaxis with one or more of the following: LMWH, low-dose UFH, fondaparinux, IPC, or graduated compression stockings. The Society of American Gastrointestinal Endoscopic Surgeons recently revised its guidelines based on the magnitude of the laparoscopic procedure and the presence of additional venous thrombosis risk factors.⁷⁴

OTHER VENOUS THROMBOTIC DISORDERS

Superficial Vein Thrombophlebitis

Superficial vein thrombophlebitis (SVT) most commonly occurs in varicose veins but can occur in normal veins. When SVT recurs at variable sites in normal superficial veins, it may signify a hidden visceral malignancy or a systemic disease such as a blood dyscrasia and/or a collagen vascular disease. This condition is known as *thrombophlebitis migrans*. SVT also frequently occurs as a complication of indwelling catheters, with or without associated extravasation of injected material. Upper extremity vein thrombosis has been reported to occur in 38% of patients with peripherally inserted central catheters; 57% of these developed in the cephalic vein (Fig. 24-12).⁷⁵ Finally, suppurative SVT may occur in veins with indwelling catheters and may be associated with generalized sepsis.

Fig. 24-12.

Duplex ultrasound of a cephalic vein containing thrombus.

Clinical signs of SVT include redness, warmth, and tenderness along the distribution of the affected veins, often associated

with a palpable cord. Patients with suppurative SVT may have fever and leukocytosis. DUS should be performed in patients with signs and symptoms of acute SVT to confirm the diagnosis and to determine if any associated DVT is present. Concomitant DVT may be present in 5 to 40% of patients with SVT; most occur in patients with SVT within 1 cm of the saphenofemoral junction. A follow-up DUS should be performed in 5 to 7 days in patients with SVT in the proximal GSV but without deep vein involvement. Approximately 10 to 20% of patients with SVT involving the proximal GSV experience progression to deep venous involvement within 1 week.^{76,77}

Treatment of SVT is quite variable. A recent Cochrane review reported that LMWHs and NSAIDs both reduce the rate of SVT extension or recurrence. Topical medications appear to improve local symptoms. Surgical treatment, combined with the use of graduated compression stockings, is associated with a lower rate of VTE and SVT progression.⁷⁸ The treatment is individualized and depends on the location of the thrombus and the severity of symptoms. In patients with SVT not within 1 cm of the saphenofemoral junction, treatment consists of compression and administration of an anti-inflammatory medication such as indomethacin. In patients with suppurative SVT, removal of any existing indwelling catheters is mandatory, and excision of the vein may be necessary. If the SVT extends proximally to within 1 cm of the saphenofemoral junction, extension into the common femoral vein is more likely to occur. In these patients, anticoagulation therapy for 6 weeks and GSV ligation appear equally effective in preventing thrombus extension into the deep venous system.^{79,80}

Upper Extremity Vein Thrombosis

Axillary-subclavian vein thromboses (ASVT) are classified into two forms. Primary ASVT occurs in only a small minority of all patients with ASVT. In the primary form, no clear cause for the thrombosis is readily identifiable at initial evaluation. Patients with primary ASVT often give a history of performing prolonged, repetitive motion activities, which results in damage to the subclavian vein, usually where it passes between the head of the clavicle and the first rib. This condition is also known as *venous thoracic outlet syndrome*, *effort thrombosis*, and *Paget-Schroetter syndrome*. Secondary ASVT is more common and is associated with an easily identified cause such as an indwelling catheter or a hypercoagulable state. Over 30% of patients with tunneled subclavian vein access devices develop ASVT.⁸¹

A patient with ASVT may be asymptomatic or may present with varying degrees of upper extremity edema and tenderness. DUS can be performed initially to confirm the diagnosis. Anticoagulation therapy should be initiated once ASVT is diagnosed to prevent PE and decrease symptoms. Patients presenting with acute symptomatic primary ASVT may be candidates for catheter-directed thrombolytic therapy. Venography is performed through a catheter placed using an ultrasound-guided percutaneous basilic vein approach to document the extent of the thrombus (Fig. 24-13). A guidewire is traversed through the thrombus and a catheter is placed within the thrombus. Typically, tissue plasminogen activator is administered through a multi-side-hole infusion catheter. Heparin is administered concurrently with the urokinase infusion. After completion of thrombolytic therapy, a follow-up venogram is obtained to identify any correctable anatomic abnormalities. Adjuvant procedures after thrombolytic therapy may include cervical or first rib resection for thoracic outlet abnormalities, surgical venous reconstruction, and balloon angioplasty for residual venous stenosis.⁸²

Upper extremity venogram showing stenosis of the right subclavian vein (arrow).

Mesenteric Vein Thrombosis

Five to 15% of cases of acute mesenteric ischemia occur as a result of mesenteric vein thrombosis (MVT). Mortality rates in patients with MVT are as high as 50%.⁸³ The major presenting symptom is nonspecific abdominal pain, followed by diarrhea, nausea, and vomiting.⁸⁴ Peritoneal signs are present in fewer than half of MVT patients. MVT is more common in patients with a hypercoagulable state and malignancy.⁸⁴

Plain abdominal radiographs are usually obtained in patients with abdominal pain. Free air suggestive of a perforated viscus should be ruled out. In most patients with MVT, plain abdominal radiographs show a nonspecific bowel gas pattern and are generally nondiagnostic. Currently, contrast-enhanced abdominal computed tomographic (CT) scanning is the diagnostic study of choice in patients suspected of having MVT. In addition to revealing MVT, CT scanning can accurately detect portal and ovarian vein thrombosis. In one series, contrast-enhanced abdominal CT scanning was diagnostic for MVT in 90% of patients.⁸⁴

Patients with MVT should undergo adequate fluid resuscitation and receive anticoagulation therapy with heparin. Urgent laparotomy is undertaken in patients presenting with peritoneal findings. Broad-spectrum antibiotics are administered perioperatively. Findings at laparotomy consist of edema and cyanotic discoloration of the mesentery and bowel wall with thrombus involving the distal mesenteric veins. Complete thrombosis of the superior mesenteric vein is rare, occurring in only 12% of patients undergoing laparotomy for suspected MVT.⁸⁵ The arterial supply to the involved bowel is usually intact. Nonviable bowel is resected, and primary anastomoses can be performed. If the viability of the remaining bowel is in

question, a second-look operation is performed within 24 to 48 hours.

In patients without peritoneal findings, anticoagulation with IV UFH is promptly initiated. Patients are maintained on bowel rest and undergo fluid resuscitation. Close clinical observation is warranted with serial abdominal examinations. Once the patient's clinical status improves, oral intake can be carefully started. The patient is transitioned to oral anticoagulation over 3 to 4 days and is usually maintained on lifelong oral anticoagulation therapy.

VARICOSE VEINS

Varicose veins are a common medical condition present in at least 10% of the general population.⁸⁶ The findings of varicose veins may include dilated and tortuous veins, telangiectasias, and fine reticular varicosities. Risk factors for varicose veins include obesity, female sex, inactivity, and family history.⁸⁷ Varicose veins can be classified as primary or secondary. Primary varicose veins result from intrinsic abnormalities of the venous wall, whereas secondary varicose veins are associated with deep and/or superficial venous insufficiency.

In addition to noting the unsightly appearance, patients with varicose veins may complain of aching, heaviness, pruritus, and early fatigue of the affected leg. These symptoms worsen with prolonged standing and sitting and are relieved by elevation of the leg above the level of the heart. A mild amount of edema is often present. More severe signs include thrombophlebitis, hyperpigmentation, lipodermatosclerosis, ulceration, and bleeding from attenuated vein clusters.

An important component of treatment for patients with varicose veins is the use of elastic compression stockings. Patients may be prescribed elastic stockings with compression ranging from 20 to 30, 30 to 40, or even 40 to 50 mmHg. Stockings range in length from knee high to waist high, and they should be able to cover the symptomatic varices. The majority of patients may be managed without additional therapy.

Additional interventions are warranted in patients whose symptoms worsen or are unrelieved despite compression therapy or who have signs of lipodermatosclerosis. Cosmetic concerns also often lead to intervention. Varicose veins may be managed by injection sclerotherapy or surgical therapy or a combination of both techniques. Injection sclerotherapy can be successful in varicose veins <3 mm in diameter and in telangiectatic vessels. Sclerotherapy acts by destroying the venous endothelium. Sclerosing agents include hypertonic saline, sodium tetradecyl sulfate, and polidocanol. Concentrations of 11.7 to 23.4% hypertonic saline, 0.125 to 0.250% sodium tetradecyl sulfate, and 0.5% polidocanol are used for telangiectasias. Larger varicose veins require higher concentrations: 23.4% hypertonic saline, 0.50 to 1% sodium tetradecyl sulfate, and 0.75 to 1.0% polidocanol.⁸³ Elastic bandages are wrapped around the leg after injection and worn continuously for 3 to 5 days to produce apposition of the inflamed vein walls and prevent thrombus formation. After the bandages are removed, elastic compression stockings should be worn for a minimum of 2 weeks. Complications from sclerotherapy include allergic reaction, pigmentation, thrombophlebitis, DVT, and possible skin necrosis.

Patients with symptomatic great or small saphenous vein reflux may be treated with endovenous ablation techniques or surgical removal. Endovenous laser treatment and radiofrequency ablation (RFA) have gained in popularity in the past several years. With either technique, the distal thigh or proximal calf GSV is punctured with a 21-gauge needle under ultrasound guidance. A sheath is placed over a guidewire, and the laser fiber or RFA catheter is advanced until it is near to, but not at, the saphenofemoral junction. Tumescence is administered around the GSV, and the vein is treated as the catheter is withdrawn. Endovenous laser treatment and RFA result in durable ablation of the GSV, with rates of varicose vein recurrence and clinical severity scores comparable to those seen with open surgery.^{88,89} Risks of endovenous ablation include DVT, ecchymosis, and saphenous nerve injury.

Saphenous vein ligation and stripping is still the more commonly performed procedure worldwide, and it may be the preferred therapy for patients with GSVs of very large diameter (>2 cm). Surgical removal of the GSV usually is performed via small incisions placed medially in the groin and just below the knee. The GSV is removed using a blunt tip catheter or an invagination pin stripper. Complications associated with GSV stripping include ecchymosis, lymphocele formation, DVT, infection, and saphenous nerve injury. GSV stripping is associated with a lower rate of recurrence of varicose veins and a better quality of life than saphenofemoral junction ligation alone.

Larger varicose veins are best treated by surgical excision using the "stab avulsion" technique. Stab avulsions are performed by making 2-mm incisions directly over branch varicosities, and the varicosity is dissected from the surrounding subcutaneous tissue as far proximally and distally as possible through the small incisions (Fig. 24-14). In most cases the vein is simply avulsed with no attempt at ligation. Bleeding is easily controlled with leg elevation, manual compression, and preprocedure tumescent anesthesia.

Removal of varicose veins via stab avulsions.

CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency (CVI) is a major and costly medical problem, affecting an estimated 600,000 people in the United States.⁹⁰ Patients complain of leg fatigue, discomfort, and heaviness. Signs of CVI may include varicose veins,

pigmentation, lipodermatosclerosis, and venous ulceration. Importantly, severe CVI can be present without varicose veins. Chronic venous ulcers carry significant negative physical, financial, and psychologic implications. A quality-of-life study reported that 65% of patients with chronic leg ulcers had severe pain, 81% had decreased mobility, and 100% experienced a negative impact of their disease on their work capacity.⁹¹ The socioeconomic impact of chronic venous leg ulcers is staggering, with an estimated 2 million workdays lost per year.⁹² The annual health care cost in the United States to treat CVI is estimated at \$1 billion.⁹³

The signs and symptoms of CVI can be attributed to venous reflux, venous obstruction, calf muscle pump dysfunction, or a combination of these factors, as well as loss of venous wall elasticity.⁹⁴ In the majority of patients with CVI, the most important factor appears to be venous reflux. Venous reflux results from abnormalities of the venous valve and can be classified as primary or secondary. Primary valvular reflux or incompetence is diagnosed when there is no known underlying cause of valvular dysfunction. Secondary valvular reflux is diagnosed when an identifiable cause is present. The most frequent secondary cause is DVT, which can lead to the dysfunction of venous valves. Signs of CVI include edema, hyperpigmentation, and ulceration.

Evaluation of Venous Insufficiency

Early diagnostic studies to evaluate CVI required invasive measurements of ambulatory venous pressure (AVP) and venous recovery time (VRT). To measure AVP and VRT, a needle is inserted into a dorsal foot vein and connected to a pressure transducer. Pressures measured in the dorsal veins of the foot are thought to reflect those in the deep veins of the calf. Once the needle is placed, the patient is asked to perform 10 tiptoe exercises. Initially there is often a slight upward deflection of pressure with the onset of exercise. With each subsequent tiptoe maneuver, the measured pressure should decrease. After approximately 10 tiptoes, the measured pressure stabilizes and reflects a balance of venous inflow and outflow. The pressure at this point is the AVP, which is measured in millimeters of mercury. The patient is then asked to stop exercising to allow the vein to fill with return of the venous pressure to baseline. The time required for the venous pressure to return from the AVP level to 90% of baseline pressure is referred to as the VRT. Elevations of AVP indicate the presence of venous hypertension. The magnitude of AVP reflects the severity of CVI. There is an 80% incidence of venous ulceration in patients with an AVP of >80 mmHg.⁹⁵

PLETHYSMOGRAPHY IN VENOUS INSUFFICIENCY

Noninvasive plethysmographic methods based on the measurement of volume changes in the leg have been used to evaluate CVI. Venous photoplethysmography indirectly evaluates venous function through the use of infrared light. A light-emitting diode is placed just above the medial malleolus and the patient then performs a series of tiptoe maneuvers. Photoplethysmography does not give accurate AVP measurements but does provide adequate VRT determinations. In limbs with CVI, VRT is shortened compared with that in a normal limb. AVP and VRT are measures of overall function in the lower extremity venous system. They cannot localize the site of reflux or evaluate the function of the calf pump in patients with CVI.

Air plethysmography can be used to assess calf pump function as well as venous reflux and overall lower extremity venous function.⁹⁶ An air-filled plastic pressure bladder is placed on the calf to detect volume changes in the leg during a standard set of maneuvers. The patient is first supine and then the leg is elevated and the minimum volume of venous blood recorded. The patient is then asked to assume an upright position with the examined leg nonweightbearing. The venous volume in the examined leg is determined when the volume curve flattens out. The venous filling index (VFI) is calculated by

dividing the maximum venous volume by the time required to achieve maximum venous volume. The VFI is a measure of reflux. Next, the patient performs a single tiptoe maneuver and the ejection fraction (EF) is determined. The EF is the volume change between the recorded volume before and after the tiptoe maneuver and is a measure of calf pump function. At this point, the veins of the leg are allowed to refill. The patient then performs 10 tiptoe maneuvers, and the residual volume fraction is calculated by dividing the venous volume in the leg after 10 tiptoe exercises by the venous volume present before the exercises. The residual volume fraction is a reflection of overall venous function. Theoretically, patients with increased VFIs and normal EFs (indicating the presence of reflux with normal calf pump function) would benefit from antireflux surgery, whereas patients with normal VFIs and diminished EFs would not.

VENOUS DUPLEX ULTRASOUND

In addition to identifying patients with DVT, DUS can be used to evaluate reflux in individual venous segments of the leg. The examination is performed with the patient in the standing position and the examined leg in a nonweightbearing position. Pneumatic pressure cuffs of appropriate size are placed around the thigh, calf, and forefoot. The ultrasound transducer is positioned over the venous segment to be examined, just proximal to the pneumatic cuff (Fig. 24-15). The cuff is then inflated to a standard pressure for 3 seconds and then rapidly deflated. Ninety-five percent of normal venous valves close within 0.5 second.⁹⁷ The presence of reflux for >0.5 second is considered abnormal. Typically, the common femoral, femoral, popliteal, and posterior tibial veins, as well as the great and small saphenous veins, are evaluated in a complete examination.

Evaluation of a patient with chronic venous insufficiency with duplex ultrasonography.

Nonoperative Treatment of Chronic Venous Insufficiency

COMPRESSION THERAPY

Compression therapy is the mainstay of CVI management. Compression can be achieved using a variety of techniques, including elastic compression stockings, paste gauze boots (Unna's boots), multilayer elastic wraps or dressings (Fig. 24-16), and pneumatic compression devices. The exact mechanism by which compression therapy can improve CVI remains uncertain. An improvement in skin and subcutaneous tissue microcirculatory hemodynamics as well as a direct effect on subcutaneous pressure have been hypothesized as the mechanism of compression therapy.⁹⁸ Clinically, routine use of elastic and nonelastic bandages reduces lower extremity edema in patients with CVI. In addition, supine perimalleolar subcutaneous pressure has been demonstrated to increase with elastic compression.⁹⁹ With edema reduction, cutaneous metabolism may improve due to enhanced diffusion of oxygen and other nutrients to the cellular elements of skin and subcutaneous tissues. Increases in subcutaneous tissue pressure with elastic compression bandages may counteract transcapillary Starling forces, which favor leakage of fluid out of the capillary.

Multilayered dressing for treatment of chronic venous insufficiency.

Before the initiation of therapy for CVI, patients must be educated about their chronic disease and the need to comply with their treatment plan to heal ulcers and prevent recurrence. A definitive diagnosis of venous ulceration must be made before treatment is initiated. A detailed history should be obtained from a patient presenting with lower extremity ulcerations, including medications used and associated medical conditions that may promote lower extremity ulceration. Arterial insufficiency is assessed by physical examination or noninvasive studies. In addition, systemic conditions that affect wound healing and leg edema, such as diabetes mellitus, immunosuppression, malnutrition, and congestive heart failure, should be improved as much as possible.

Compression therapy is most commonly achieved with graduated elastic compression stockings. Graduated elastic compression stockings, initially developed by Conrad Jobst in the 1950s, were made to simulate the gradient of hydrostatic forces exerted by water in a swimming pool. Elastic compression stockings are available in various compositions, strengths, and lengths, and can be customized for a particular patient.

The benefits of elastic compression stocking therapy for the treatment of CVI and healing of ulcerations have been well documented.^{100–103} In a retrospective study involving 113 venous ulcer patients,¹⁰¹ the use of below-knee, 30- to 40-mmHg elastic compression stockings, after edema and cellulitis were first resolved if present, resulted in 93% healing. Complete ulcer healing occurred in 99 of 102 patients (97%) who were compliant with stocking use vs. 6 of 11 patients (55%) who were noncompliant ($P < .0001$). The mean time to ulcer healing was 5 months. The rate of ulcer recurrence was lower in patients who were compliant with their compression therapy. By life table analysis, ulcer recurrence was 29% at 5

years for compliant patients and 100% at 3 years for noncompliant patients. In more recent studies, the reported rate of venous ulcer healing with compression therapy is approximately 40 to 50% at 6 months.^{104,105}

In addition to promoting ulcer healing, elastic compression therapy can also improve quality of life in patients with CVI. In one prospective study,¹⁰⁶ 112 patients with CVI documented by DUS were administered a questionnaire to quantify the symptoms of swelling, pain, skin discoloration, cosmesis, activity tolerance, depression, and sleep alterations. Patients were treated with 30- to 40-mmHg elastic compression stockings. There were overall improvements in symptom severity scores at 1 month after initiation of treatment. Further improvements were noted at 16 months after treatment.

Patient compliance with compression therapy is crucial in treating venous leg ulcers. Many patients are initially intolerant of compression in areas of hypersensitivity adjacent to an active ulcer or at sites of previously healed ulcers. They may also have difficulty applying elastic stockings. To improve compliance, patients should be instructed to wear their stockings initially only as long as it is easily tolerated and then gradually to increase the amount of time the stockings are worn. Alternatively, patients can be fitted with lower-strength stockings initially followed by introduction of higher-strength stockings over a period of several weeks. Many commercially available devices, such as silk inner toe liners, stockings with zippered sides (Fig. 24-17), and metal fitting aids (Fig. 24-18), are available to assist patients in applying elastic stockings.

Metal fitting aid to assist in placement of elastic compression stockings.

Another method of compression was developed by the German dermatologist Paul Gerson Unna in 1896. Unna's boot has been used for many years to treat venous ulcers and is available in many versions. A typical Unna's boot consists of a three-layer dressing and requires application by trained personnel. A rolled gauze bandage impregnated with calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate is first applied with graded compression from the forefoot to just below the knee. The next layer consists of a 4-in-wide continuous gauze dressing followed by an outer layer of elastic wrap, also applied with graded compression. The bandage becomes stiff after drying and the rigidity may aid in preventing edema formation. Unna's boot is changed weekly, or sooner if the patient experiences significant drainage from the ulcer bed.

Once applied, Unna's boot requires minimal patient involvement and provides continuous compression and topical therapy. However, Unna's boot has several disadvantages. It is uncomfortable to wear because of its bulkiness, which may affect patient compliance. In addition, the ulcer cannot be monitored after the boot is applied, the technique is labor intensive, and the degree of compression provided is operator dependent. Occasionally, patients may develop contact dermatitis to the components of Unna's boot, which may require discontinuation of therapy.

The efficacy of Unna's dressing has been studied. A retrospective 15-year survey encompassing 998 patients with one or more venous ulcers treated weekly with Unna's dressing¹⁰⁷ reported that 73% of ulcers healed in patients who returned for more than one treatment. The median time to healing for individual ulcers was 9 weeks. Unna's dressing has been compared to other forms of treatment. A randomized, prospective study¹⁰⁸ comparing Unna's boot to polyurethane foam dressing in 36 patients with venous ulcers demonstrated superior healing over 12 months in patients treated with Unna's boot (94.7% vs. 41.2%).

Other forms of compression dressing available to treat CVI include multilayered dressings and legging orthoses. The purported advantages of multilayered dressings include maintenance of compression for a longer period of time, more even distribution of compression, and better absorption of wound exudates. However, the efficacy of multilayered dressings depends on the wrapping technique of health care personnel. A commercially available legging orthosis consisting of multiple adjustable loop-and-hook closure compression bands provides compression similar to that of Unna's boot and can be applied daily by the patient.¹⁰⁹

SKIN SUBSTITUTES

Several types of skin substitutes are commercially available or under clinical study in the United States.⁹² Bioengineered skin ranges in composition from acellular skin substitutes to partial living skin substitutes. Their mechanism of action in healing venous ulcers is uncertain; however, they may serve as delivery vehicles for various growth factors and cytokines important in wound healing.

Apligraf is a commercially available bilayered living skin construct that closely approximates human skin for use in the treatment of venous ulcers. It contains a protective stratum corneum and a keratinocyte-containing epidermis overlying a dermis consisting of dermal fibroblasts in a collagen matrix.¹¹⁰ Apligraf is between 0.5 mm and 1.0 mm thick and is supplied as a disk of living tissue on an agarose gel nutrient medium. It must be used within 5 days of release from the manufacturer¹¹⁰ (Fig. 24-19). The disk is easily handled and applied, and easily conforms to irregularly contoured ulcer beds.

Fig. 24-19.

Apligraf skin graft material supplied as a disk on an agarose gel nutrient medium.

A prospective randomized study comparing multilayer compression therapy alone to treatment with Apligraf in addition to multilayered compression therapy has been performed to assess the efficacy of Apligraf in the treatment of venous ulcers.¹⁰⁴ More patients treated with Apligraf had ulcer healing at 6 months (63% vs. 49%, $P = .02$). The median time to complete ulcer closure was significantly shorter in patients treated with Apligraf (61 days vs. 181 days, $P = .003$). The ulcers that showed the greatest benefit with the living skin construct were ones that were large and deep ($>1000 \text{ mm}^2$) or were longstanding (>6 months). No evidence of rejection or sensitization has been reported in response to Apligraf application.

Surgical Treatment of Chronic Venous Insufficiency

PERFORATOR VEIN LIGATION

Incompetence of the perforating veins connecting the superficial and deep venous systems of the lower extremities has been implicated in the development of venous ulcers. The classic open technique described by Linton in 1938 for perforator vein ligation has a high incidence of wound complications and has largely been abandoned.¹¹¹ A minimally invasive technique termed *subfascial endoscopic perforator vein surgery* (SEPS) has evolved with the improvement in endoscopic equipment.

DUS is performed preoperatively in patients undergoing SEPS to document deep venous competence and to identify perforating veins in the posterior compartment. The patient is positioned on the operating table with the affected leg elevated at 45 to 60 degrees. An Esmarch bandage and a thigh tourniquet are used to exsanguinate the limb. The knee is then flexed, and two small incisions are made in the proximal medial leg away from areas of maximal induration at the ankle.

Laparoscopic trocars are then positioned, and the subfascial dissection is performed with a combination of blunt and sharp dissection. Carbon dioxide is then used to insufflate the subfascial space. The thigh tourniquet is inflated to prevent air embolism. The perforators are then identified and doubly clipped and divided. After completion of the procedure, the leg is wrapped in a compression bandage for 5 days postoperatively.

In a report from a large North American registry of 146 patients undergoing SEPS¹¹² (Fig. 24-20), healing was achieved in 88% of ulcers (75 of 85) at 1 year. Adjunctive procedures, primarily superficial vein stripping, were performed in 72% of patients. Ulcer recurrence was predicted to be 16% at 1 year and 28% at 2 years by life table analysis. The efficacy of the technique has not been confirmed in a randomized trial.

Trocar placement for subfascial endoscopic perforator vein surgery.

VENOUS RECONSTRUCTION

In the absence of significant deep vein valvular incompetence, saphenous vein stripping and perforator vein ligation can be effective in the treatment of CVI. However, in patients with a combination of superficial and deep vein valvular

incompetence, the addition of deep vein valvular reconstruction theoretically may improve ulcer healing.¹¹³ Numerous techniques of deep vein valve correction have been reported. These techniques consist of repair of existing valves, transplant of venous segments from the arm, and transposition of an incompetent vein onto an adjacent competent vein. A method in which cryopreserved venous valve allografts are placed below incompetent vein segments surgically or percutaneously is currently in the early phases of development but does not seem effective.¹¹⁴

Successful long-term outcomes of 60 to 80% have been reported for venous valve reconstructions by internal suture repair.^{113,115,116} However, among patients who initially had ulceration, 40 to 50% still had persistence or recurrence of ulcers in the long term.^{115,116} Valve transplantation involves replacement of a segment of incompetent femoral vein or popliteal vein with a segment of axillary or brachial vein with competent valves. Early results are similar to those for venous valve reconstruction.^{113,115,116} However, in the long term, the transplanted venous segments tend to develop incompetence, and long-term outcomes are poorer than those for venous valve reconstructions. The outcomes for venous transposition are similar to those for valve transplantation.

LYMPHEDEMA

Pathophysiology

Lymphedema is extremity swelling that results from a reduction in lymphatic transport, with resultant pooling of lymph within the interstitial space. It is caused by anatomic problems such as lymphatic hypoplasia, functional insufficiency, or absence of lymphatic valves.

The original classification system, described by Allen, is based on the cause of the lymphedema. Primary lymphedema is further subdivided into congenital lymphedema, lymphedema praecox, and lymphedema tarda. *Congenital lymphedema* may involve a single lower extremity, multiple limbs, the genitalia, or the face. The edema typically develops before 2 years of age and may be associated with specific hereditary syndromes (Turner syndrome, Milroy syndrome, Klippel-Trénaunay-Weber syndrome). *Lymphedema praecox* is the most common form of primary lymphedema, accounting for 94% of cases. Lymphedema praecox is far more common in women, with the gender ratio favoring women 10:1. The onset is during childhood or the teenage years, and the swelling involves the foot and calf. *Lymphedema tarda* is uncommon, accounting for <10% of cases of primary lymphedema. The onset of edema is after 35 years of age.

Secondary lymphedema is far more common than primary lymphedema. Secondary lymphedema develops as a result of lymphatic obstruction or disruption. Axillary node dissection leading to lymphedema of the arm is the most common cause of secondary lymphedema in the United States. Other causes of secondary lymphedema include radiation therapy, trauma, infection, and malignancy. Globally, filariasis (caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*) is the most common cause of secondary lymphedema.

Clinical Diagnosis

In most patients the diagnosis of lymphedema can be made based on the history and physical examination alone. Patients commonly complain of heaviness and fatigue in the affected extremity. The limb size increases throughout the day and decreases over the course of the night when the patient is in bed. The limb, however, never completely normalizes. In the lower extremity the swelling involves the dorsum of the foot, and the toes have a squared-off appearance. In advanced cases, hyperkeratosis of the skin develops, and fluid weeps from lymph-filled vesicles (Fig. 24-21).

Hyperkeratosis of the skin in a patient with longstanding lymphedema.

Recurrent cellulitis is a common complication of lymphedema. Repeated infection results in further lymphatic damage, worsening existing disease. The clinical presentation of cellulitis ranges from subtle erythema and worsening of edema to a rapidly progressive soft tissue infection with systemic toxicity.

Many medical conditions can cause edema. If the symptoms are mild, distinguishing lymphedema from other causes of leg swelling can be difficult. Venous insufficiency is often confused with lymphedema. However, patients with advanced venous insufficiency typically have lipodermatosclerosis in the gaiter region, skin ulceration, and/or varicose veins. Bilateral pitting edema is typically associated with congestive heart failure, renal failure, or a hypoproteinemic state.

Radiologic Diagnosis

DUPLEX ULTRASOUND

When a patient is evaluated for edema, it is often difficult to distinguish the early stages of lymphedema from venous insufficiency. Duplex ultrasound of the venous system can determine if there is concomitant venous thrombosis or venous reflux, perhaps contributing to extremity edema. The diagnostic modalities discussed in the following sections have limited use in clinical practice. They are invasive and tedious, and rarely change the management of a patient with lymphedema. Most physicians rely on the patient's history and physical examination alone to make the diagnosis of lymphedema.

LYMPHOSCINTIGRAPHY

Lymphoscintigraphy has become the most commonly used diagnostic test to identify lymphatic abnormalities. It has largely replaced lymphangiography. A radiolabeled sulfur colloid (technetium 99m sulfur colloid) is injected into the subdermal, interdigital region of the affected limb. The lymphatic transport is monitored with a whole body gamma camera, and major lymphatics and nodes can be visualized (Fig. 24-22). In normal individuals, tracer activity may be detected in the inguinal region within 15 to 60 minutes. Within 3 hours, uptake should be present in the pelvic and abdominal lymph nodes. In

patients with lymphedema, various patterns may be seen on lymphoscintigraphy. There may be delayed or absent transport to the inguinal nodes. Increased cutaneous collaterals may be seen with obstruction of the primary axial channels. There may be localized regions of reduced uptake in patients with prior node dissection or radiation therapy.

Lymphoscintigraphy of the lower extremity.

LYMPHANGIOGRAPHY

Radiologic lymphology is performed by first visualizing the lymphatics by injecting colored dye into the hand or foot. The visualized lymphatic segment is exposed through a small incision and cannulated with a 27- to 30-gauge needle. An oil-based dye is then injected slowly into the lymphatics over several hours. The lymphatic channels and nodes are then visualized with traditional radiographs (Figs. 24-23 and 24-24). Lymphangiography is reserved for patients with lymphangiectasia or lymphatic fistulas, and patients who are being considered for microvascular reconstruction.

Management

An important aspect of the management of lymphedema is patient understanding that there is no cure for lymphedema. The primary goals of treatment are to minimize swelling and to prevent recurrent infections. Controlling the chronic limb swelling can improve discomfort, heaviness, and tightness, and potentially reduce the progression of disease.¹¹⁷

COMPRESSION GARMENTS

Graded compression stockings are widely used in the treatment of lymphedema. The stockings reduce the amount of swelling in the involved extremity by preventing the accumulation of edema while the extremity is dependent. When worn daily, compression stockings have been associated with long-term maintenance of reduced limb circumference.¹¹⁸ They may also protect the tissues against chronically elevated intrinsic pressures, which lead to thickening of the skin and subcutaneous tissue.¹¹⁹ Compression stockings also offer a degree of protection against external trauma.

The amount of compression required for controlling lymphedema ranges from 20 to 60 mmHg and varies among patients. The stockings can be custom made or prefabricated and are available in above- and below-knee lengths. The stockings should be worn during waking hours. The garments should be replaced approximately every 6 months when they lose elasticity.

BEDREST AND LEG ELEVATION

Elevation is an important aspect of controlling lower extremity swelling and is often the first recommended intervention. However, continuous elevation throughout the day can interfere with quality of life more than lymphedema itself. Elevation is an adjunct to lymphedema therapy but is not the mainstay of treatment.

SEQUENTIAL EXTERNAL PNEUMATIC COMPRESSION

The use of intermittent pneumatic compression with a single-chamber or multichamber pump temporarily reduces edema and provides another adjunct to the use of compression stockings. These devices have been shown to be effective in reducing limb volume^{120,121} ; however, use of compression stockings is necessary to maintain the volume reduction when the patient is no longer supine. Typically, intermittent pneumatic compression is used for 4 to 6 hours per day at home when the patient is supine.

LYMPHATIC MASSAGE

Manual lymphatic drainage is a form of massage developed by Vodder¹²² that is directed at reducing edema. In combination with the use of compression stockings, manual lymphatic drainage is associated with a long-term reduction in edema and fewer infections per patient per year.¹²³

ANTIBIOTIC THERAPY

Patients with lymphedema are at increased risk of developing cellulitis in the affected extremity. Recurrent infection can damage the lymphatics, aggravating the edema. *Staphylococcus* and beta-hemolytic *Streptococcus* are the most common organisms causing soft tissue infection. Aggressive antibiotic therapy is recommended at the earliest signs or symptoms of cellulitis. The drug of choice is penicillin, usually 500 mg orally three to four times per day. Patients with a history of lymphedema and recurrent cellulitis should be prescribed antibiotics that they can keep at home and begin taking at the first sign of infection.

SURGERY

A variety of surgical procedures have been devised for the treatment of lymphedema. Surgical treatment involves either excision of extra tissue¹²⁴ or anastomosis of a lymphatic vessel to another lymphatic or vein.¹²⁵ In excisional procedures, part or all of the edematous tissue is removed. This does not improve lymphatic drainage but debulks redundant tissue. The microsurgical procedures involve the creation of a lymphaticolymphatic or lymphaticovenous anastomosis, which theoretically improves lymphatic drainage. No long-term follow-up data are available for these interventions, and therefore operative therapy for lymphedema is not well accepted worldwide. Furthermore, operative intervention can further obliterate lymphatic channels, worsening the edema.¹²⁶

Summary

Lymphedema is a chronic condition caused by ineffective lymphatic transport, which results in edema and skin damage. Lymphedema is not curable, but the symptoms can be controlled with a combination of elastic compression stockings, limb elevation, pneumatic compression, and massage. Controlling the edema protects the skin and potentially prevents cellulitis.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 25. Esophagus and Diaphragmatic Hernia >

KEY POINTS

1. Objective esophageal physiology testing is cornerstone to making the diagnosis of benign esophageal disorders and in developing an individualized treatment plan for patients.
2. While most esophageal procedures can be performed using either a videoscopic or flexible endoscopic approach, the surgeon must be familiar with the surgical anatomy and open approaches to the esophagus along its entire length.
3. Laparoscopic cardiomyotomy is now considered the most effective treatment for achalasia and should include division of the gastric collar sling musculature.
4. While esophageal replacement is most commonly performed with the tubularized stomach, the surgeon should be familiar with the anatomy and techniques which enable the use of colon and jejunum.
5. Giant paraesophageal hernia should be repaired surgically in patients with symptoms, anemia, or signs of strangulation.
6. The cornerstone to esophageal cancer clinical staging includes the use of endoscopy, CT, PET, and endoscopic ultrasound.
7. In surgical candidates with esophageal cancer confined to the posterior mediastinum, esophagectomy represents the best possible chance for cure.

SURGICAL ANATOMY

The esophagus is a muscular tube that starts as the continuation of the pharynx and ends as the cardia of the stomach. When the head is in a normal anatomic position, the transition from pharynx to esophagus occurs at the lower border of the sixth cervical vertebra. Topographically this corresponds to the cricoid cartilage anteriorly and the palpable transverse process of the sixth cervical vertebra laterally (Fig. 25-1). The esophagus is firmly attached at its upper end to the cricoid cartilage and at its lower end to the diaphragm; during swallowing, the proximal points of fixation move cranial the distance of one cervical vertebral body.

Fig. 25-1.

A. Topographic relationships of the cervical esophagus: (a) hyoid bone, (b) thyroid cartilage, (c) cricoid cartilage, (d) thyroid gland, (e) sternoclavicular. **B.** Lateral radiographic appearance with landmarks identified as labeled in **A**. The location of C6 is also included (f).

The esophagus lies in the midline, with a deviation to the left in the lower portion of the neck and upper portion of the thorax, and returns to the midline in the midportion of the thorax near the bifurcation of the trachea (Fig. 25-2). In the lower portion of the thorax, the esophagus again deviates to the left and anteriorly to pass through the diaphragmatic hiatus.

Fig. 25-2.

Barium esophagogram. **A.** Posterior-anterior view. *White arrow* shows deviation to left. *Black arrow* shows return to midline. **B.** Lateral view. *Black arrow* shows anterior deviation.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 77.]

Three normal areas of esophageal narrowing are evident on the barium esophagogram or during esophagoscopy. The uppermost narrowing is located at the entrance into the esophagus and is caused by the cricopharyngeal muscle. Its luminal diameter is 1.5 cm, and it is the narrowest point of the esophagus. The middle narrowing is due to an indentation of the anterior and left lateral esophageal wall caused by the crossing of the left main stem bronchus and aortic arch. The luminal diameter at this point is 1.6 cm. The lowermost narrowing is at the hiatus of the diaphragm and is caused by the gastroesophageal sphincter mechanism. The luminal diameter at this point varies somewhat, depending on the distention of the esophagus by the passage of food, but has been measured at 1.6 to 1.9 cm. These normal constrictions tend to hold up swallowed foreign objects, and the overlying mucosa is subject to injury by swallowed corrosive liquids due to their slow passage through these areas.

Figure 25-3 shows the average distance in centimeters measured during endoscopic examination between the incisor teeth and the cricopharyngeus, aortic arch, and cardia of the stomach. Manometrically, the length of the esophagus between the lower border of the cricopharyngeus and upper border of the lower sphincter varies according to the height of the individual.

Fig. 25-3.

Important clinical endoscopic measurements of the esophagus in adults.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 78.]

The pharyngeal musculature consists of three broad, flat, overlapping fan-shaped constrictors (Fig. 25-4). The opening of the esophagus is collared by the cricopharyngeal muscle, which arises from both sides of the cricoid cartilage of the larynx and forms a continuous transverse muscle band without interruption by a median raphe. The fibers of this muscle blend inseparably with those of the inferior pharyngeal constrictor above and the inner circular muscle fibers of the esophagus below. Some investigators believe that the cricopharyngeus is part of the inferior constrictor; that is, that the inferior constrictor has two parts, an upper or retrothyroid portion having diagonal fibers, and a lower or retrocricoid portion having transverse fibers. Keith in 1910 showed that these two parts of the same muscle serve totally different functions. The retrocricoid portion serves as the upper sphincter of the esophagus and relaxes when the retrothyroid portion contracts, to force the swallowed bolus from the pharynx into the esophagus.

External muscles of the pharynx. **A.** Posterolateral view. **B.** Posterior view. Dotted line represents usual site of myotomy.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 78.]

The cervical portion of the esophagus is approximately 5 cm long and descends between the trachea and the vertebral column, from the level of the sixth cervical vertebra to the level of the interspace between the first and second thoracic vertebrae posteriorly, or the level of the suprasternal notch anteriorly. The recurrent laryngeal nerves lie in the right and left grooves between the trachea and the esophagus. The left recurrent nerve lies somewhat closer to the esophagus than the right, owing to the slight deviation of the esophagus to the left, and the more lateral course of the right recurrent nerve around the right subclavian artery. Laterally, on the left and right sides of the cervical esophagus are the carotid sheaths and the lobes of the thyroid gland.

The thoracic portion of the esophagus is approximately 20 cm long. It starts at the thoracic inlet. In the upper portion of the thorax, it is in intimate relationship with the posterior wall of the trachea and the prevertebral fascia. Just above the tracheal bifurcation, the esophagus passes to the right of the aorta. This anatomic positioning can cause a notch indentation in its left lateral wall on a barium swallow radiogram. Immediately below this notch, the esophagus crosses both the bifurcation of the trachea and the left main stem bronchus, owing to the slight deviation of the terminal portion of the trachea to the right by the aorta (Fig. 25-5). From there down, the esophagus passes over the posterior surface of the subcarinal lymph nodes (LNs), and then descends over the pericardium of the left atrium to reach the diaphragmatic hiatus (Fig. 25-6). From the bifurcation of the trachea downward, both the vagal nerves and the esophageal nerve plexus lie on the muscular wall of the esophagus.

Fig. 25-5.

Dorsally, the thoracic esophagus follows the curvature of the spine and remains in close contact with the vertebral bodies. From the eighth thoracic vertebra downward, the esophagus moves vertically away from the spine to pass through the hiatus of the diaphragm. The thoracic duct passes through the hiatus of the diaphragm on the anterior surface of the vertebral column behind the aorta and under the right crus. In the thorax, the thoracic duct lies dorsal to the esophagus between the azygos vein on the right and the descending thoracic aorta on the left.

The abdominal portion of the esophagus is approximately 2 cm long and includes a portion of the lower esophageal sphincter (LES) (Fig. 25-7). It starts as the esophagus passes through the diaphragmatic hiatus and is surrounded by the phrenoesophageal membrane, a fibroelastic ligament arising from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen (Fig. 25-8). The upper leaf of the membrane attaches itself in a circumferential fashion around the esophagus, about 1 to 2 cm above the level of the hiatus. These fibers blend in with the elastic-containing adventitia of the abdominal esophagus and the cardia of the stomach. This portion of the esophagus is subjected to the positive-pressure environment of the abdomen.

Fig. 25-7.

Schematic drawing shows correlation between radial muscle thickness (*left*) and three-dimensional manometric pressure image (*right*) at human gastroesophageal junction. Muscle thickness across the gastroesophageal junction at the posterior gastric wall (PW), greater curvature (GC), anterior gastric wall (AW), and lesser curvature (LC) is shown in millimeters. Radial pressures at gastroesophageal junction (in millimeters of mercury) are plotted around an axis representing atmospheric pressure.

Attachments and structure of the phrenoesophageal membrane. Transversalis fascia lies just above the parietal peritoneum.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 83.]

The musculature of the esophagus can be divided into an outer longitudinal and an inner circular layer. The upper 2 to 6 cm of the esophagus contains only striated muscle fibers. From there on, smooth muscle fibers gradually become more abundant. Most clinically significant esophageal motility disorders involve only the smooth muscle in the lower two thirds of the esophagus. When a surgical esophageal myotomy is indicated, the incision needs to extend only this distance.

The longitudinal muscle fibers originate from a cricoesophageal tendon arising from the dorsal upper edge of the anteriorly located cricoid cartilage. The two bundles of muscle diverge and meet in the midline on the posterior wall of the esophagus about 3 cm below the cricoid (see Fig. 25-4). From this point on, the entire circumference of the esophagus is covered by a layer of longitudinal muscle fibers. This configuration of the longitudinal muscle fibers around the most proximal part of the esophagus leaves a V-shaped area in the posterior wall covered only with circular muscle fibers. Contraction of the longitudinal muscle fibers shortens the esophagus. The circular muscle layer of the esophagus is thicker than the outer longitudinal layer. In situ, the geometry of the circular muscle is helical and makes the peristalsis of the esophagus assume a worm-like drive, as opposed to segmental and sequential squeezing. As a consequence, severe motor abnormalities of the esophagus assume a corkscrew-like pattern on the barium swallow radiogram.

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives its blood supply from the bronchial arteries, with 75% of individuals having one right-sided and two left-sided branches. Two esophageal branches arise directly from the aorta. The abdominal portion of the esophagus receives its blood supply from the ascending branch of the left gastric artery and from inferior phrenic arteries (Fig. 25-9). On entering the wall of the esophagus, the arteries assume a T-shaped division to form a longitudinal plexus, giving rise to an intramural vascular network in the muscular and submucosal layers. As a consequence, the esophagus can be mobilized from the stomach to the level of the aortic arch without fear of devascularization and ischemic necrosis. Caution should be exercised as to the extent of esophageal mobilization in patients who have had a previous thyroidectomy with ligation of the inferior thyroid arteries proximal to the origin of the esophageal branches.

Arterial blood supply of the esophagus.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 84.]

Blood from the capillaries of the esophagus flows into a submucosal venous plexus, and then into a periesophageal venous plexus from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region, they empty into the bronchial, azygos, or hemiazygos veins; and in the abdominal region, they empty into the coronary vein (Fig. 25-10). The submucosal venous networks of the esophagus and stomach are in continuity with each other, and, in patients with portal venous obstruction, this communication functions as a collateral pathway for portal blood to enter the superior vena cava via the azygos vein.

Venous drainage of the esophagus.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 85.]

The parasympathetic innervation of the pharynx and esophagus is provided mainly by the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is on the posterior lateral surface of the middle constrictor muscle, and is formed by pharyngeal branches of the vagus nerves with a small contribution from cranial nerves IX and XI (Fig. 25-11). The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both recurrent laryngeal nerves, which originate from the vagus nerves—the right recurrent nerve at the lower margin of the subclavian artery and the left at the lower margin of the aortic arch. They are slung dorsally around these vessels and ascend in the groove between the esophagus and trachea, giving branches to each. Damage to these nerves interferes not only with the function of the vocal cords, but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the individual to pulmonary aspiration on swallowing.

Innervation of the esophagus.

[Reproduced with permission from Rothberg M, DeMeester TR: Surgical anatomy of the esophagus, in Shields TW (ed): *General Thoracic Surgery*, 3rd ed. Philadelphia: Lea & Febiger, 1989, p 85.]

Afferent visceral sensory pain fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord, using a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart; hence, both organs have similar symptomatology.

The lymphatics located in the submucosa of the esophagus are so dense and interconnected that they constitute a single plexus (Fig. 25-12). There are more lymph vessels than blood capillaries in the submucosa. Lymph flow in the submucosal plexus runs in a longitudinal direction, and, on injection of a contrast medium, the longitudinal spread is seen to be about six times that of the transverse spread. In the upper two-thirds of the esophagus, the lymphatic flow is mostly cephalad, and, in the lower third, caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, a primary tumor can extend for a considerable length superiorly or inferiorly in the submucosal plexus. Consequently, free tumor cells can follow the submucosal lymphatic plexus in either direction for a long distance before they pass through the muscularis and on into the regional LNs. The cervical esophagus has a more direct segmental lymph drainage into the regional nodes, and, as a result, lesions in this portion of the esophagus have less submucosal extension and a more regionalized lymphatic spread.

Lymphatic drainage of the esophagus.

(Reproduced with permission from DeMeester TR, Barlow AP: Surgery and current management for cancer of the esophagus and cardia: Part I. *Curr Probl Surg* 25:498, 1988. Copyright Elsevier.)

The efferent lymphatics from the cervical esophagus drain into the paratracheal and deep cervical LNs, and those from the upper thoracic esophagus empty mainly into the paratracheal LNs. Efferent lymphatics from the lower thoracic esophagus drain into the subcarinal nodes and nodes in the inferior pulmonary ligaments. The superior gastric nodes receive lymph not only from the abdominal portion of the esophagus, but also from the adjacent lower thoracic segment.

PHYSIOLOGY

Swallowing Mechanism

The act of alimentation requires the passage of food and drink from the mouth into the stomach. One third of this distance consists of the mouth and hypopharynx, and two thirds is made up by the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves, and the body of the esophagus and cardia function as a worm-drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft palate, epiglottis, and cricopharyngeus. The valve of the esophageal pump is the LES. Failure of the valves or the pumps leads to abnormalities in swallowing—that is, difficulty in food propulsion from mouth to stomach—or regurgitation of gastric contents into the esophagus or pharynx.

Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Once initiated, swallowing is entirely a reflex act. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 25-13). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, for example, after a cerebrovascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue (see Fig. 25-13). The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The entire pharyngeal part of swallowing occurs within 1.5 seconds.

Sequence of events during the oropharyngeal phase of swallowing.

[Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): *Shackelford's Surgery of the Alimentary Tract*, 3rd ed., Vol. I. Philadelphia: W.B. Saunders, 1991, p 95. Copyright Elsevier.]

During swallowing, the pressure in the hypopharynx rises abruptly, to at least 60 mmHg, due to the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less-than-atmospheric midesophageal or intrathoracic pressure (Fig. 25-14). This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost due to muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 second of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mmHg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 25-15). The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

Fig. 25-14.

Resting pressure profile of the foregut showing the pressure differential between the atmospheric pharyngeal pressure (*P*) and the less-than-atmospheric midesophageal pressure (*E*) and greater-than-atmospheric intragastric pressure (*G*), with the interposed high pressure zones of the cricopharyngeus (*C*) and distal esophageal sphincter (*DES*). The necessity for relaxation of the cricopharyngeus and *DES* pressure to move a bolus into the stomach is apparent. Esophageal work occurs when a bolus is pushed from the midesophageal area (*E*), with a pressure less than atmospheric, into the stomach, which has a pressure greater than atmospheric (*G*).

Intraluminal esophageal pressures in response to swallowing.

(Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management. *Med Clin North Am* 65:1238, 1981. Copyright Elsevier.)

Swallowing can be started at will, or it can be reflexively elicited by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through cranial nerves V, VII, X, XI, and XII, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 second. Little is known about the organization of the swallowing center, except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebrovascular accident, this coordinated outflow may be altered, causing mild to severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper one third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The

integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction, and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function, and predispose the patient to aspiration.

The pharyngeal activity in swallowing initiates the esophageal phase. The body of the esophagus functions as a worm-drive propulsive pump due to the helical arrangement of its circular muscles, and is responsible for transferring a bolus of food into the stomach. The esophageal phase of swallowing represents esophageal work done during alimentation, in that food is moved into the stomach from a negative-pressure environment of -6 mmHg intrathoracic pressure, to a positive-pressure environment of 6 mmHg intra-abdominal pressure, or over a gradient of 12 mmHg (see Fig. 25-14). Effective and coordinated smooth muscle function in the lower one third of the esophagus is therefore important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30 to 120 mmHg (see Fig. 25-15). The wave rises to a peak in 1 second, lasts at the peak for about 0.5 second, and then subsides in about 1.5 seconds. The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3 to 5 seconds. The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2 to 4 cm/s and reaches the distal esophagus about 9 seconds after swallowing starts (see Fig. 25-15). Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles, initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut across, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be done without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because, if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought.

Despite the powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5 to 10 g. Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm-drive pump of the esophageal body. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that, in humans, the sphincter-like function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch (Fig. 25-16). The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow (see Fig. 25-15). The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

Wall thickness and orientation of fibers on microdissection of the cardia. At the junction of the esophageal tube and gastric pouch, there is an oblique muscular ring composed of an increased muscle mass inside the inner muscular layer. On the lesser curve side of the cardia, the muscle fibers of the inner layer are oriented transversely and form semicircular muscle clasps. On the greater curve side of the cardia, these muscle fibers form oblique loops that encircle the distal end of the cardia and gastric fundus. Both the semicircular muscle clasps and the oblique fibers of the fundus contract in a circular manner to close the cardia.

[Reproduced with permission from DeMeester TR, Skinner DB: Evaluation of esophageal function and disease, in Glenn WWL (ed): *Thoracic and Cardiovascular Surgery*, 4th ed. Norwalk, CT: Appleton-Century-Crofts, 1983, p 461.]

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous lower esophageal relaxation, thought by some to be a causative factor in gastroesophageal reflux disease (GERD). The power of the worm-drive pump of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction.

The antireflux mechanism in human beings is composed of three components: a mechanically effective LES, efficient esophageal clearance, and an adequately functioning gastric reservoir. A defect of any one of these three components can lead to increased esophageal exposure to gastric juice and the development of mucosal injury.

Physiologic Reflux

On 24-hour esophageal pH monitoring, healthy individuals have occasional episodes of gastroesophageal reflux. This physiologic reflux is more common when awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position.

There are several explanations for the observation that physiologic reflux in normal subjects is more common when they are awake and in the upright position than during sleep in the supine position. First, reflux episodes occur in healthy volunteers primarily during transient losses of the gastroesophageal barrier, which may be due to a relaxation of the LES or intragastric pressure overcoming sphincter pressure. Gastric juice can also reflux when a swallow-induced relaxation of the LES is not protected by an oncoming peristaltic wave. The average frequency of these "unguarded moments" or of transient losses of the gastroesophageal barrier is far less while asleep and in the supine position than while awake and in the upright position. Consequently, there are fewer opportunities for reflux to occur in the supine position. Second, in the upright position, there is a 12-mmHg pressure gradient between the resting, positive intra-abdominal pressure measured in the stomach and the most negative intrathoracic pressure measured in the esophagus at midthoracic level. This gradient favors the flow of gastric juice up into the thoracic esophagus when upright. The gradient diminishes in the supine position. Third, the LES pressure in normal subjects is significantly higher in the supine position than in the upright position. This is due to the apposition of the hydrostatic pressure of the abdomen to the abdominal portion of the sphincter when supine. In the upright position, the abdominal pressure surrounding the sphincter is negative compared with atmospheric pressure, and, as expected, the abdominal pressure gradually increases the more caudally it is measured. This pressure gradient tends to move the gastric contents toward the cardia and encourages the occurrence of reflux into the esophagus when the individual is

upright. By contrast, in the supine position, the gastroesophageal pressure gradient diminishes, and the abdominal hydrostatic pressure under the diaphragm increases, causing an increase in sphincter pressure and a more competent cardia.

The LES has intrinsic myogenic tone, which is modulated by neural and hormonal mechanisms. Alpha-adrenergic neurotransmitters or beta blockers stimulate the LES, and alpha blockers and beta stimulants decrease its pressure. It is not clear to what extent cholinergic nerve activity controls LES pressure. The vagus nerve carries both excitatory and inhibitory fibers to the esophagus and sphincter. The hormones gastrin and motilin have been shown to increase LES pressure; and cholecystokinin, estrogen, glucagon, progesterone, somatostatin, and secretin decrease LES pressure. The peptides bombesin, I-enkephalin, and substance P increase LES pressure; and calcitonin gene-related peptide, gastric inhibitory peptide, neuropeptide Y, and vasoactive intestinal polypeptide decrease LES pressure. Some pharmacologic agents such as antacids, cholinergics, agonists, domperidone, metoclopramide, and prostaglandin F2 are known to increase LES pressure; and anticholinergics, barbiturates, calcium channel blockers, caffeine, diazepam, dopamine, meperidine, prostaglandin E1 and E2, and theophylline decrease LES pressure. Peppermint, chocolate, coffee, ethanol, and fat are all associated with decreased LES pressure and may be responsible for esophageal symptoms after a sumptuous meal.

ASSESSMENT OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient’s underlying anatomic and functional deficits before making therapeutic decisions is fundamental to the successful treatment of esophageal disease. The diagnostic tests, as presently used, may be divided into four broad groups: (a) tests to detect structural abnormalities of the esophagus; (b) tests to detect functional abnormalities of the esophagus; (c) tests to detect increased esophageal exposure to gastric juice; and (d) tests of duodenogastric function as they relate to esophageal disease.

Tests to Detect Structural Abnormalities

RADIOGRAPHIC EVALUATION

The first diagnostic test in patients with suspected esophageal disease should be a barium swallow including a full assessment of the stomach and duodenum. Esophageal motility can be assessed by observing several individual swallows of barium traversing the entire length of the organ, with the patient in the horizontal position. Hiatal hernias are best demonstrated with the patient prone because the increased intra-abdominal pressure produced in this position promotes displacement of the esophagogastric junction above the diaphragm. To detect lower esophageal narrowing, such as rings and strictures, fully distended views of the esophagogastric region are crucial. The density of the barium used to study the esophagus can potentially affect the accuracy of the examination. Esophageal disorders shown clearly by a full-column technique include circumferential carcinomas, peptic strictures, large esophageal ulcers, and hiatal hernias. A small hiatal hernia is usually not associated with significant symptoms or illness, and its presence is an irrelevant finding unless the hiatal hernia is large (Fig. 25-17), the hiatal opening is narrow and interrupts the flow of barium into the stomach (Fig. 25-18), or the hernia is of the paraesophageal variety. Lesions extrinsic but adjacent to the esophagus can be reliably detected by the full-column technique if they contact the distended esophageal wall. Conversely, a number of important disorders may go undetected if this is the sole technique used to examine the esophagus. These include small esophageal neoplasms, mild esophagitis, and esophageal varices. Thus, the full-column technique should be supplemented with mucosal relief or double-contrast films to enhance detection of these smaller or more subtle lesions.

impingement on the stomach and the lack of contraction of the supradiaphragmatic stomach prevent passage of the bolus into the distal stomach (**C**). As a consequence, the contents in the supradiaphragmatic portion of the stomach are regurgitated into the thoracic esophagus (**D**, **E**, and **F**). The patient experiences dysphagia and regurgitation. On endoscopy, no anatomic abnormality other than a hiatal hernia was found, and on 24-hour pH monitoring, the patient had normal esophageal acid exposure. Symptoms of dysphagia and regurgitation were relieved by hiatal herniorrhaphy.

(Reproduced with permission from Kaul BJ, DeMeester TR, Oka M, et al: The cause of dysphagia in uncomplicated sliding hiatal hernia and its relief by hiatal herniography. A roentgenographic manometric and clinical study. *Ann Surg* 211:409, 1990.)

Motion-recording techniques greatly aid in evaluating functional disorders of the pharyngoesophageal and esophageal phases of swallowing. The technique and indications for cine- and videoradiography will be discussed in the section entitled Video- and Cineradiography, as they are more useful to evaluate function and seldom used to detect structural abnormalities.

The radiographic assessment of the esophagus is not complete unless the entire stomach and duodenum have been examined. A gastric or duodenal ulcer, partially obstructing gastric neoplasm, or scarred duodenum and pylorus may contribute significantly to symptoms otherwise attributable to an esophageal abnormality.

When a patient's complaints include dysphagia and no obstructing lesion is seen on the barium swallow, it is useful to have the patient swallow a barium-impregnated marshmallow, a barium-soaked piece of bread, or a hamburger mixed with barium. This test may bring out a functional disturbance in esophageal transport that can be missed when liquid barium is used.

ENDOSCOPIC EVALUATION

In any patient complaining of dysphagia, esophagoscopy is indicated, even in the face of a normal radiographic study. A barium study obtained before esophagoscopy is helpful to the endoscopist by directing attention to locations of subtle change, and alerting the examiner to such potential danger spots as a cervical vertebral osteophyte, esophageal diverticulum, a deeply penetrating ulcer, or a carcinoma. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be confirmed visually.

For the initial endoscopic assessment, the flexible fiber-optic esophagoscope is the instrument of choice because of its technical ease, patient acceptance, and the ability to simultaneously assess the stomach and duodenum. Rigid endoscopy may be required in specific instances and should be part of the armamentarium of the endoscopist. The rigid esophagoscope may be an essential instrument when deeper biopsies are required or the cricopharyngeus and cervical esophagus need closer assessment.

When GERD is the suspected diagnosis, particular attention should be paid to detecting the presence of esophagitis and Barrett's columnar-lined esophagus (CLE). When endoscopic esophagitis is seen, severity and the length of esophagus involved are recorded. Grade I esophagitis is defined as small, circular, nonconfluent erosions. Grade II esophagitis is defined by the presence of linear erosions lined with granulation tissue that bleeds easily when touched. Grade III esophagitis represents a more advanced stage, in which the linear erosions coalesce into circumferential loss of the epithelium and the mucosa may take a "cobblestone" appearance. Grade IV esophagitis is the presence of a stricture. Its severity can be assessed by the ease of passing a 36F endoscope. When a stricture is observed, the severity of the esophagitis above it should be recorded. The absence of esophagitis above a stricture suggests a chemical-induced injury or a neoplasm as a cause. The latter should always be considered and is ruled out only by evaluation of a tissue biopsy of adequate size.

Barrett's esophagus (BE) is a condition in which the tubular esophagus is lined with columnar epithelium, as opposed to the normal squamous epithelium. Histologically, it appears as intestinal metaplasia (IM). It is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location, and by the appearance of a redder, more luxuriant mucosa than is normally seen in the lower esophagus. Its presence is confirmed by biopsy. Multiple biopsies should be taken in a cephalad direction to determine the level at which the junction of Barrett's epithelium with normal squamous mucosa occurs. BE is susceptible to ulceration, bleeding, stricture formation, and, most important, malignant degeneration. The earliest sign of the latter is severe dysplasia or intramucosal adenocarcinoma (Fig. 25-19). These dysplastic changes have a patchy distribution, so a minimum of four biopsy samples spaced 2 cm apart should be taken from the Barrett's-lined portion of the esophagus. Changes seen in one biopsy are significant. Nishimaki has determined that the tumors occur in an area of specialized columnar epithelium near the squamocolumnar junction in 85% of patients, and within 2 cm of the squamocolumnar junction in virtually all patients. Particular attention should be focused on this area in patients suspected of harboring a carcinoma.

Complications of reflux disease as seen on endoscopy. **A.** Linear erosion of grade II esophagitis. **B.** Cobblestone mucosa of grade III esophagitis. **C.** Stricture associated with grade III esophagitis. **D.**

Abnormalities of the gastroesophageal flap valve can be visualized by retroflexion of the endoscope. Hill has graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal valve architecture (Fig. 25-20). The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with grade III and IV valves.

Fig. 25-20.

A. Grade I flap valve appearance. Note the ridge of tissue that is closely approximated to the shaft of the retroflexed endoscope. It extends 3–4 cm along the lesser curve. **B.** Grade II flap valve appearance. The ridge is slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. **C.** Grade III flap valve appearance. The ridge is barely present, and there is often failure to close around the endoscope. It is nearly always accompanied by a hiatal hernia. **D.** Grade IV flap valve appearance. There is no muscular ridge at all. The gastroesophageal valve stays open all the time, and squamous epithelium can often be seen from the retroflexed position. A hiatal hernia is always present.

(Reproduced with permission from Hill LD, Kozarek RA, et al: The gastroesophageal flap valve. In vitro and in vivo observations. *Gastrointest Endosc* 44:541, 1996. Copyright Elsevier.)

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura, identified by having the patient sniff. A prominent sliding hiatal hernia frequently is associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia (PEH) is observed, particular attention is taken to exclude a gastric ulcer or gastritis within the pouch. The intragastric retroflex or J maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach.

When an esophageal diverticulum is seen, it should be carefully explored with the flexible endoscope to exclude ulceration or neoplasia. When a submucosal mass is identified, biopsies are usually not performed. At the time of surgical resection, a submucosal leiomyoma or reduplication cyst can generally be dissected away from the intact mucosa, but if a biopsy sample is taken, the mucosa may become fixed to the underlying abnormality. This complicates the surgical dissection by increasing the risk of mucosal perforation.

Tests to Detect Functional Abnormalities

In many patients with symptoms of an esophageal disorder, standard radiographic and endoscopic evaluation fails to demonstrate a structural abnormality. In these situations, esophageal function tests are necessary to identify a functional disorder.

STATIONARY MANOMETRY

Esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. Manometry is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain, and the barium swallow or endoscopy does not show a clear structural abnormality. Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders [i.e., achalasia, diffuse esophageal spasm (DES), nutcracker esophagus, and hypertensive LES]. It also identifies nonspecific esophageal motility abnormalities and motility disorders secondary to systemic disease such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic GERD, manometry of the esophageal body can identify a mechanically defective LES, and evaluate the adequacy of esophageal peristalsis and contraction amplitude. Manometry has become an essential tool in the preoperative evaluation of patients before antireflux surgery, allowing selection of the appropriate procedure based upon the patient's underlying esophageal function.

Esophageal manometry is performed using electronic, pressure-sensitive transducers located within the catheter, or water-perfused catheters with lateral side holes attached to transducers outside the body. The traditional catheter consists of a train of five pressure transducers or five or more water-perfused tubes bound together. The transducers or lateral openings are placed at 5-cm intervals from the tip and oriented radially at 72° from each other around the circumference of the catheter. A special catheter assembly consisting of four lateral openings at the same level, oriented at 90° to each other, is of special use in measuring the three-dimensional vector volume of the LES. Other specially designed catheters can be used to assess the upper sphincter.

As the pressure-sensitive station is brought across the gastroesophageal junction (GEJ), a rise in pressure above the gastric baseline signals the beginning of the LES. The respiratory inversion point is identified when the positive excursions that occur in the abdominal cavity with breathing change to negative deflections in the thorax. The respiratory inversion point serves as a reference point at which the amplitude of LES pressure and the length of the sphincter exposed to abdominal pressure are measured. As the pressure-sensitive station is withdrawn into the body of the esophagus, the upper border of the LES is identified by the drop in pressure to the esophageal baseline. From these measurements, the pressure, abdominal length, and overall length of the sphincter are determined (Fig. 25-21). To account for the asymmetry of the sphincter (Fig. 25-22), the pressure profile is repeated with each of the five radially oriented transducers, and the average values for sphincter pressure above gastric baseline, overall sphincter length, and abdominal length of the sphincter are calculated.

Table 25-1 shows the values for these parameters in 50 normal volunteers without subjective or objective evidence of a foregut disorder. The level at which a deficiency in the mechanics of the LES occurs was defined by comparing the frequency distribution of these values in the 50 healthy volunteers with a population of similarly studied patients with symptoms of GERD. The presence of increased esophageal exposure to gastric juice was documented by 24-hour esophageal pH monitoring. Based on these studies, a mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of <6 mmHg, an average length exposed to the positive-pressure environment in the abdomen of 1 cm or less, and/or an average overall sphincter length of 2 cm or less. Compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure and overall length and for abdominal length.

Table 25-1 Normal Manometric Values of the Distal Esophageal Sphincter, $n = 50$

		Percentile	
	Median	2.5	97.5
Pressure (mmHg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7
	Mean	Mean - 2 SD	Mean + 2 SD
Pressure (mmHg)	13.8 ± 4.6	4.6	23.0
Overall length (cm)	3.7 ± 0.8	2.1	5.3
Abdominal length (cm)	2.2 ± 0.8	0.6	3.8

SD = standard deviation.

To assess the relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with the distal transducer located in the stomach and the proximal transducer within the esophageal body. Ten wet swallows (5 mL water each) are performed. The normal pressure of the LES should drop to the level of gastric pressure during each wet swallow.

The function of the esophageal body is assessed with the five pressure transducers located in the esophagus. The standard procedure is to locate the most proximal pressure transducer 1 cm below the well-defined cricopharyngeal sphincter, allowing a pressure response throughout the whole esophagus to be obtained on one swallow. Ten wet swallows are recorded. Amplitude, duration, and morphology of contractions following each swallow are calculated at all recorded levels of the esophageal body. The delay between the onset or peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation. The relationship of the esophageal contractions following a swallow is classified as peristaltic or simultaneous. The data are used to identify motor disorders of the esophagus.

The position, length, and pressure of the cricopharyngeal sphincter are assessed with a stationary pull-through technique similar to that used for the LES. The manometric catheter is withdrawn in 0.5-cm intervals from the upper esophagus through the upper esophageal sphincter region into the pharynx. The relaxation of the upper esophageal sphincter is studied by straddling the eight pressure transducers across the sphincter so that some are in the pharynx and some are in the upper esophagus. High-speed graphic recordings (50 mm/s) are necessary to obtain an assessment of the coordination of cricopharyngeal relaxation with hypopharyngeal contraction. It has been difficult to consistently demonstrate a motility abnormality in patients with pharyngoesophageal disorders.

HIGH-RESOLUTION MANOMETRY

Esophageal manometry was introduced into clinical practice in the 1970s and, until recently, has changed little. In 1991, Ray Clouse introduced the concept of improving conventional manometry by increasing the number of recording sites and adding a three-dimensional assessment. This "high-resolution manometry" is a variant of the conventional manometry in which multiple, circumferential recording sites are used, in essence creating a "map" of the esophagus and its sphincters. High-resolution catheters contain 36 miniaturized pressure sensors positioned every centimeter along the length of the catheter. The vast amount of data generated by these sensors is then processed and presented in traditional linear plots or as a visually enhanced spatiotemporal video tracing that is readily interpreted (Fig. 25-23).

High-resolution manometry motility study. Pressure measurements are recorded with color coding (red = high; blue = low). LES = lower esophageal sphincter; PIP = pressure inversion point; UES = upper esophageal sphincter.

Simultaneous acquisition of data for the upper esophageal sphincter, esophageal body, LES, and gastric pressure minimizes the movement artifacts and study time associated with conventional esophageal manometry. Powerful, computer-based, and easy-to-use tools give unprecedented data analysis capability. This technology significantly enhances esophageal diagnostics, bringing it into the realm of "image" based studies. High-resolution manometry may allow the identification of focal motor abnormalities previously overlooked. It has enhanced the ability to predict bolus propagation and increased sensitivity in the measurement of pressure gradients.

ESOPHAGEAL IMPEDANCE

New technology recently introduced into the clinical realm allows measurement of esophageal function and gastroesophageal reflux in a way that has heretofore not been possible. An intraluminal electrical impedance catheter has recently been developed for the measurement of GI function. *Impedance* is the ratio of voltage to current, and is a measure of the electrical conductivity of a hollow organ and its contents. Intraluminal electrical impedance is inversely proportional to the electrical conductivity of the luminal contents and the cross-sectional area of the lumen. Air has a very low electrical conductivity and, therefore, high impedance. Saliva and food cause an impedance decrease because of their increased conductivity. Luminal dilatation results in a decrease in impedance, whereas luminal contraction yields an impedance increase. Investigators have established the impedance waveform characteristics that define esophageal bolus transport. This allows for the characterization of both esophageal function, via quantification of bolus transport, and gastroesophageal reflux (Fig. 25-24). The probe measures impedance between adjacent electrodes, with measuring segments located at 2, 4, 6, 8, 14, and 16 cm

from the distal tip. An extremely low electric current of 0.00025 μ W is transmitted across the electrodes at a frequency of 1 to 2 kHz and is limited to 8 μ A. This is below the stimulation threshold for nerves and muscles, and is three orders of magnitude below the threshold of cardiac stimulation. A standard pH electrode is located 5 cm from the distal tip, so that the acidic or nonacidic nature of refluxate can be correlated with the number of reflux events.

Esophageal impedance probe measures electrical resistance between evenly spaced electrodes. LES = lower esophageal sphincter.

Esophageal impedance has been validated as an appropriate method for the evaluation of GI function and is becoming increasingly used for the diagnosis of gastroesophageal reflux. It has been compared to cineradiography showing that impedance waves correspond well with actual bolus transport illustrated by radiography. Bolus entry, transit, and exit can be clearly identified by impedance changes in the corresponding measuring segments. Preliminary studies comparing standard esophageal manometry with impedance measurements in healthy volunteers have been performed, and have validated the ability of esophageal impedance to correlate with peristaltic wave progression and bolus length. Clinical investigators are beginning to examine and validate impedance measurement in the evaluation of esophageal and small intestinal pathophysiology.

It is increasingly recognized that 24-hour pH monitoring as the historical gold standard for diagnosing and quantifying gastroesophageal reflux has significant limitations. With 24-hour ambulatory pH testing, reflux is defined as a drop in the pH below 4, which effectively "blinds" the test to reflux occurring at higher pH values. Furthermore, in patients with persistent symptoms on proton pump inhibitor (PPI) therapy, pH monitoring has limited use as it can only detect abnormal acid reflux (pH <4), the occurrence of which has been altered by the antisecretory medication. Given that PPI antisecretory therapy is highly effective in neutralizing gastric acid, the question of whether persistent symptoms are a result of persistent acid reflux, nonacid reflux, or are not reflux related becomes a key issue in surgical decision making. Until recently, this differentiation could not be made. A reliable method for detecting both acid and nonacid reflux has potential to define these populations of patients and thus improve patient selection for antireflux surgery. The recent introduction of multichannel intraluminal impedance technology allows the measurement of both acid and nonacid reflux, with potential to significantly enhance diagnostic accuracy.

Using this technology, Balaji and colleagues showed that most gastroesophageal reflux remains despite acid suppression. Impedance pH may be particularly useful in evaluating patients with persistent symptoms despite PPI treatment, patients with respiratory symptoms, and postoperative patients who are having symptoms that are elusive to diagnosis.

ESOPHAGEAL TRANSIT SCINTIGRAPHY

The esophageal transit of a 10-mL water bolus containing technetium-99m (^{99m}Tc) sulfur colloid can be recorded with a gamma camera. Using this technique, delayed bolus transit has been shown in patients with a variety of esophageal motor disorders, including achalasia, scleroderma, DES, and nutcracker esophagus.

VIDEO- AND CINERADIOGRAPHY

High-speed cinematic or video recording of radiographic studies allows re-evaluation by reviewing the studies at various speeds. This technique is more useful than manometry in the evaluation of the pharyngeal phase of swallowing. Observations suggesting oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle, a Zenker's diverticulum, a narrow pharyngoesophageal segment, and stasis of the contrast medium in the valleculae or hypopharyngeal recesses (Fig. 25-25). These findings are usually not specific, but rather common manifestations of neuromuscular disorders affecting the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills aid the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position correlates with abnormal motility of the esophageal body. In addition, structural abnormalities such as small diverticula, webs, and minimal extrinsic impressions of the esophagus may be recognized only with motion-recording techniques. The simultaneous computerized capture of videofluoroscopic images and manometric tracings is now available, and is referred to as *manofluorography*. Manofluorographic studies allow precise correlation of the anatomic events, such as opening of the upper esophageal sphincter, with manometric observations, such as sphincter relaxation. Manofluorography, although not widely available, is presently the best means available to evaluate complex functional abnormalities.

Tests to Detect Increased Exposure to Gastric Juice

24-HOUR AMBULATORY PH MONITORING

The most direct method of measuring increased esophageal exposure to gastric juice is by an indwelling pH electrode, or, more recently, via a radiotelemetric pH monitoring capsule that can be clipped to the esophageal mucosa. The latter consists of an antimony pH electrode fitted inside a small, capsule-shaped device accompanied by a battery and electronics that allow 48-hour monitoring and transmission of the pH data via transcutaneous radio telemetry to a waist-mounted data logger. The device can be introduced either transorally or transnasally, and clipped to the esophageal mucosa using endoscopic fastening techniques. It passes spontaneously within 1 to 2 weeks. Prolonged monitoring of esophageal pH is performed by placing the pH probe or telemetry capsule 5 cm above the manometrically measured upper border of the distal sphincter for 24 hours. It measures the actual time the esophageal mucosa is exposed to gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient's symptoms. A 24- to 48-hour period is necessary so that measurements can be made over one or two complete circadian cycles. This allows measuring the effect of physiologic activity, such as eating or sleeping, on the reflux of gastric juice into the esophagus (Fig. 25-26).

The 24-hour esophageal pH monitoring should not be considered a test for reflux, but rather a measurement of the esophageal exposure to gastric juice. The measurement is expressed by the time the esophageal pH was below a given threshold during the 24-hour period. This single assessment, although concise, does not reflect how the exposure has occurred; that is, did it occur in a few long episodes or several short episodes? Consequently, two other assessments are necessary: the frequency of the reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are (a) cumulative time the esophageal pH is below a chosen threshold, expressed as the percentage of the total, upright, and supine monitored time; (b) frequency of reflux episodes below a chosen threshold, expressed as number of episodes per 24 hours; and (c) duration of the episodes, expressed as the number of episodes >5 minutes per 24 hours, and the time in minutes of the longest episode recorded. Table 25-2 shows the normal values for these components of the 24-hour record at the whole-number pH threshold derived from 50 normal asymptomatic subjects. The upper limits of normal were established at the ninety-fifth percentile. Most centers use pH 4 as the threshold.

Table 25-2 Normal Values for Esophageal Exposure to pH <4 (n = 50)

Component	Mean	SD	95%
Total time	1.51	1.36	4.45
Upright time	2.34	2.34	8.42
Supine time	0.63	1.0	3.45
No. of episodes	19.00	12.76	46.90
No. >5 min	0.84	1.18	3.45
Longest episode	6.74	7.85	19.80

SD = standard deviation.

Source: Reproduced with permission from DeMeester TR, et al: Gastroesophageal reflux disease, in Moody FG, Carey LC, et al (eds): *Surgical Treatment of Digestive Disease*. Chicago: Year Book Medical, 1990, p 68. Copyright Elsevier.

The components' 24-hour pH record are then combined into one expression of the overall esophageal acid exposure below a pH threshold; the pH score is calculated by using the standard deviation (SD) of the mean of each of the six components measured in the 50 normal subjects as a weighting factor. By accepting an abstract zero level two SDs below the mean, the data measured in normal subjects could be treated as though they had a normal distribution. Thus, any measured patient value could be referenced to this zero point, and, in turn, be awarded points based on whether it was below or above the normal mean value for that component, according to this formula:

Component score = $\frac{\text{Point value} - \text{mean}}{\text{SD} + 1}$

The upper limits of normal for the composite score for each whole-number pH threshold are shown in Table 25-3.

Table 25-3 Normal Composite Score for Various pH Thresholds: Upper Level of Normal Value	
pH Threshold	95th Percentile
<1	14.2
<2	17.37
<3	14.10
<4	14.72
<5	15.76
<6	12.76
>7	14.90
>8	8.50

The detection of increased esophageal exposure to acid gastric juice is more dependable than the detection of increased exposure to alkaline gastric juice. The latter is suggested by an increased alkaline exposure time above pH 7 or 8. Increased exposure in this pH range can be caused by abnormal calibration of the pH recorder; dental infection, which increases salivary pH; esophageal obstruction, which results in static pools of saliva with an increase in pH secondary to bacterial overgrowth; or regurgitation of alkaline gastric juice into the esophagus. Using a properly calibrated probe, in the absence of dental infections or esophageal obstruction, the percentage of time the pH is measured above 7 correlates with the concentration of bile acids continuously aspirated over a 24-hour period.

When done in a test population with an equal distribution of normal healthy subjects and patients with the classic reflux symptoms and a defective sphincter, 24-hour esophageal pH monitoring had a sensitivity and specificity of 96%. (*Sensitivity* is the ability to detect a disease when known to be present; *specificity* is the ability to exclude the disease when known to be absent.) This gave a predictive value of a positive and negative test of 96%, and an overall accuracy of 96%. Based on these studies and extensive clinical experience, 24-hour esophageal pH monitoring has emerged as the gold standard for the diagnosis of GERD.

Catheter-based, 24-hour, ambulatory, esophageal pH monitoring does have a significant drawback of the physical presence of a transnasal catheter that must be worn for 24 hours. Although most doctors ask patients to go about their normal activities of daily living, many do not comply due to embarrassment about the catheter or from discomfort. The recent development of a wireless capsule, which can be implanted in the esophagus and record pH data for 48 hours, has significantly changed patient satisfaction with the procedure.

The Bravo pH Capsule (Medtronic, Minneapolis, Minn) measures pH levels in the esophagus and transmits continuous esophageal pH readings to a receiver worn on the patient's belt or waistband (Fig. 25-27). Symptoms that the patient experiences are recorded in a diary and/or by pressing buttons on the receiver unit. Generally, 48 hours of pH data are measured with this probe. A recent study has shown that the addition of a second day of pH monitoring increased the sensitivity of pH measurement by 22%. The capsule eventually detaches and passes through the digestive tract in 5 to 7 days.

Wireless pH monitoring. **A.** Delivery device. **B.** Capsule engaged in the wall of the esophagus.

RADIOGRAPHIC DETECTION OF GASTROESOPHAGEAL REFLUX

The definition of radiographic gastroesophageal reflux varies depending on whether reflux is spontaneous or induced by various maneuvers. In only about 40% of patients with classic symptoms of GERD is spontaneous reflux (i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position) observed by the radiologist. In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-hour esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. Failure to see this does not indicate the absence of disease.

Tests of Duodenogastric Function

Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Abnormalities of the gastric reservoir or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. Reflux of alkaline duodenal juice, including bile salts, pancreatic enzymes, and bicarbonate, is thought to have a role in the pathogenesis of esophagitis and complicated Barrett's esophagus. Furthermore, functional disorders of the esophagus are often not confined to the esophagus alone, but are associated with functional disorders of the rest of the foregut (i.e., stomach and duodenum). Tests of duodenogastric function that are helpful to investigate esophageal symptoms include gastric emptying studies, gastric acid analysis, and cholescintigraphy (for the diagnosis of pathologic duodenogastric reflux). The single test of 24-hour gastric pH monitoring can be used to identify gastric hypersecretion and imply the presence of duodenogastric reflux and delayed gastric emptying.

GASTRIC EMPTYING

Gastric emptying studies are performed with radionuclide-labeled meals. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-minute intervals for 1.5 to 2 hours. After correction for decay, the counts in the gastric area are plotted as the percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59% of a meal within 90 minutes.

GASTRIC ACID ANALYSIS

The gastric secretory state is usually evaluated by determination of the titratable gastric acid in aspirated gastric juice. Interdigestive or basal gastric acid secretion is measured in the fasting state, and varies between 0 and 5 mmol/h in normal volunteers. The maximal acid secretory capacity of the stomach, which reflects the available parietal cell mass, is calculated following stimulation of gastric acid secretion with pentagastrin or histamine. Acid hypersecretors have a basal gastric acid secretory capacity of >5 mmol/h and a maximal acid secretory capacity of more than 30 mmol/h.

CHOLESCINTIGRAPHY

Scintigraphic hepatobiliary imaging is performed after IV injection of 5 µCi of ^{99m}Tc iminodiacetic acid derivatives such as disofenin (^{99m}Tc-DISIDA). Gamma camera images of the upper abdomen, including the gallbladder and stomach, are obtained at 5-minute intervals for 60 minutes. Imaging is continued for an additional 30 minutes after stimulation of gallbladder contraction with 20 mg/kg of synthetic C-terminal octapeptide of cholecystokinin. Duodenogastric reflux is demonstrated as an increase of radioactivity in the stomach in the sequential images. The clinical value of this test is limited due to its short duration and a relatively high false-positive rate in normal volunteers.

24-HOUR GASTRIC PH MONITORING

Monitoring is performed over a complete circadian cycle with a pH electrode placed 5 cm below the manometrically located LES. The patient is fully ambulatory during the test and is encouraged to perform normal daily activity. The gastric pH profile is assessed separately for the meal, postprandial period, and fasting period. The latter is divided into the time spent upright and supine.

The interpretation of continuous gastric pH recordings is more difficult than that of esophageal pH recordings. This is because the gastric pH environment is determined by a complex interplay of acid secretion; mucus secretion; ingested food; swallowed saliva; regurgitated duodenal, pancreatic, and biliary secretions; and the effectiveness of the mixing and evacuation of the chyme. Using 24-hour gastric pH monitoring to evaluate the gastric secretory state is based on studies that have shown that a good correlation exists between increased basal acid output on standard gastric acid analysis, and a left shift on the frequency distribution graph of gastric pH recordings during the supine fasting period. The evaluation of gastric emptying by 24-hour gastric pH monitoring is based on studies demonstrating a good correlation between the emptying of a solid meal and the duration of the postprandial plateau and decline phase of the gastric pH record.

Using 24-hour gastric pH monitoring to evaluate duodenogastric reflux is based on the observation that reflux of alkaline duodenal juice into the stomach can alkalinize the gastric pH environment. The measurement is not straightforward because of the effect of meals, and reduction in acid secretion can result in changes in gastric pH that mimic alkaline reflux episodes. To overcome this problem, computerized measurements of the number and height of alkalinizing peaks, the baseline pH, the postprandial pH plateau, and the pattern of pH decline from the plateau can be used to identify the probability of duodenogastric reflux. The results are presented as an overall score that indicates the likelihood of pathologic duodenogastric reflux. Initial data indicate that this approach has a higher sensitivity and specificity for the diagnosis of pathologic duodenogastric reflux than scintigraphic methods do.

Combined 24-hour esophageal and gastric pH monitoring can identify excessive alkaline duodenogastric and alkaline gastroesophageal reflux in symptomatic patients. The combined tracings can often identify simultaneous gastric and esophageal alkalinization, suggesting a duodenal origin for the esophageal alkaline exposure (Fig. 25-28).

GASTROESOPHAGEAL REFLUX DISEASE

GERD was not recognized as a significant clinical problem until the mid-1930s and was not identified as a precipitating cause for esophagitis until after World War II. In the early twenty-first century, it has grown to be a very common problem and now accounts for a majority of esophageal pathology. It is recognized as a chronic disease, and when medical therapy is required, it is often lifelong. Recent efforts at the development of various endoscopic antireflux interventions, although innovative, have not been successful in consistently controlling gastroesophageal reflux. Antireflux surgery is an effective and long-term therapy and is the only treatment that is able to restore the gastroesophageal barrier. Despite the common prevalence of GERD, it can be one of the most challenging diagnostic and therapeutic problems in clinical medicine. A contributing factor to this is the lack of a universally accepted definition of the disease.

The most simplistic approach is to define the disease by its symptoms. However, symptoms thought to be indicative of GERD, such as heartburn or acid regurgitation, are very common in the general population and many individuals consider them to be normal and do not seek medical attention. Even when excessive, these symptoms are not specific for gastroesophageal reflux. They can be caused by other diseases such as achalasia, DES, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease.

A thorough, structured evaluation of the patient's symptoms is essential before any therapy, particularly any form of esophageal surgery. The presence and severity of both typical symptoms of heartburn, regurgitation, and dysphagia, and atypical symptoms of cough, hoarseness, chest pain, asthma, and aspiration should be discussed with the patient in detail. Many of these atypical symptoms may not be esophageal related and hence will not improve and may even worsen with antireflux surgery.

Heartburn is generally defined as a substernal burning-type discomfort, beginning in the epigastrium and radiating upward. It is often aggravated by meals, spicy or fatty foods, chocolate, alcohol, and coffee and can be worse in the supine position. It is commonly, although not universally, relieved by antacid or antisecretory medications. Epidemiologic studies have shown that heartburn occurs monthly in as

many as 40 to 50% of the Western population. The occurrence of heartburn at night and its effect on quality of life have recently been highlighted by a Gallup poll conducted by the American Gastroenterologic Society (Table 25-4).

Table 25-4 American Gastroenterologic Association Gallup Poll on Nighttime Gastroesophageal Reflux Disease Symptoms
• 50 million Americans have nighttime heartburn at least 1/wk
• 80% of heartburn sufferers had nocturnal symptoms—65% both day & night
• 63% report that it affects their ability to sleep and impacts their work the next day
• 72% are on prescription medications
• Nearly half (45%) report that current remedies do not relieve all symptoms

Regurgitation, the effortless return of acid or bitter gastric contents into the chest, pharynx, or mouth, is highly suggestive of foregut pathology. It is often particularly severe at night when supine or when bending over and can be secondary to either an incompetent or obstructed GEJ. With the later, as in achalasia, the regurgitant is often bland, as if food was put into a blender. When questioned, most patients can distinguish the two. It is the regurgitation of gastric contents that may result in associated pulmonary symptoms, including cough, hoarseness, asthma, and recurrent pneumonia. Bronchospasm can be precipitated by esophageal acidification and cough by either acid stimulation or distention of the esophagus.

Dysphagia, or *difficulty swallowing*, is a relatively nonspecific term but arguably the most specific symptom of foregut disease. It is often a sign of underlying malignancy and should be aggressively investigated until a diagnosis is established. Dysphagia refers to the sensation of difficulty in the passage of food from the mouth to the stomach and can be divided into oropharyngeal and esophageal etiologies. Oropharyngeal dysphagia is characterized by difficulty transferring food out of the mouth into the esophagus, nasal regurgitation, and/or aspiration. Esophageal dysphagia refers to the sensation of food sticking in the lower chest or epigastrium. This may or may not be accompanied by pain (odynophagia) that will be relieved by the passage of the bolus.

Chest pain, although commonly and appropriately attributed to cardiac disease, is frequently secondary to esophageal pathology as well. As early as 1982, DeMeester and associates showed that nearly 50% of patients with severe chest pain, normal cardiac function, and normal coronary arteriograms had positive 24-hour pH studies, implicating gastroesophageal reflux as the underlying etiology. Exercise-induced gastroesophageal reflux is well known to occur, and may result in exertional chest pain similar to angina. It can be quite difficult, if not impossible, to distinguish between the two etiologies, particularly on clinical grounds alone. Nevens and colleagues evaluated the ability of experienced cardiologists to differentiate pain of cardiac vs. esophageal origin. Of 248 patients initially seen by cardiologists, 185 were thought to have typical angina and 63 atypical chest pain. Forty eight (26%) of those thought to have classic angina had normal coronary angiograms and 16 of the 63 with atypical pain had abnormal angiogram. Thus, the cardiologists' clinical impression was wrong 25% of the time. Finally, Pope and associates investigated the ultimate diagnosis in 10,689 patients presenting to an emergency room with acute chest pain. Seventeen percent were found to have acute ischemia, 6% stable angina, 21% other cardiac causes and 55% had noncardiac causes. They concluded that the majority of people presenting to the emergency room with chest pain do not have an underlying cardiac etiology for their symptoms. Chest pain precipitated by meals, occurring at night while supine, nonradiating, responsive to antacid medication, or accompanied by other symptoms suggesting esophageal disease such as dysphagia or regurgitation should trigger the thought of possible esophageal origin. Further, the distinction between heartburn and chest pain is also difficult and largely dependent upon the individual patient. One person's heartburn is another's chest pain.

The precise mechanisms accounting for the generation of symptoms secondary to esophageal pathology remain unclear. Considerable insight has been acquired, however. Investigations into the effect of luminal content, esophageal distention and muscular function, neural pathways, and brain localization have provided a basic understanding of the stimuli responsible for symptom generation. It is also clear that the visceroneural pathways of the foregut are complexly intertwined with that of the tracheobronchial tree and heart. This fact accounts for the common overlap of clinical presentations with diverse disease processes in upper GI, cardiac, and pulmonary systems.

The Human Antireflux Mechanism and the Pathophysiology of Gastroesophageal Reflux Disease

There is a high-pressure zone located at the esophagogastric junction in humans. Although this is typically referred to as the lower esophageal "sphincter," there are no distinct anatomical landmarks which define its beginning and end. Architecturally speaking, there is a specialized thickening in this region that is made up of the collar sling musculature and the clasp fibers. The collar sling is located on the greater curvature side of the junction, and the clasp fibers are located on the lesser curvature side. These muscles remain in tonic opposition until the act of swallowing, whereupon receptive relaxation occurs allowing passage of a food bolus into the stomach. In addition, the LES will also open when the gastric fundus is distended with gas and liquid, thus resulting in an unfolding of the valve and enabling venting of gas (a belch). Whether physiologic or pathologic, the common denominator for most episodes of gastroesophageal reflux is the loss of the high-pressure zone and thus a decrease in the resistance it imparts to the retrograde flow of gastric juice into the esophageal body. The primary cause of GERD is secondary to the permanent attenuation of the collar sling musculature, with a resultant opening of the gastric cardia and loss of the high-pressure zone as measured with esophageal manometry.

THE LOWER ESOPHAGEAL SPHINCTER

As defined by esophageal manometry, there are three characteristics of the LES that work in unison to maintain its barrier function. These characteristics include the resting LES pressure, its overall length, and the intra-abdominal length that is exposed to the positive pressure environment of the abdomen (Table 25-5). The resistance to gastroesophageal reflux is a function of both the resting LES pressure and length over which this pressure is exerted. Thus, as the sphincter becomes shorter, a higher pressure will be required in order to prevent a given amount of reflux (Fig. 25-29). Much like the neck of a balloon as it is inflated, as the stomach fills and distends, sphincter length decreases. Therefore, if the overall length of the sphincter is permanently short from repeated distention of the fundus secondary to large volume meals, then with minimal episodes of gastric distention and pressure, there will be insufficient sphincter length for the barrier to remain competent, and reflux will occur.

Table 25-5 Normal Manometric Values of the Distal Esophageal Sphincter, n = 50			
Parameter	Median Value	2.5th Percentile	97.5th Percentile
Pressure (mmHg)	13	5.8	27.7
Overall length (cm)	3.6	2.1	5.6
Abdominal length (cm)	2	0.9	4.7

A third characteristic of the LES that impacts its ability to prevent reflux is its position about the diaphragm. It is important that a portion of the total length of the LES be exposed to the effects of intra-abdominal pressure. That is, during periods of elevated intra-abdominal pressure, the resistance of the barrier would be overcome if pressure were not applied equally to both the LES and stomach simultaneously. Thus, in the presence of a hiatal hernia, the sphincter resides entirely within the chest cavity and cannot respond to an increase in intra-abdominal pressure because the pinch valve mechanism is lost and gastroesophageal reflux is more liable to occur.

Therefore, a permanently defective sphincter is defined by one or more of the following characteristics: An LES with a mean resting pressure of less than 6 mmHg, an overall sphincter length of <2 cm, and intra-abdominal sphincter length of <1 cm. When compared to normal subjects without GERD these values are below the 2.5 percentile for each parameter. The most common cause of a defective sphincter is an inadequate abdominal length.

Once the sphincter is permanently defective, this condition is irreversible, and although esophageal mucosal injury may be healed with antisecretory medication, reflux will continue to occur. Additionally, the presence of a defective LES may be associated with reduced esophageal body function and thus decreased clearance times of refluxed material. In addition, with the progressive loss of effective esophageal clearance the patient may be predisposed to severe mucosal injury, volume regurgitation, aspiration, and pulmonary failure. Reflux may occur in the face of a normal LES resting pressure. This condition is usually due to a functional problem of gastric emptying or excessive air swallowing. These conditions may lead to gastric distention, increased intra-gastric pressure, a resultant shortening or unfolding of the LES, and subsequent reflux. The mechanism by which gastric distention contributes to LES unfolding provides a mechanical explanation for "transient LES relaxation." It is thought that with repeated gastric distention secondary to large meal volume or chronic air swallowing, there is repeated unfolding of the LES and subsequent attenuation of the collar sling musculature. It is at this point that the

physiologic and normal mechanism of gastric venting is replaced with pathologic and severe postprandial reflux disease. In addition, patients with GERD will increase the frequency of swallowing in an effort to neutralize the refluxed acid with their saliva (pH 7.0). This phenomenon leads to increased air swallowing and further gastric distention thus compounding the problem. Therefore GERD may have its origins in the stomach secondary to gastric distention due to over-eating, and this may be further compounded by the ingestion of fatty meals, which result in delayed gastric emptying.

RELATIONSHIP BETWEEN HIATAL HERNIA AND GASTROESOPHAGEAL REFLUX DISEASE

As the collar sling musculature and clasp fibers become attenuated with repeated gastric distention, the esophagogastric junction begins to assume an "upside down funnel" appearance, with progressive opening of the acute angle of His. This in turn may result in attenuation and stretching of the phrenoesophageal ligament, with subsequent enlargement of the hiatal opening and axial herniation. There is a high degree of correlation between reflux threshold and the degree of hiatal herniation (Fig. 25-30).

Fig. 25-30.

Yield pressure of the lower esophageal sphincter decreases as hiatal hernia size increases.

It is believed that the source of postprandial esophageal acid exposure results from a "pocket of acid" at the esophageal gastric junction that is unaffected by the buffering action of the meal. This same process is thought to occur in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring at a location of 5 cm proximal to the upper boarder of the LES.

SUMMARY

It is believed that GERD has its origins within the stomach. Distention of the fundus occurs because of over-eating and delayed gastric emptying secondary to a high-fat diet. The resultant distention causes "unrolling" of the sphincter by the expanding fundus, and this subsequently exposes the squamous epithelium in the region of the distal LES to gastric juice. Repeated exposure results in inflammation and the development of columnar epithelium at the cardia. This is the initial step of the development of carditis and explains why in early disease esophagitis is mild and commonly limited to the very distal aspect of the esophagus. The patient attempts to compensate for this by increased swallowing, allowing the saliva to neutralize the refluxed gastric juice and thus alleviate the discomfort induced by the reflux event. The increased swallowing results in aerophagia, bloating, and belching. This in turn creates a viscous cycle of increased gastric distention and thus further exposure and repetitive injury to the distal esophagus. The development of carditis explains the complaint of epigastric pain often experienced by patients with early reflux disease. Additionally this process can lead to a fibrotic mucosal ring located at the squamocolumnar junction, which is termed a "Schatzki ring," and may result in dysphagia. This inflammatory process may extend into muscularis propria and thus result in a progressive loss in the length and pressure of the LES. This explanation for the pathophysiology of GERD is supported by the observation that severe esophagitis is almost always associated with a defective LES.

Complications Associated with Gastroesophageal Reflux Disease

The complications of gastroesophageal reflux disease may result from the direct injurious effects of gastric fluid on the mucosa, larynx, or respiratory epithelium. Complications due to repetitive reflux are esophagitis, stricture, and BE; repetitive aspiration may lead to progressive pulmonary fibrosis. The severity of the complications is directly related to the prevalence of a structurally defective sphincter (Table 25-6). The observation that a structurally defective sphincter occurs in 42% of patients without complications (most of whom have one or two components failed) suggests that disease may be confined to the sphincter due to compensation by a vigorously contracting esophageal body. Eventually, all three components of the sphincter fail, allowing unrestricted reflux of gastric juice into the esophagus and overwhelming its normal clearance mechanisms. This leads to esophageal mucosal injury with progressive deterioration of esophageal contractility, as is commonly seen in patients with strictures and BE. The loss of esophageal clearance increases the potential for regurgitation into the pharynx with aspiration.

Table 25-6 Complications of Gastroesophageal Reflux Disease: 150 Consecutive Cases with Proven Gastroesophageal Reflux Disease (24-Hour Esophageal pH Monitoring Endoscopy, and Motility)			
Complication	No.	Structurally Normal Sphincter (%)	Structurally Defective Sphincter (%)
None	59	58	42
Erosive esophagitis	47	23	77 ^a
Stricture	19	11	89
Barrett's esophagus	25	0	100
Total	150		

^aGrade more severe with defective cardia.

The potential injurious components that reflux into the esophagus include gastric secretions such as acid and pepsin, as well as biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. There is a considerable body of experimental evidence to indicate that maximal epithelial injury occurs during exposure to bile salts combined with acid and pepsin. These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, although the combination of duodenal juice and gastric acid is particularly noxious (Table 25-7).

Table 25-7 Relation of the Type of Reflux to Injury				
	No Injury	Esophagitis	Uncomplicated Barrett's	Complicated Barrett's
Gastric reflux	15 (54%)	13 (38%)	8 (32%)	1 (8%)
Gastroduodenal reflux	13 (38%)	21 (62%)	17 (68%)	12 (92%)

Experimental animal studies have shown that the reflux of duodenal contents into the esophagus enhances inflammation, increases the prevalence of Barrett's esophagus, and results in the development of esophageal adenocarcinoma. The component of duodenal juice thought to be most damaging is bile acids. For bile acids to injure mucosal cells, it is necessary that they be both soluble and un-ionized, so that the un-ionized, nonpolar form may enter mucosal cells. Before the entry of bile into the GI tract, 98% of bile acids are conjugated with either taurine or glycine in a ratio of about 3:1. Conjugation increases the solubility and ionization of bile acids by lowering their pK_a. At the normal duodenal pH of approximately 7, over 90% of bile salts are in solution and completely ionized. At pH ranges from 2 to 7, there is a mixture of the ionized salt and the lipophilic, nonionized acid. Acidification of bile to below pH 2 results in an irreversible bile acid precipitation. Consequently, under normal physiologic conditions, bile acids precipitate and are of minimal consequence when an acid gastric environment exists. On the other hand, in a more alkaline gastric environment, such as occurs with excessive duodenogastric reflux and after acid suppression therapy or vagotomy and partial or total gastrectomy, bile salts remain in solution, are partially dissociated, and when refluxed into the esophagus can cause severe mucosal injury by crossing the cell membrane and damaging the mitochondria.

Complications of gastroesophageal reflux such as esophagitis, stricture, and Barrett's metaplasia occur in the presence of two predisposing factors: a mechanically defective LES and an increased esophageal exposure to fluid with a pH of <4 and >7 (Fig. 25-31). The duodenal origin of esophageal contents in patients with an increased exposure to a pH >7 has been confirmed by esophageal aspiration studies (Fig. 25-32). Studies have clarified and expanded these observations by measuring esophageal bilirubin exposure over a 24-hour period as a marker for the presence of duodenal juice. Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58% of patients with GERD have increased esophageal exposure to duodenal juice, and that this exposure occurs most

commonly when the esophageal pH is between 4 and 7 (Fig. 25-33). Furthermore, it is associated with more severe mucosal injury (Fig. 25-34).

Prevalence of abnormal esophageal bilirubin exposure in healthy subjects and in patients with gastroesophageal reflux disease with varied degrees of mucosal injury. (* $P < .03$ vs. all other groups, ** $P < .03$ vs. healthy subjects.)

(Reproduced with permission from Kauer WK, Peters JH, DeMeester TR, et al: Mixed reflux of gastric juice is more harmful to the esophagus than gastric juice alone: The need for surgical therapy reemphasized. *Ann Surg* 222:525, 1995.)

The fact that the combination of refluxed gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may explain the repeated observation that 25% of patients with reflux esophagitis develop recurrent and/or progressive mucosal damage, often despite medical therapy. A potential reason is that acid suppression therapy is unable to consistently maintain the pH of refluxed gastric and duodenal juice above the range of 6. Lapses into pH ranges from 2 to 6 encourage the formation of undissociated, nonpolarized, soluble bile acids, which are capable of penetrating the cell wall and injuring mucosal cells. To assure that bile acids remain completely ionized in their polarized form, and thus unable to penetrate the cell, requires that the pH of the refluxed material be maintained above 7, 24 hours a day, 7 days a week, for the patient's lifetime. In practice, this would not only be impractical but likely impossible, unless very high doses of medications were used. The use of lesser doses would allow esophageal mucosal damage to occur while the patient was relatively asymptomatic. Antireflux operative procedures re-establish the barrier between stomach and esophagus, protecting the esophagus from damage in patients with mixed gastroesophageal reflux.

If reflux of gastric juice is allowed to persist and sustained or repetitive esophageal injury occurs, two sequelae can result. First, a luminal stricture can develop from submucosal and eventually intramural fibrosis. Second, the tubular esophagus may become replaced with columnar epithelium. The columnar epithelium is resistant to acid and is associated with the alleviation of the complaint of heartburn. This columnar epithelium often becomes intestinalized, identified histologically by the presence of goblet cells. This specialized IM is currently required for the diagnosis of BE. Endoscopically, BE can be quiescent or associated with complications of esophagitis, stricture, Barrett's ulceration, and dysplasia. The complications associated with BE may be due to the continuous irritation from refluxed duodenogastric juice. This continued injury is pH dependent and may be modified by medical therapy. The incidence of metaplastic Barrett's epithelium becoming dysplastic and progressing to adenocarcinoma is approximately 1% per year.

An esophageal stricture can be associated with severe esophagitis or BE. In the latter situation, it occurs at the site of maximal inflammatory injury (i.e., the columnar-squamous epithelial interface). As the columnar epithelium advances into the area of inflammation, the inflammation extends higher into the proximal esophagus, and the site of the stricture moves progressively up the esophagus. Patients who have a stricture in the absence of Barrett's esophagus should have the presence of gastroesophageal reflux documented before the presence of the stricture is ascribed to reflux esophagitis. In patients with normal acid exposure, the stricture may be due to cancer or a drug-induced chemical injury, the latter resulting from the lodgment of a capsule or tablet in the distal esophagus. In such patients, dilation usually corrects the problem of dysphagia. Heartburn, which may have occurred only because of the chemical injury, need not be treated. It is also possible for drug-induced injuries to occur in patients who have underlying esophagitis and a distal esophageal stricture secondary to gastroesophageal reflux. In this situation, a long, string-like stricture progressively develops as a result of repetitive caustic injury from capsule or tablet lodgment on top of an initial reflux stricture. These strictures are often resistant to dilation.

Metaplastic (Barrett's Esophagus) and Neoplastic (Adenocarcinoma) Complications

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950. He incorrectly believed it to be congenital in

origin. It is now realized that it is an acquired abnormality, occurs in 10 to 15% of patients with GERD, and represents the end stage of the natural history of this disease. It is also distinctly different from the congenital condition in which islands of gastric fundic epithelium are found in the upper half of the esophagus.

The definition of BE has evolved considerably over the past decade. Traditionally, BE was identified by the presence of columnar mucosa extending at least 3 cm into the esophagus. It is now recognized that the specialized, intestinal-type epithelium found in the Barrett's mucosa is the only tissue predisposed to malignant degeneration. Consequently, the diagnosis of BE is presently made given any length of endoscopically identifiable columnar mucosa that proves, on biopsy, to show IM. Although long segments of columnar mucosa without IM do occur, they are uncommon and are probably congenital in origin.

The hallmark of IM is the presence of intestinal goblet cells. There is a high prevalence of biopsy-demonstrated IM at the cardia, on the gastric side of the squamocolumnar junction, in the absence of endoscopic evidence of a CLE. Evidence is accumulating that these patches of what appears to be Barrett's in the cardia have a similar malignant potential as in the longer segments, and are precursors for carcinoma of the cardia.

The long-term relief of symptoms remains the primary reason for performing antireflux surgery in patients with BE. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with BE are no different than the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient data suggest severe disease or predict the need for long-term medical management. Most patients with BE are symptomatic. Although it has been argued that some patients with BE may not have symptoms, careful history taking will reveal the presence of symptoms in most, if not all, patients.

Patients with BE have a spectrum of disease ranging from visually identifiable but short segments, to long segments of classic BE. In general, however, they represent a relatively severe stage of gastroesophageal reflux, usually with markedly increased esophageal acid exposure, deficient LES characteristics, poor esophageal body function, and a high prevalence of duodenogastroesophageal reflux. Gastric hypersecretion occurs in 44% of patients. Most will require long-term PPI therapy for relief of symptoms and control of coexistent esophageal mucosal injury. Given such profound deficits in esophageal physiology, antireflux surgery is an excellent means of long-term control for most patients with BE. In years past, referral for antireflux surgery was reserved for patients with associated complications such as stricture, ulceration, or progression of the metaplastic segment. The advent of laparoscopic fundoplication and its successful control of gastroesophageal reflux in more than 90% of patients has lowered the threshold for referral. Patients with quiescent, uncomplicated BE, particularly young patients, are now considered by many to be excellent candidates for antireflux surgery.

The typical complications in BE include ulceration in the columnar-lined segment, stricture formation, and a dysplasia-cancer sequence. Barrett's ulceration is unlike the erosive ulceration of reflux esophagitis in that it more closely resembles peptic ulceration in the stomach or duodenum, and has the same propensity to bleed, penetrate, or perforate. The strictures found in BE occur at the squamocolumnar junction, and are typically higher than peptic strictures in the absence of BE. Ulceration and stricture in association with BE were commonly reported before 1975, but, with the advent of potent acid suppression medication, they have become less common. In contrast, the complication of adenocarcinoma developing in Barrett's mucosa has become more common. Adenocarcinoma developing in Barrett's mucosa was considered a rare tumor before 1975. Today, it occurs in approximately one in every 100 patient-years of follow-up, which represents a risk 40 times that of the general population. Most, if not all, cases of adenocarcinoma of the esophagus arise in Barrett's epithelium (Fig. 25-35). About one third of all patients with BE present with malignancy.

malignant cells in the mucosa (*upper arrow*), but not invading the muscularis mucosae (*bottom arrow*)

[Reproduced with permission from DeMeester TR, Stein HJ, Fuchs KH: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): *Shackelford's Surgery of the Alimentary Tract*, 3rd ed, Vol. I. Philadelphia: W.B. Saunders, 1991, p 113. Copyright Elsevier.]

The long-term risk of progression to dysplasia and adenocarcinoma, although not the driving force behind the decision to perform antireflux surgery, is a significant concern for both patient and physician. Although to date, there have been no prospective randomized studies documenting that antireflux surgery has an effect on the risk of progression to dysplasia and carcinoma, complete control of reflux of gastric juice into the esophagus is clearly a desirable goal. As data accumulate regarding the relative impact of medical and surgical therapy on the natural history of Barrett's metaplasia, the risk of progression may play a larger role in therapeutic decisions.

Respiratory Complications

A significant proportion of patients with GERD will have associated respiratory symptoms. These patients may have laryngopharyngeal reflux-type symptoms, adult-onset asthma, or even idiopathic pulmonary fibrosis. These symptoms and organ injury may occur in isolation or in conjunction with typical reflux symptoms such as heartburn and regurgitation. Several studies have demonstrated that up to 50% of patients with asthma have either endoscopically evident esophagitis or abnormal distal esophageal acid exposure. These findings support a causal relationship between GERD and aerodigestive symptoms and complications in a proportion of patients.

ETIOLOGY OF REFLUX-INDUCED RESPIRATORY SYMPTOMS

There are two mechanisms that have been proposed as the cause of reflux-induced respiratory symptoms. The *reflux theory* suggests that these symptoms are the direct result of laryngopharyngeal exposure and aspiration of gastric contents. The *reflex theory* suggests that the vagal-mediated afferent fibers result in bronchoconstriction during episodes of distal esophageal acidification. The evidence supporting a mechanism of direct exposure to the aerodigestive system is based in clinical studies that have documented a strong correlation between idiopathic pulmonary fibrosis and hiatal hernia. In addition, the presence of GERD was demonstrated to be highly associated with several pulmonary diseases in a recent Department of Veteran Affairs multivariate analysis. Next, with ambulatory pH testing, acid exposure within the proximal esophagus is more frequently identified in patients with gastroesophageal reflux and respiratory symptoms than in patients who have gastroesophageal reflux symptoms alone. These findings are supported by scintigraphic studies, which have demonstrated aspiration of ingested radioisotope in patients with both gastroesophageal reflux and pulmonary symptoms. In animal studies, tracheal instillation of acid has been demonstrated to profoundly increase airway resistance. Finally, in patients who have undergone multichannel intraluminal impedance testing with a catheter configured to detect laryngopharyngeal reflux, a correlation between proximal fluid movement and laryngopharyngeal symptoms, such as cough, can be demonstrated.

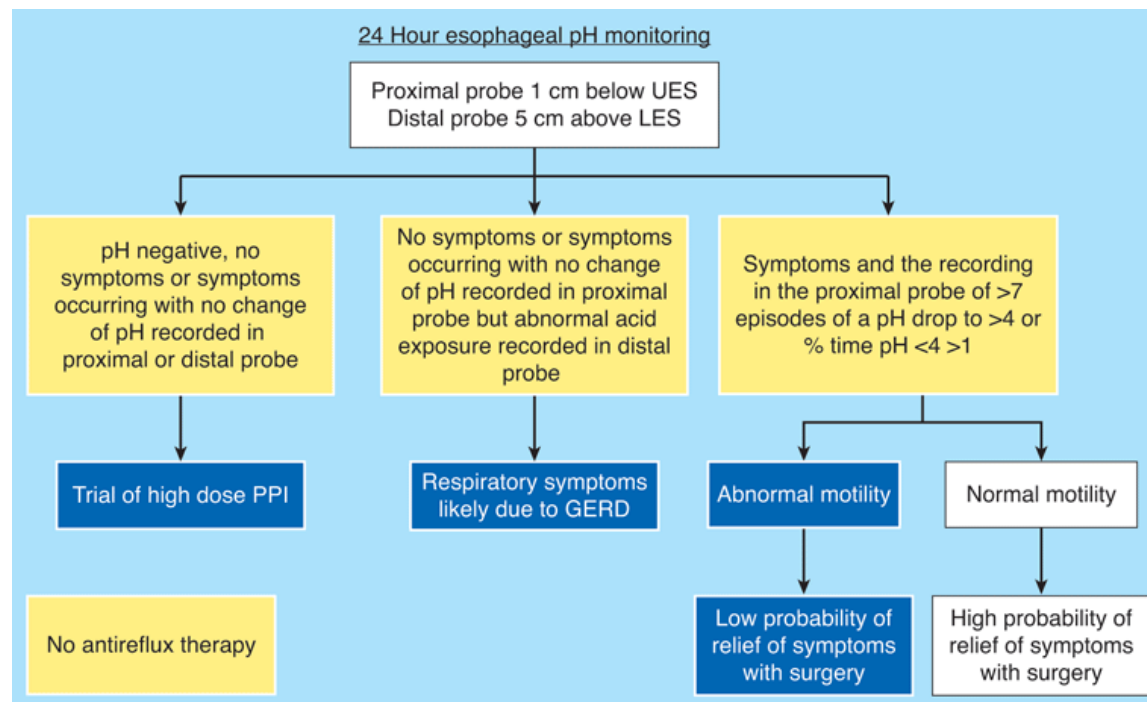

The reflex mechanism is supported by the bronchoconstriction that occurs with the infusion of acid into the distal esophagus. There is a shared embryologic origin of the tracheoesophageal tract and vagus nerve, and this reflex is thought to be an afferent fiber-mediated reflex that protects the aerodigestive system from the aspiration of refluxate. In patients with respiratory symptoms and documented gastroesophageal reflux without proximal esophageal acid exposure, pulmonary symptoms will often times significantly improve or completely resolve after undergoing laparoscopic fundoplication. It is likely that both of the proposed mechanisms work simultaneously to cause these symptoms in the face of GERD.

The most difficult clinical challenge in formulating a treatment plan for reflux-associated respiratory symptoms resides in establishing the diagnosis. Although the diagnosis made be straightforward in patients with predominately typical reflux symptoms and secondary respiratory complaints, a substantial number of patients will have respiratory symptoms that dominate the clinical scenario. Typical gastroesophageal reflux symptoms, such as heartburn and regurgitation, may often be completely absent only to be uncovered with objective esophageal physiology testing. Traditionally, the diagnosis of reflux-induced respiratory injury is established using ambulatory dual probe pH monitoring, with one probe positioned within the distal esophagus and the other at a proximal location. Proximal probe positioning has included multiple locations such as the trachea, pharynx, and proximal esophagus. Although ambulatory esophageal pH monitoring allows a direct correlation between esophageal acidification and respiratory symptoms, sensitivity of this testing modality is poor, and the temporal relationship between laryngeal or pulmonary symptoms and reflux events is complex. In addition, as the refluxed gastric fluid travels proximally, it may be neutralized by saliva and therefore go undetected with pH monitoring. Impedance testing is a novel technology that may be used more to detect the movement of fluid throughout the entire esophageal column regardless of pH content.

TREATMENT

Once the diagnosis is established, treatment may be initiated with either PPI therapy or antireflux surgery. A trial of high-dose PPI therapy may help establish the fact that reflux is partly or completely responsible for the respiratory symptoms. It is important to note that the persistence of symptoms in the face of aggressive PPI treatment does not necessarily rule out reflux as a possible cofactor or sole etiology. The algorithm suggested in Fig. 25-36 represents a useful starting point for the diagnostic evaluation in this patient population.

Fig. 25-36.

Correlation of symptoms with pH measurements predict the likelihood that reflux symptoms are caused directly by acid reflux. GERD = gastroesophageal reflux disease; LES = lower esophageal sphincter; PPI = proton pump inhibitor; UES = upper esophageal sphincter.

Although there is most likely some elements of a placebo effect, relief of respiratory symptoms can be anticipated in up to 50% of patients with reflux-induced asthma treated with antisecretory medications. However, when examined objectively, <15% of patients can be expected to have improvement in their pulmonary function with medical therapy. In properly selected patients, antireflux surgery improves respiratory symptoms in nearly 90% of children and 70% of adults with asthma and reflux disease. Improvements in pulmonary function can be demonstrated in around 30% of patients. Uncontrolled studies of the two forms of therapy (PPI and surgery) and the evidence from the two randomized controlled trials of medical vs. surgical therapy indicate that surgical valve reconstruction is the most effective therapy for reflux-induced asthma. The superiority of the surgery over PPI is most noticeable in the supine position, which corresponds with the nadir of PPI blood levels and resultant acid breakthrough and is the time in the circadian cycle when asthma symptoms are at their worst.

In asthmatic patients with an esophageal motility disorder, performing an antireflux operation will not prevent the regurgitation and possible aspiration of swallowed liquid or food "upstream" to the valve reconstruction. It is critical that esophageal body function be considered prior to surgical intervention in this patient population.

MEDICAL THERAPY FOR GASTROESOPHAGEAL REFLUX DISEASE

With the widespread availability of over-the-counter antisecretory medications, most patients with mild or moderate symptoms will carry self-medication. When initially identified with mild symptoms of uncomplicated GERD, patients can be placed on 12 weeks of simple antacids before diagnostic testing is initiated. This approach may successfully and completely resolve the symptoms. Patients should be counseled to elevate the head of the bed; avoid tight-fitting clothing; eat small, frequent meals; avoid eating the nighttime meal immediately prior to bedtime; and avoid alcohol, coffee, chocolate, and peppermint, which are known to reduce resting LES pressure and may aggravate symptoms.

Used in combination with simple antacids, alginic acid may augment the relief of symptoms by creating a physical barrier to reflux, as well as by acid reduction. Alginic acid reacts with sodium bicarbonate in the presence of saliva to form a highly viscous solution that floats like a raft on the surface of the gastric contents. When reflux occurs, this protective layer is refluxed into the esophagus, and acts as a protective barrier against the noxious gastric contents. Medications to promote gastric emptying, such as metoclopramide or domperidone, are beneficial in early disease, but of little value in more severe disease.

In patients with persistent symptoms, the mainstay of medical therapy is acid suppression. High-dosage regimens of hydrogen potassium PPIs, such as omeprazole (up to 40 mg/d), can reduce gastric

acidity by as much as 80 to 90%. This usually heals mild esophagitis. In severe esophagitis, healing may occur in only one half of the patients. In patients who reflux a combination of gastric and duodenal juice, acid-suppression therapy may give relief of symptoms, while still allowing mixed reflux to occur. This can allow persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.

Once initiated, most patients with GERD will require lifelong treatment with PPIs, both to relieve symptoms and control any coexistent esophagitis or stricture. Although control of symptoms has historically served as the endpoint of therapy, the wisdom of this approach has recently been questioned, particularly in patients with BE. Evidence suggesting that reflux control may prevent the development of adenocarcinoma and lead to regression of dysplastic and nondysplastic Barrett's segments has led many to consider control of reflux, and not symptom control, a better therapeutic endpoint. However, complete control of reflux can be difficult, as has been highlighted by studies of acid breakthrough while on PPI therapy, and of persistent reflux following antireflux surgery. Castell, Triadafilopoulos, and others have shown that 40 to 80% of patients with BE continue to have abnormal esophageal acid exposure despite up to 20 mg twice daily of PPIs. Ablation trials have shown that mean doses of 56 mg of omeprazole were necessary to normalize 24-hour esophageal pH studies. It is likely that antireflux surgery results in more reproducible and reliable elimination of reflux of both acid and duodenal contents, although long-term outcome studies suggest that as many as 25% of post-Nissen patients will have persistent pathological esophageal acid exposure confirmed by positive 24-hour pH studies.

SUGGESTED THERAPEUTIC APPROACH

The traditional stepwise approach to the therapy of GERD should be re-examined in view of a more complete understanding of the pathophysiology of gastroesophageal reflux, the rising incidence of BE, and the increasing mortality rates associated with end-stage reflux disease. The approach should be to identify risk factors for persistent and progressive disease early in the course of the disease, and encourage surgical treatment when these factors are present. The following approach is suggested.

Medical therapy for most patients will be started with H₂ blockade. Failure of this medication, or the immediate return of symptoms after stopping treatment, suggests either that the patient may have relatively severe disease or a non-GERD cause for his or her symptoms. Endoscopic examination at this stage of the patient's evaluation is recommended and will provide the opportunity to assess the degree of mucosal injury and screening for BE and esophageal adenocarcinoma. In addition, the measurement of esophageal acid exposure via 24-hour pH or impedance monitoring should also be obtained at this point. The status of the LES and esophageal body function with esophageal manometry should also be performed. These studies will serve to establish the diagnosis and characterize the severity and patterns of gastroesophageal reflux such as the supine reflux, esophageal body dysfunction, erosive esophagitis, or BE, bile reflux, and a defective LES. Patients who present with these risk factors should be offered laparoscopic antireflux surgery as a primary therapy, with the expectation of long-term control of symptoms and prevention of GERD-related complications.

Surgical Therapy for Gastroesophageal Reflux Disease

SELECTION OF PATIENTS FOR SURGERY

Studies of the natural history of GERD indicate that most patients have a relatively benign form of the disease that is responsive to lifestyle changes and dietary and medical therapy, and do not need surgical treatment. Approximately 25 to 50% of the patients with GERD have persistent or progressive disease, and it is this patient population that is best suited to surgical therapy. These patients are identified by the same risk factors that predict a poor response to medical therapy. In the past, the presence of esophagitis and a structurally defective LES were the primary indications for surgical treatment, and many internists and surgeons were reluctant to recommend operative procedures in their absence. However, one should not be deterred from considering antireflux surgery in a symptomatic patient with or without esophagitis or a defective sphincter, provided the disease process has been objectively documented by 24-hour pH monitoring. This is particularly true in patients who have become dependent upon therapy with PPIs, or require increasing doses to control their symptoms. It is important to note that a good response to medical therapy in this group of patients predicts an excellent outcome following antireflux surgery.

A structurally defective LES is the most important factor predicting failure of medical therapy. Although patients with normal sphincter pressures tend to remain well controlled with medical therapy, patients with a structurally defective LES do not respond well to medical therapy, usually developing recurrent symptoms within 1 to 2 years of beginning therapy. These patients should be considered for an antireflux operation, regardless of the presence or absence of endoscopic esophagitis.

Young patients with documented reflux disease with or without a defective LES are also excellent candidates for antireflux surgery. They usually will require long-term medical therapy for control of their symptoms, and many will go on to develop complications of the disease. An analysis of the cost of therapy based on data from the Veterans Administration Cooperative trial indicates that surgery has a cost advantage over medical therapy in patients <49 years of age.

Severe endoscopic esophagitis in a symptomatic patient with a structurally defective LES is also an indication for early surgical therapy. These patients are prone to breakthrough of their symptoms while receiving medical therapy. Symptoms and mucosal injury can be controlled in such patients, but careful monitoring is required, and increasing dosages of PPIs are necessary. In everyday clinical practice, however, such treatment can be both difficult and impractical, and, in such cases, antireflux surgery should be considered early as a therapeutic option.

The development of a stricture in a patient represents a failure of medical therapy, and is also an indication for a surgical antireflux procedure. In addition, strictures are often associated with a structurally

defective sphincter and loss of esophageal contractility. Before proceeding with surgical treatment, malignancy and a drug-related etiology of the stricture should be excluded, and the stricture progressively dilated up to a 60F bougie. When the stricture is fully dilated, the relief of dysphagia is evaluated and esophageal manometry is performed to determine the adequacy of peristalsis in the distal esophagus. If dysphagia is relieved and the amplitude of esophageal contractions is adequate, an antireflux procedure should be performed; if there is a global loss of esophageal contractility, caution should be exercised in performing an antireflux procedure with a complete fundoplication, and a partial fundoplication should be considered.

Barrett's CLE is commonly associated with a severe structural defect of the LES and often poor contractility of the esophageal body. Patients with BE are at risk of progression of the mucosal abnormality up the esophagus, formation of a stricture, hemorrhage from a Barrett's ulcer, and the development of an adenocarcinoma. An antireflux procedure may arrest the progression of the disease, heal ulceration, and resolve strictures. Evidence is accumulating that surgical treatment also reduces the risk of progression to cancer. If severe dysplasia or intramucosal carcinoma is found on mucosal biopsy specimens, an esophageal resection should be done.

The majority of patients requiring treatment have a relatively mild form of disease and will respond to antisecretory medications. Patients with more severe forms of disease, particularly those with risk factors predictive of medical failure and those who develop persistent or progressive disease, should be considered for early definitive therapy. Laparoscopic Nissen fundoplication will provide a long-term cure in the majority of these patients, with minimal discomfort and an early return to normal activity. If the disease has resulted in global failure of esophageal contractility, Barrett's metaplasia with high-grade dysplasia, or esophageal adenocarcinoma, an esophagectomy may be the best surgical treatment option.

PREOPERATIVE EVALUATION

Before proceeding with an antireflux operation, several factors should be evaluated. First, the propulsive force of the body of the esophagus should be evaluated by esophageal manometry to determine if it has sufficient power to propel a bolus of food through a newly reconstructed valve. Patients with normal peristaltic contractions do well with a 360° Nissen fundoplication. When peristalsis is absent a partial fundoplication may be the procedure of choice, but only if achalasia has been ruled out.

Second, anatomic shortening of the esophagus can compromise the ability to do an adequate repair without tension, and lead to an increased incidence of breakdown or thoracic displacement of the repair. Esophageal shortening is identified on a barium swallow roentgenogram by a sliding hiatal hernia that will not reduce in the upright position, or that measures larger than 5 cm between the diaphragmatic crura and GEJ on endoscopy. When esophageal shortening is present, the motility of the esophageal body must be carefully evaluated, and, if inadequate, a gastroplasty should be performed. In patients who have a global absence of contractility, more than 50% interrupted or dropped contractions, or a history of several failed previous antireflux procedures, esophageal resection should be considered as an alternative.

Third, the surgeon should specifically query the patient for complaints of nausea, vomiting, and loss of appetite. In the past, these symptoms were accepted as part of the reflux syndrome, but we now realize that they can be due to excessive duodenogastric reflux or gastric pathology. This problem is most pronounced in patients who have had previous upper GI surgery, particularly cholecystectomy, although this is not always the case. In such patients, these symptoms may persist after an antireflux procedure, and patients should be given this information before the operation. In these patients, 24-hour bilirubin monitoring and gastric emptying studies can be performed to detect and quantify duodenogastric abnormalities. Antireflux surgery alone may influence these symptoms by improving the efficiency of gastric emptying.

Fourth, approximately 30% of patients with proven gastroesophageal reflux on 24-hour pH monitoring will have hypersecretion on gastric analysis, and 2 to 3% of patients who have an antireflux operation will develop a gastric or duodenal ulcer. The presence of *Helicobacter pylori* should be assessed in these patients and treated if present.

PRINCIPLES OF SURGICAL THERAPY

The primary goal of antireflux surgery is to safely restore the structure of the sphincter or to prevent its shortening with gastric distention, while preserving the patient's ability to swallow normally, to belch to relieve gaseous distention, and to vomit when necessary. Regardless of the choice of the procedure, this goal can be achieved if attention is paid to five principles in reconstructing the cardia. First, the operation should restore the pressure of the distal esophageal sphincter to a level twice the resting gastric pressure (i.e., 12 mmHg for a gastric pressure of 6 mmHg), and its length to at least 3 cm. This not only augments sphincter characteristics in patients in whom they are reduced before surgery, but prevents unfolding of a normal sphincter in response to gastric distention (Fig. 25-37). Preoperative and postoperative esophageal manometry measurements have shown that the resting sphincter pressure and the overall sphincter length can be surgically augmented over preoperative values, and that the change in the former is a function of the degree of gastric wrap around the esophagus (Fig. 25-38).

The relationship between the augmentation of sphincter pressure over preoperative pressure (ΔP) and the degree of gastric fundic wrap in three popular antireflux procedures.

(Reproduced with permission from O'Sullivan GC, et al: Interaction of lower esophageal pressure and length of sphincter in the abdomen as detractors of gastroesophageal competence. *Am J Surg* 143:43, 1982. Copyright Elsevier.)

Second, the operation should place an adequate length of the distal esophageal sphincter in the positive-pressure environment of the abdomen by a method that ensures its response to changes in intra-abdominal pressure. The permanent restoration of 1.5 to 2 cm of abdominal esophagus in a patient whose sphincter pressure has been augmented to twice resting gastric pressure will maintain the competency of the cardia over various challenges of intra-abdominal pressure. All three of the popular antireflux procedures increase the length of the sphincter exposed to abdominal pressure by an average of 1 cm. When poorly performed, however, an operation may result in a reduction of the length of abdominal sphincter. Increasing the length of sphincter exposed to abdominal pressure will improve competency only if it is acted on by challenges of intra-abdominal pressure. The creation of a conduit that will ensure the transmission of intra-abdominal pressure changes around the abdominal portion of the sphincter is a necessary aspect of surgical repair. The fundoplication in the Nissen and Belsey repairs serves this purpose.

Third, the operation should allow the reconstructed cardia to relax on deglutition. In normal swallowing, a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs. The relaxation lasts for approximately 10 seconds and is followed by a rapid recovery to the former tonicity. To ensure relaxation of the sphincter, three factors are important: (a) Only the fundus of the stomach should be used to buttress the sphincter, because it is known to relax in concert with the sphincter; (b) the gastric wrap should be properly placed around the sphincter and not incorporate a portion of the stomach or be placed around the stomach itself, because the body of the stomach does not relax with swallowing; and (c) damage to the vagal nerves during dissection of the thoracic esophagus should be avoided because it may result in failure of the sphincter to relax.

Fourth, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic power of the body of the esophagus. The resistance of the relaxed sphincter

depends on the degree, length, and diameter of the gastric fundic wrap, and on the variation in intra-abdominal pressure. A 360° gastric wrap should be no longer than 2 cm and constructed over a 60F bougie. This will ensure that the relaxed sphincter will have an adequate diameter with minimal resistance. This is not necessary when constructing a partial wrap.

Fifth, the operation should ensure that the fundoplication can be placed in the abdomen without undue tension, and maintained there by approximating the crura of the diaphragm above the repair. Leaving the fundoplication in the thorax converts a sliding hernia into a PEH, with all the complications associated with that condition. Maintaining the repair in the abdomen under tension predisposes to an increased incidence of recurrence. This can occur in patients who have a stricture or BE, and is due to shortening of the esophagus from the inflammatory process. This problem can be resolved by lengthening the esophagus by gastropasty and constructing a partial fundoplication.

PROCEDURE SELECTION

A laparoscopic approach is used in patients with normal esophageal contractility and length. Patients with questionable esophageal length may be best approached transthoracically, where full esophageal mobilization serves as a lengthening procedure. Those with a failed esophagus characterized by absent esophageal contractions and/or absent peristalsis such as those with scleroderma are best treated either medically or with a partial fundoplication to avoid the increased outflow resistance associated with a complete fundoplication. If the esophagus is short after it is mobilized from diaphragm to aortic arch, a Collis gastropasty is done to provide additional length and avoid placing the repair under tension. In the majority of patients who have good esophageal contractility and normal esophageal length, the laparoscopic Nissen fundoplication is the procedure of choice for a primary antireflux repair. Experience and randomized studies have shown that the Nissen fundoplication is an effective and durable antireflux repair with minimal side effects that provides long-lasting relief of reflux symptoms in over 90% of patients.

Primary Antireflux Repairs

NISSEN FUNDOPLICATION

The most common antireflux procedure is the Nissen fundoplication. The procedure can be performed through an abdominal or a chest incision, as well as through a laparoscope. Rudolph Nissen described the procedure as a 360° fundoplication around the lower esophagus for a distance of 4 to 5 cm. Although this provided good control of reflux, it was associated with a number of side effects that have encouraged modifications of the procedure as originally described. These include using only the gastric fundus to envelop the esophagus in a fashion analogous to a Witzel jejunostomy, sizing the fundoplication with a 60F bougie, and limiting the length of the fundoplication to 1 to 2 cm. The essential elements necessary for the performance of a transabdominal fundoplication are common to both the laparoscopic and open procedures and include the following:

- 1. Crural dissection and preservation of both vagi along their entire length
- 2. Circumferential esophageal mobilization
- 3. Posterior crural closure
- 4. Division of short gastric vessels and posterior fundus
- 5. Creation of a short and floppy fundoplication over an esophageal dilator

THE LAPAROSCOPIC APPROACH

Laparoscopic fundoplication has become commonplace and has replaced the open abdominal Nissen fundoplication as the procedure of choice. Five 10-mm ports are used (Fig. 25-39). Dissection is begun by an incision of the portion of the gastrohepatic omentum above the hepatic branch of the anterior vagus nerve. The circumference of the diaphragmatic crura is dissected and the esophagus is mobilized by careful dissection of the anterior and posterior soft tissues within the hiatus. The esophagus is held anterior and to the left and the crura approximated with three to four interrupted 0 silk sutures, starting just above the aortic decussation and working anterior. Complete fundic mobilization allows construction of a tension-free fundoplication. Short gastric vessels along the upper one third of the greater curvature are sequentially dissected and divided. Following complete mobilization, the posterior wall of the fundus is gently brought behind the esophagus to the right side. The anterior wall of the fundus is brought anterior to the esophagus, and the fundic lips are manipulated to allow the fundus to envelop the esophagus without twisting (Fig. 25-40). A 60F bougie is passed to properly size the fundoplication, and it is sutured by using a single U stitch of 2-0 polypropylene buttressed with felt pledgets (Fig. 25-41).

A. Laparoscopic Nissen fundoplication is performed with a five-trocar technique. **B.** The liver retractor is affixed to a mechanical arm to hold it in place throughout the operation. **C.** After division of the gastrohepatic omentum above the hepatic branch of the vagus (pars flaccida), the surgeon places a blunt atraumatic grasper beneath the phrenoesophageal ligament. **D.** After completion of the crural

closure, an atraumatic grasper is placed right to left behind the gastroesophageal junction. The grasper is withdrawn, pulling the posterior aspect of the gastric fundus behind the esophagus. **E.** Once the suture positions are chosen, the first stitch (2-0 silk, 20 cm long) is introduced through the 10-mm trocar, and the needle is passed first through the left limb of the fundus, then the esophagus (2.5 cm above the gastroesophageal junction), then through the right limb of the fundus. **F.** Final position of the fundoplication.

TRANSTHORACIC NISSEN FUNDOPLICATION

The indications for performing an antireflux procedure by a transthoracic approach are as follows:

1. A patient has had a previous hiatal hernia repair. In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
2. A patient who requires a concomitant esophageal myotomy for achalasia or diffuse spasm.
3. A patient who has a short esophagus. This is usually associated with a stricture or BE. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus, and to perform a Collis gastroplasty to place the repair without tension below the diaphragm.
4. A patient with a sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position. This can indicate esophageal shortening, and again, a thoracic approach is preferred for maximum mobilization of the esophagus, and, if necessary, the performance of a Collis gastroplasty.
5. A patient who has associated pulmonary pathology. In this situation, the nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.
6. An obese patient. In this situation, the abdominal repair is difficult because of poor exposure, particularly in men, in whom the intra-abdominal fat is more abundant.

When employing the thoracic approach, the hiatus is exposed through a left posterior lateral thoracotomy incision in the sixth intercostal space. The diaphragm can be incised circumferentially and laterally for a distance of approximately 10 to 15 cm. The esophagus is circumferentially mobilized from the level of the diaphragm to the aortic arch. The proximal stomach is then freed from below the diaphragm and the fundus and part of the body of the stomach are drawn up through the hiatus into the chest cavity. The gastroesophageal fat pad is then excised. A crural closure is then performed, and the fundoplication is constructed by enveloping the fundus around the distal esophagus. When complete, the fundoplication is placed into the abdomen.

LAPAROSCOPIC TOUPET AND BELSEY MARK IV PARTIAL FUNDOPLICATIONS

In the presence of severely altered esophageal motility, where the propulsive force of the esophagus is not sufficient to overcome the outflow obstruction of a complete fundoplication, a partial fundoplication is indicated. A partial fundoplication may be performed laparoscopically, a Toupet fundoplication, or transthoracically, a Belsey Mark IV repair. Both consist of a 270° gastric fundoplication around the distal 4 cm of esophagus, performed either laparoscopically or through a left chest incision (Fig. 25-42).

Fig. 25-42.

A. After removal of the fat pad and release of tension on the Penrose drain, the gastroesophageal junction (GES) retracts to the level of the hiatus. The interior end of the staple line is marked $2\frac{2}{5}$ cm below the angle of His. **B.** The first horizontal firing of the stapler occurs by maximally articulating the stapler to the left, aiming toward the previously marked spot adjacent to the dilator. **C.** The vertical staple line is created by a single firing of the GIA placed parallel and flush against the 48F dilator. **D.** The highest Nissen fundoplication suture is placed on the native esophagus, and the second suture tucks in the apex of the staple line.

In patients with a short esophagus secondary to a stricture, BE, or a large hiatal hernia, the esophagus is lengthened with a Collis gastroplasty (see Fig. 25-42). The esophagus is lengthened by constructing a gastric tube along the lesser curvature. This allows a tension-free constriction of a Belsey Mark IV or Nissen fundoplication around the newly formed gastric tube, with placement of the repair in the abdomen. Because a short esophagus is commonly associated with a reduction in esophageal contraction amplitude and the gastric tube is inert, most surgeons prefer to combine the gastroplasty procedure with a 280° Belsey Mark IV fundoplication rather than a 360° Nissen fundoplication.

OUTCOME AFTER FUNDOPLICATION

Studies of long-term outcome following both open and laparoscopic fundoplication document the ability of laparoscopic fundoplication to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80 to 90% of patients 5 years or more following surgery. This includes evidence-based reviews of antireflux surgery, prospective randomized trials comparing antireflux surgery to PPI therapy and open to laparoscopic fundoplication and analysis of U.S. national trends in use and outcomes. Laparoscopic fundoplication results in a significant increase in LES pressure and length, generally restoring these values to normal. Postoperative pH studies indicate that more than 90% of patients will normalize their pH tracings. The results of laparoscopic fundoplication compare favorably with those of the "modern" era of open fundoplication. They also indicate the less predictable outcome of atypical reflux symptoms (cough, asthma, laryngitis) after surgery, being relieved in only two thirds of patients.

The goal of surgical treatment for GERD is to relieve the symptoms of reflux by re-establishing the gastroesophageal barrier. The challenge is to accomplish this without inducing dysphagia or other untoward side effects. Dysphagia, existing before surgery, usually improves following laparoscopic fundoplication. Temporary dysphagia is common after surgery and generally resolves within 3 months. Dysphagia persisting beyond 3 months has been reported in up to 10% of patients. In the authors' experience, dysphagia, manifest by occasional difficulty swallowing solids, was present in 7% of patients at 3 months, 5% at 6 months, 2% at 12 months, and in a single patient at 24 months following surgery. Others have observed a similar improvement in postoperative dysphagia with time. Induced dysphagia is usually mild, does not require dilatation, and is temporary. It can be induced by technical misjudgments, but this explanation does not hold in all instances. In experienced hands, its prevalence should be <3% at 1 year. Other side effects common to antireflux surgery include the inability to vomit and increased flatulence. Most patients cannot vomit through an intact wrap, though this is rarely clinically relevant. Hyperflatulence is a common and noticeable problem, likely related to increased air swallowing that is present in most patients with reflux disease.

Quality-of-life analyses have become an important part of surgical outcome assessment, with both generic and disease-specific questionnaires in use, in an attempt to quantitate quality of life before and after surgical intervention. In general, these measures relate the effect of disease management to the overall well being of the patient. Most studies have used the Short Form 36 instrument, as it is rapidly administered and well validated. This questionnaire measures 12 different health-related quality-of-life parameters encompassing mental and physical well-being. Data generally indicate significant improvements in scores for most areas of the general health index.

Outcome of Antireflux Surgery in Patients with Barrett's Esophagus

Few studies have focused on the alleviation of symptoms after antireflux surgery in patients with BE (Table 25-8). Those that are available document excellent to good results in 72 to 95% of patients at 5 years following surgery. Several studies have compared medical and surgical therapy. Attwood and associates, in a prospective but nonrandomized study, reported on 45 patients undergoing either medical (26) or surgical (19) treatment of BE. The groups were similar in age, length of Barrett's segment, the percentage of time during which pH was <4, and length of follow-up. Improvement of symptoms was dramatic after antireflux surgery. Symptoms of heartburn or dysphagia recurred in 88% of patients treated with medical therapy alone, and 21% after antireflux surgery. Complications, most commonly the development of an esophageal stricture, occurred in 38% of medically treated patients and 16 percent of surgically treated patients ($P < .05$) over the 3-year follow-up period. One patient in each group developed esophageal adenocarcinoma. It was concluded that antireflux surgery was superior to acid suppression for both the control of symptoms and the prevention of complications in patients with BE. Other nonrandomized comparisons of medical and surgical therapy have reported similar results. Parrilla and colleagues recently reported an update of a study originally published in the *British Journal of Surgery* in 1996. The study enrolled 101 patients over 18 years (1982 to 2000). Median follow-up was 6 years. Medical therapy consisted of 20 mg of omeprazole (PPI) twice daily since 1992 in all medically treated patients. Surgical therapy consisted of an open 1.5 to 3.0 cm Nissen, over a 48 to 50F bougie, with division of the short gastric arteries in 39% of patients, and crural closure in all. Symptomatic outcome in the two groups was nearly identical, although esophagitis and/or stricture persisted in 20% of the medically treated patients, compared to only 3 to 7% of patients following antireflux surgery. Fifteen percent of patients had abnormal acid exposure after surgery. Although pH data were not routinely collected in patients on PPI therapy, in the subgroup of 12 patients that did have 24-hour monitoring on treatment, three of 12 (25%) had persistently high esophageal acid exposure, and most (75%) had persistently high bilirubin exposure.

Table 25-8 Symptomatic Outcome of Surgical Therapy for Barrett's Esophagus				
Author	Year	No. of Patients	% Excellent to Good Response	Mean Follow-Up, Years
Starnes	1984	8	75	2
Williamson	1990	37	92	3
DeMeester	1990	35	77	3
McDonald	1996	113	82.2	6.5
Ortiz	1996	32	90.6	5

The outcome of laparoscopic Nissen fundoplication in patients with BE has been assessed at 1 to 3 years after surgery. Hofstetter and colleagues reported the experience at the University of Southern California with 85 patients with BE at a median of 5 years after surgery. Fifty-nine patients had long- and 26 had short-segment Barrett's; 50 had a laparoscopic approach. Reflux symptoms were absent in 67 of 85 patients (79%). Eighteen (20%) developed recurrent symptoms, while four patients were back on daily acid-suppressive medication. Seven patients underwent a secondary repair and were asymptomatic, raising the eventual successful outcome to 87%. Postoperative 24-hour pH was normal in 17 of 21 patients (81%). Ninety-nine percent of the patients considered themselves cured (77%) or improved (22%), and 97% were satisfied with the surgery.

Farrell and associates also reported symptomatic outcome of laparoscopic Nissen fundoplication in 50 patients with both long- and short-segment BE. Mean scores for heartburn, regurgitation, and dysphagia all improved dramatically post-Nissen. Importantly, there was no significant decrement in symptom scores when 1-year results were compared to those at 2 to 5 years postoperatively. They did find a higher prevalence of "anatomic" failures requiring reoperation in patients with BE when compared to non-Barrett's patients with GERD. Others have reported similar results. Taken together these studies document the ability of antireflux surgery to provide long-term symptomatic relief in patients with BE.

Three relevant questions arise concerning the fate, over time, of the metaplastic tissue found in BE: (a) Does antireflux surgery cause regression of Barrett's epithelium? (b) Does it prevent progression? and (c) Can the development of Barrett's metaplasia be prevented by early antireflux surgery in patients with reflux disease?

The common belief that Barrett's epithelium cannot be reversed is likely false. DeMeester and associates reported that, after antireflux surgery, loss of IM in patients with visible BE was rare, but occurred in 73% of patients with inapparent IM of the cardia. This suggests that the metaplastic process may indeed be reversible if reflux is eliminated early in its process, that cardiac mucosa is dynamic, and that, as opposed to IM extending several centimeters into the esophagus, IM of the cardia is more likely to regress following antireflux surgery. Gurski and colleagues reviewed pre- and posttreatment endoscopic biopsies from 77 Barrett's patients treated surgically and 14 treated with PPIs. Posttreatment histology was classified as having regressed if two consecutive biopsies taken more than 6 months apart, plus all subsequent biopsies, showed loss of IM or loss of dysplasia. Histopathologic regression occurred in 28 of 77 patients (36.4%) following antireflux surgery, and in one of 14 (7.1%) patients treated with PPIs

alone ($P < .03$). After surgery, regression from low-grade dysplastic to nondysplastic BE occurred in 17 of 25 (68%) patients and from IM to no IM in 11 of 52 (21.2%) patients. Both types of regression were significantly more common in short- (<3 cm) compared to long-segment (>3 cm) BE. Eight patients progressed; five from IM alone to low-grade dysplasia, and three from low- to high-grade dysplasia. All those who progressed had long-segment BE. On multivariate analysis, the presence of short-segment Barrett's and the type of treatment were significantly associated with regression; age, sex, and surgical procedure, and preoperative LES and pH characteristics were not. The median time of biopsy-proven regression was 18.5 months after surgery, with 95% occurring within 5 years. Similar findings have been reported by the University of Washington group and Hunter and colleagues. Although these studies do not conclusively prove the ability of antireflux surgery to reverse the changes of early BE, they do provide encouragement that, given early changes, the process may indeed be reversible.

Recent evidence suggests that the development of BE may even be preventable. Although a very difficult hypothesis to study, Oberg and coworkers followed a cohort of 69 patients with short-segment, nonintestinalized, CLE over a median of 5 years of surveillance endoscopy. Forty-nine of the patients were maintained on PPI therapy and 20 had antireflux surgery. Patients with antireflux surgery were 10 times less likely to develop IM in these CLE segments over a follow-up span of nearly 15 years than those on medical therapy. This rather remarkable observation supports the two-step hypothesis of the development of BE (cardiac metaplasia followed by IM), and suggests that the second step can be prevented if reflux disease is recognized and treated early and aggressively.

Current data indicate that patients with BE should remain in an endoscopic surveillance program following antireflux surgery. Biopsy specimens should be reviewed by a pathologist with expertise in the field. If low-grade dysplasia is confirmed, biopsies should be repeated after 12 weeks of high-dose acid suppression therapy. If high-grade dysplasia is evident on more than one biopsy specimen, esophageal resection is advisable because of the more than 50% probability that an invasive cancer is already present. Early detection and resection have been shown to decrease the mortality rate from esophageal cancer in these patients. Because BE results from chronic, uncontrolled gastroesophageal reflux, and esophageal adenocarcinoma is virtually always associated with IM, there are strong theoretical grounds for halting the progression toward malignancy by permanently and effectively stopping reflux of gastric contents. Thus, prevention of progression, not regression, becomes the central issue. Although some cancers have developed after antireflux surgery, the absence of pre-existent dysplasia before surgery or the efficacy of the operative procedure in reducing 24-hour esophageal acid exposure to normal has not been documented. If the dysplasia is reported as lower grade or indeterminant, then inflammatory change that is often confused with dysplasia should be suppressed by a course of acid suppression therapy in high doses for 2 to 3 weeks, followed by rebiopsy of the Barrett's segment.

There is a growing body of evidence to attest to the ability of fundoplication to protect against dysplasia and invasive malignancy. Three studies suggest that an effective antireflux procedure can impact the natural history of BE in this regard. Two prospective randomized studies found less adenocarcinoma in the surgically treated groups. Parrilla and associates reported that, although the development of dysplasia and adenocarcinoma was no different overall, the subgroup of surgical patients with normal postoperative pH studies developed significantly less dysplasia and had no adenocarcinoma. Spechler identified one adenocarcinoma 11 to 13 years after antireflux surgery, compared to four following medical treatment. Most of these authors concluded that there is a critical need for future trials exploring the role of antireflux surgery in protecting against the development of dysplasia in patients with BE.

Data from the Mayo Clinic strongly suggest that antireflux surgery impacts the development of adenocarcinoma in patients with BE. The authors reviewed the outcome of 118 patients with BE undergoing antireflux surgery between 1960 and 1990. Three cancers occurred over an 18.5-year follow-up period, all within the first 3 years after surgery. The fact that the development of adenocarcinoma was clustered in the early years after antireflux surgery, and not randomly dispersed throughout the follow-up period, suggests that antireflux surgery altered the natural history of the disease. Hammeetman has shown that once dysplasia has developed, carcinoma ensues in an average of 3 years. The occurrence of all observed cancers in the first few years suggests that the point of no return in the dysplasia-cancer sequence had already occurred before the time of antireflux surgery.

Reoperation for Failed Antireflux Repairs

Failure of an antireflux procedure occurs when, after the repair, the patient is unable to swallow normally, experiences upper abdominal discomfort during and after meals, or has recurrence or persistence of reflux symptoms. The assessment of these symptoms and the selection of patients who need further surgery are challenging problems. Functional assessment of patients who have recurrent, persistent, or emergent new symptoms following a primary antireflux repair is critical to identifying the cause of the failure. Analysis of patients requiring reoperation after a previous antireflux procedure shows that placement of the wrap around the stomach is the most frequent cause for failure after open procedures, while herniation of the repair into the chest is the most frequent cause of failure after a laparoscopic procedure. Partial or complete breakdown of the fundoplication and construction of a too-tight or too-long wrap of a fundoplication occurs with both open and closed procedures. The fact that 10% of these patients had an undiagnosed underlying esophageal motor disorder underlines the critical role of preoperative esophageal function tests before the initial procedure.

Patients who have recurrence of heartburn and regurgitation without dysphagia and have good esophageal motility are most amenable to reoperation, and can be expected to have an excellent outcome. When dysphagia is the cause of failure, the situation is more difficult to manage. If the dysphagia occurred immediately following the repair, it is usually due to a technical failure, most commonly a misplaced fundoplication around the upper stomach, and reoperation is usually satisfactory. When dysphagia is associated with poor motility and multiple previous repairs, serious consideration should be given to esophageal resection and replacement. With each reoperation the esophagus is damaged further, and the chances of preserving function become less. Also, blood supply is reduced, and ischemic necrosis of the esophagus can occur after several previous mobilizations.

GIANT DIAPHRAGMATIC (HIATAL) HERNIAS

With the advent of clinical radiology, it became evident that a diaphragmatic hernia was a relatively common abnormality and was not always accompanied by symptoms. Three types of esophageal hiatal hernia were identified: (a) the sliding hernia, type I, characterized by an upward dislocation of the cardia in the posterior mediastinum (Fig. 25-43A); (b) the rolling or PEH, type II, characterized by an upward dislocation of the gastric fundus alongside a normally positioned cardia (Fig. 25-43B); and (c) the combined sliding-rolling or mixed hernia, type III, characterized by an upward dislocation of both the cardia and the gastric fundus (Fig. 25-43C). The end stage of type I and type II hernias occurs when the whole stomach migrates up into the chest by rotating 180° around its longitudinal axis, with the cardia and pylorus as fixed points. In this situation the abnormality is usually referred to as an *intrathoracic stomach* (Fig. 25-43D). In some taxonomies, a type IV hiatal hernia is declared when an additional organ, usually the colon, herniates as well.

Incidence and Etiology

The true incidence of a hiatal hernia is difficult to determine because of the absence of symptoms in a large number of patients who are subsequently shown to have a hernia. When radiographic examinations are done in response to GI symptoms, the incidence of a sliding hiatal hernia is seven times higher than that of a PEH. The PEH is also known as the *giant hiatal hernia*. Over time the pressure gradient between the abdomen and chest enlarges the hiatal hernia. In many cases the type 1 sliding hernia will evolve into a type III mixed hernia. Type II hernias are quite rare. The age distribution of patients with PEHs is significantly different from that observed in sliding hiatal hernias. The median age of the former is 61 years old; of the latter, 48 years old. PEHs are more likely to occur in women by a ratio of 4:1.

Structural deterioration of the phrenoesophageal membrane over time may explain the higher incidence of hiatal hernias in the older age group. These changes involve thinning of the upper fascial layer of the phrenoesophageal membrane (i.e., the supradiaphragmatic continuation of the endothoracic fascia) and loss of elasticity in the lower fascial layer (i.e., the infradiaphragmatic continuation of the transversalis fascia). Consequently, the phrenoesophageal membrane yields to stretching in the cranial direction due to the persistent intra-abdominal pressure and the tug of esophageal shortening on swallowing. Interestingly, the stretching and thinning occurs more anteriorly and posteriorly, with fixation of the left crus of the diaphragm to the stomach at the 3 o'clock position, as viewed from the foot. This creates an anterior and posterior hernia sac, the latter of which is often filled with epiphrenic and retroperitoneal fat. These observations point to the conclusion that the development of a hiatal hernia is an age-related phenomenon secondary to repetitive upward stretching of the phrenoesophageal membrane.

Clinical Manifestations

The clinical presentation of a giant hiatal (paraesophageal) hernia differs from that of a sliding hernia. There is usually a higher prevalence of symptoms of dysphagia and postprandial fullness with PEHs, but the typical symptoms of heartburn and regurgitation present in sliding hiatal hernias can also occur. Both are caused by gastroesophageal reflux secondary to an underlying mechanical deficiency of the cardia. The symptoms of dysphagia and postprandial fullness in patients with a PEH are explained by the compression of the adjacent esophagus by a distended cardia, or twisting of the GEJ by the torsion of

the stomach that occurs as it becomes progressively displaced in the chest. Many patients with sliding hernias and reflux symptoms will lose the reflux symptoms when the hernia evolves into the paraesophageal variety. This can be explained by the re-creation of the cardiophrenic angle when the stomach herniates alongside the GEJ or becomes twisted in the sac. Repair of the hernia without addressing the reflux can create extremely bothersome heartburn. Respiratory complications are frequently associated with a PEH, and consist of dyspnea from mechanical compression and recurrent pneumonia from aspiration.

Approximately one third of patients with a PEH are found to be anemic, which is due to recurrent bleeding from ulceration of the gastric mucosa in the herniated portion of the stomach, even if ulcerations are not detected at the time of endoscopy. The association of anemia and PEH is best proven by fixing the hernia. Anemia is corrected in >90% of patients with this condition. With time, more and more stomach migrates into the chest and can cause intermittent foregut obstruction due to the rotation that has occurred. In contrast, many patients with paraesophageal hiatal hernia are asymptomatic or complain of minor symptoms. However, the presence of a PEH can be life threatening in that the hernia can lead to sudden catastrophic events, such as excessive bleeding or volvulus with acute gastric obstruction or infarction. With mild dilatation of the stomach, the gastric blood supply can be markedly reduced, causing gastric ischemia, ulceration, perforation, and sepsis. The probability of incarceration is not well known, although recent analysis using mathematical modeling suggests the risk is small.

The symptoms of sliding hiatal hernias are usually due to functional abnormalities associated with gastroesophageal reflux and include heartburn, regurgitation, and dysphagia. These patients have a mechanically defective LES, giving rise to the reflux of gastric juice into the esophagus and the symptoms of heartburn and regurgitation. The symptom of dysphagia occurs from the presence of mucosal edema, Schatzki's ring, stricture, or the inability to organize peristaltic activity in the body of the esophagus as a consequence of the disease.

There is a group of patients with sliding hiatal hernias not associated with reflux disease who have dysphagia without any obvious endoscopic or manometric explanation. Video barium radiograms have shown that the cause of dysphagia in these patients is an obstruction of the swallowed bolus by diaphragmatic impingement on the herniated stomach. Manometrically, this is reflected by a double-humped high-pressure zone at the GEJ. The first pressure rise is due to diaphragmatic impingement on the herniated stomach, and the second to the true distal esophageal sphincter. These patients usually have a mechanically competent sphincter, but the impingement of the diaphragm on the stomach can result in propelling the contents of the supradiaphragmatic portion of the stomach up into the esophagus and pharynx, resulting in complaints of pharyngeal regurgitation and aspiration. Consequently, this abnormality is often confused with typical GERD. Surgical reduction of the hernia results in relief of the dysphagia in 91% of patients.

Diagnosis

A radiogram of the chest with the patient in the upright position can diagnose a hiatal hernia if it shows an air-fluid level behind the cardiac shadow. This is usually caused by a PEH or an intrathoracic stomach. The accuracy of the upper GI barium study in detecting a paraesophageal hiatal hernia is greater than for a sliding hernia because the latter can often spontaneously reduce. The paraesophageal hiatal hernia is a permanent herniation of the stomach into the thoracic cavity, so a barium swallow provides the diagnosis in virtually every case. Attention should be focused on the position of the GEJ, when seen, to differentiate it from a type II hernia (see Fig. 25-43B and C). Fiber-optic esophagoscopy is useful in the diagnosis and classification of a hiatal hernia because the scope can be retroflexed. In this position, a sliding hiatal hernia can be identified by noting a gastric pouch lined with rugal folds extending above the impression caused by the crura of the diaphragm, or measuring at least 2 cm between the crura, identified by having the patient sniff, and the squamocolumnar junction on withdrawal of the scope (Fig. 25-44). A PEH is identified on retroversion of the scope by noting a separate orifice adjacent to the GEJ into which gastric rugal folds ascend. A sliding-rolling or mixed hernia can be identified by noting a gastric pouch lined with rugal folds above the diaphragm, with the GEJ entering about midway up the side of the pouch.

Pathophysiology

Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60% of the patients with a paraesophageal hiatal hernia, compared with the observed 71% incidence in patients with a sliding hiatal hernia. It is now recognized that paraesophageal hiatal hernia can be associated with pathologic gastroesophageal reflux.

Physiologic studies have also shown that the competency of the cardia depends on an interrelationship between distal esophageal sphincter pressure, the length of the sphincter that is exposed to the positive-pressure environment of the abdomen, and the overall length of the sphincter. A deficiency in any one of these manometric characteristics of the sphincter is associated with incompetency of the cardia regardless of whether a hernia is present. Patients with a PEH who have an incompetent cardia have been shown to have a distal esophageal sphincter with normal pressure, but a shortened overall length and displacement outside the positive-pressure environment of the abdomen. One might expect esophageal body function to be diminished with the esophagus "accordioned" up into the chest. Surprisingly, esophageal peristalsis in patients with PEH is normal in 88%.

Treatment

The treatment of paraesophageal hiatal hernia is largely surgical. Controversial aspects include (a) indications for repair, (b) surgical approach, and (c) role of fundoplication.

INDICATIONS

The presence of a paraesophageal hiatal hernia has traditionally been considered an indication for surgical repair. This recommendation is largely based upon two clinical observations. First, retrospective studies have shown a significant incidence of catastrophic, life-threatening complications of bleeding, infarction, and perforation in patients being followed with known paraesophageal herniation. Second, emergency repair carries a high mortality. In the classic report of Skinner and Belsey, six of 21 patients with a PEH, treated medically because of minimal symptoms, died from the complications of strangulation, perforation, exsanguinating hemorrhage, or acute dilatation of the herniated intrathoracic stomach. These catastrophes occurred for the most part without warning. Others have reported similar findings.

Recent studies suggest that catastrophic complications may be somewhat less common. Allen and colleagues followed 23 patients for a median of 78 months with only four patients progressively worsening. There was a single mortality secondary to aspiration that occurred during a barium swallow examination to investigate progressive symptoms. Although emergency repairs had a median hospital stay of 48 days compared to a stay of 9 days in those having elective repair, there were only three cases of gastric strangulation in 735 patient-years of follow-up.

If surgery is delayed and repair is done on an emergency basis, operative mortality is high, compared to <1% for an elective repair. With this in mind, patients with a PEH are generally counseled to have elective repair of their hernia, particularly if they are symptomatic. Watchful waiting of asymptomatic PEHs may be an acceptable option.

SURGICAL APPROACH

The surgical approach to repair of a paraesophageal hiatal hernia may be either transabdominal (laparoscopic or open) or transthoracic. Each has its advantages and disadvantages. A transthoracic approach facilitates complete esophageal mobilization but is rarely used because the access trauma and postoperative pain are significantly greater than a laparoscopic approach.

The transabdominal approach facilitates reduction of the volvulus that is often associated with PEHs. Although some degree of esophageal mobilization can be accomplished transhiatally, complete mobilization to the aortic arch is difficult or impossible without risk of injury to the vagal nerves.

Laparoscopic repair of PEH would appear to have become the standard approach; however, a recent review of large national databases suggests that most giant hernias are still repaired through an open approach. Laparoscopic repair of a pure type II, or mixed type III PEH is an order of magnitude more difficult than a standard laparoscopic Nissen fundoplication. Most would recommend that these procedures are best avoided until the surgeon has accumulated considerable experience with laparoscopic antireflux surgery. There are several reasons for this. First, the vertical and horizontal volvulus of the stomach often associated with PEHs makes identification of the anatomy, in particular the location of the esophagus, difficult. Second, dissection of a large PEH sac may result in significant bleeding if the surgeon deviates from the correct plane of dissection between the peritoneal sac and the endothoracic fascia. Finally, redundant tissue present at the GEJ following dissection of the sac frustrates the creation of a fundoplication, which these authors believe should accompany the repair of all PEHs. Mindful of these difficulties, and given appropriate experience, patients with PEH may be approached laparoscopically, with expectation of success in the majority.

Giant PEH can be associated with a short esophagus in up to 5 to 20% of patients as a result of chronic cephalad displacement of the GEJ. The presence of a short esophagus increases the difficulty of laparoscopic PEH repair. Up to 10 to 20% of surgical failures with PEH repair is due to the lack of recognition of a short esophagus. Preoperative results of barium swallow and esophagogastroduodenoscopy may provide an indication of short esophagus, but no combination of preoperative clinical variables reliably predict the presence of short esophagus, defined as the failure to achieve 2.5 cm of intra-abdominal esophagus with standard mediastinal dissection techniques. Hence, the diagnosis of this entity continues to be made definitively only in the operating room. Collis gastroplasty achieves esophageal lengthening by creation of a neoesophagus using the gastric cardia. The totally laparoscopic approach to the short esophagus has evolved from a method using an end-to-end anastomosis circular stapler to the current approach that uses a linear stapler creating a stapled wedge gastroplasty. Elements of importance in fashioning the fundoplication after Collis gastroplasty include placement of the initial suture of the fundoplication on the esophagus, immediately above the GEJ to ensure that acid-secreting (gastric) mucosa does not reside above the fundoplication. A second element that ensures safety and avoids wrap deformation is to place the gastric portion of the staple line against the neoesophagus, such that the tip of the gastric staple line sits adjacent to the middle suture of the fundoplication on the right side of the esophagus.

It has been shown that PEH repair has a relatively high incidence of recurrence (10 to 40%) when the crura is closed primarily with permanent suture. Recently, there has been an interest in using a biomaterial as a reinforcement of the standard crural closure. Randomized control studies have demonstrated a reduction in PEH recurrence rate when a synthetic mesh was used. However, the use of a nonabsorbable mesh at the hiatus is not universally accepted because of a potential risk of esophagus or gastric erosion and mesh infection. There is also a higher incidence of postoperative dysphagia when a nonabsorbable mesh is used, as it stimulates a more intense inflammatory reaction and subsequent fibrosis. The associated postoperative dysphagia may not be amenable to endoscopic dilatation. A biomaterial like the porcine small intestinal submucosa is an acellular xenograft consisting primarily of type I collagen. This biomaterial generally degrades rapidly intracorporeally and yet allows the remodeling tissue to be incorporated into the native tissue, providing a better tensile strength. A recent multicenter, prospective randomized study demonstrated that adding this type of mesh to the primarily closed hiatus in patients with PEH repair can result in a 2.5-fold reduction of hiatal hernia recurrence in 6 months in the absence of any mesh-related complication. This form of repair appears to be safe, but the long-term durability of this mesh-based reinforcement of the hiatus in PEH repair is yet to be validated.

ROLE OF FUNDOPLICATION IN GIANT HIATAL HERNIA REPAIR

Controversy remains as to whether to perform an antireflux procedure at all, in selected cases only, or in all patients. The case against an antireflux procedure rests on the frequency of significant postoperative complications secondary to the fundoplication, as well as the slightly longer operative time and increased cost that additional surgery entails. Most advocate the routine addition of an antireflux procedure following repair of the hernia defect. There are several reasons for this. Physiologic testing with 24-hour esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60 to 70% of patients with a paraesophageal hiatal hernia, nearly identical to the observed 71% incidence in patients with a sliding hiatal hernia. Furthermore, there is no relation between the symptoms experienced by the patient with a PEH and the competency of the cardia. Finally, dissection of the gastroesophageal esophagus may lead to postoperative reflux despite a negative preoperative pH score.

Results

Most outcome studies report relief of symptoms following surgical repair of PEHs in more than 90% of patients. The current literature suggests that laparoscopic repair of a paraesophageal hiatal hernia can be successful. Most authors report symptomatic improvement in 80 to 90% of patients, and <10 to 15% prevalence of recurrent hernia. However, the problem of recurrent hernia following PEH repair, open or laparoscopic, is becoming increasingly appreciated. Recurrent hiatal hernia is now the most common cause of anatomic failure following laparoscopic Nissen fundoplication done for GERD (5 to 10%), but this risk is compounded for the giant hernia where radiologic recurrence is detected in 25 to 40% of patients, when mesh is not used. It appears that optimal results with open or laparoscopic giant hiatal hernia repair should include options for mesh buttressing of hiatal closure and selective esophageal lengthening with one of the many techniques developed for the creation of a Collis gastroplasty.

SCHATZKI'S RING

Schatzki's ring is a thin submucosal circumferential ring in the lower esophagus at the squamocolumnar junction, often associated with a hiatal hernia. Its significance and pathogenesis are unclear (Fig. 25-45). The ring was first noted by Templeton, but Schatzki and Gary defined it as a distinct entity in 1953. Its prevalence varies from 0.2 to 14% in the general population, depending on the technique of diagnosis and the criteria used. Stiennon believed the ring to be a pleat of mucosa formed by infolding of redundant esophageal mucosa due to shortening of the esophagus. Others believe the ring to be congenital, and still others suggest it is an early stricture resulting from inflammation of the esophageal mucosa caused by chronic reflux.

Barium esophagogram showing Schatzki's ring (i.e., a thin circumferential ring in the distal esophagus at the squamocolumnar junction). Below the ring is a hiatal hernia.

Schatzki's ring is a distinct clinical entity having different symptoms, upper GI function studies, and response to treatment when compared with patients with a hiatal hernia, but without a ring. Twenty-four-hour esophageal pH monitoring has shown that patients with a Schatzki's ring have a lower incidence of reflux than hiatal hernia controls. They also have better LES function. This, together with the presence of a ring, could represent a protective mechanism to prevent gastroesophageal reflux.

Symptoms associated with Schatzki's ring are brief episodes of dysphagia during hurried ingestion of solid foods. Its treatment has varied from dilation alone to dilation with antireflux measures, antireflux procedure alone, incision, and even excision of the ring. Little is known about the natural progression of Schatzki's rings. Using radiologic techniques, Chen and colleagues showed progressive stenosis of rings in 59% of patients, whereas Schatzki found that the rings decreased in diameter in 29% of patients and remained unchanged in the rest.

Symptoms in patients with a ring are caused more by the presence of the ring than by gastroesophageal reflux. Most patients with a ring but without proven reflux respond to one dilation, while most patients with proven reflux require repeated dilations. In this regard, the majority of Schatzki's ring patients without proven reflux have a history of ingestion of drugs known to be damaging to the esophageal mucosa. Bonavina and associates have suggested drug-induced injury as the cause of stenosis in patients with a ring, but without a history of reflux. Because rings also occur in patients with proven reflux, it is likely that gastroesophageal reflux also plays a part. This is supported by the fact that there is less drug ingestion in the history of these patients. Schatzki's ring is probably an acquired lesion that can lead to stenosis from chemical-induced injury by pill lodgment in the distal esophagus, or from reflux-induced injury to the lower esophageal mucosa.

The best form of treatment of a symptomatic Schatzki's ring in patients who do not have reflux consists of esophageal dilation for relief of the obstructive symptoms. In patients with a ring who have proven reflux and a mechanically defective sphincter, an antireflux procedure is necessary to obtain relief and avoid repeated dilation.

SCLERODERMA

Scleroderma is a systemic disease accompanied by esophageal abnormalities in approximately 80% of patients. In most, the disease follows a prolonged course. Renal involvement occurs in a small percentage of patients and signals a poor prognosis. The onset of the disease is usually in the third or fourth decade of life, occurring twice as frequently in women as in men.

Small vessel inflammation appears to be an initiating event, with subsequent perivascular deposition of normal collagen, which may lead to vascular compromise. In the GI tract, the predominant feature is smooth muscle atrophy. Whether the atrophy in the esophageal musculature is a primary effect or occurs secondary to a neurogenic disorder is unknown. The results of pharmacologic and hormonal manipulation, with agents that act either indirectly via neural mechanisms or directly on the muscle, suggest that scleroderma is a primary neurogenic disorder. Methacholine, which acts directly on smooth muscle receptors, causes a similar increase in LES pressure in normal controls and in patients with scleroderma. Edrophonium, a cholinesterase inhibitor that enhances the effect of acetylcholine when given to patients with scleroderma, causes an increase in LES pressure that is less marked in these patients than in normal controls, suggesting a neurogenic rather than myogenic etiology. Muscle ischemia due to perivascular compression has been suggested as a possible mechanism for the motility abnormality in scleroderma. Others have observed that in the early stage of the disease, the manometric abnormalities may be reversed by reserpine, an agent that depletes catecholamines from the adrenergic system. This suggests that, in early scleroderma, an adrenergic overactivity may be present that causes a parasympathetic inhibition, supporting a neurogenic mechanism for the disease. In advanced disease manifested by smooth muscle atrophy and collagen deposition, reserpine no longer produces this reversal. Consequently, from a clinical perspective, the patient can be described as having a poor esophageal pump and a poor valve.

The diagnosis of scleroderma can be made manometrically by the observation of normal peristalsis in the proximal striated esophagus, with absent peristalsis in the distal smooth muscle portion (Fig. 25-46). The LES pressure is progressively weakened as the disease advances. Because many of the systemic sequelae of the disease may be nondiagnostic, the motility pattern is frequently used as a specific diagnostic indicator. Gastroesophageal reflux commonly occurs in patients with scleroderma, because they have both hypotensive sphincters and poor esophageal clearance. This combined defect can lead to severe esophagitis and stricture formation. The typical barium swallow shows a dilated, barium-filled esophagus, stomach, and duodenum, or a hiatal hernia with distal esophageal stricture and proximal dilatation (Fig. 25-47).

Traditionally, esophageal symptoms have been treated with PPIs, antacids, elevation of the head of the bed, and multiple dilations for strictures, with generally unsatisfactory results. The degree of esophagitis is usually severe and may lead to marked esophageal shortening as well as stricture. Scleroderma patients have frequently had numerous dilations before they are referred to the surgeon. The surgical management is somewhat controversial, but the majority of opinion suggests that a partial fundoplication (anterior or posterior) performed laparoscopically is the procedure of choice. The need for a partial fundoplication is dictated by the likelihood of severe dysphagia if a total fundoplication is performed in the presence of aperistalsis. Esophageal shortening may require a Collis gastroplasty in combination with a partial fundoplication. Surgery reduces esophageal acid exposure, but does not return it to normal because of the poor clearance function of the body of the esophagus. Only 50% of the patients have a good-to-excellent result. If the esophagitis is severe, or there has been a previous failed antireflux procedure and the disease is associated with delayed gastric emptying, a gastric resection with Roux-en-Y gastrojejunostomy has proved the best option.

MOTILITY DISORDERS OF THE PHARYNX AND ESOPHAGUS

Clinical Manifestations

Dysphagia (i.e., difficulty in swallowing) is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia, and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient's dietary history. It must be known whether the patient experiences pain, chokes, or vomits with eating; whether the patient requires liquids with the meal, is the last to finish, or is forced to interrupt or avoid a social meal; and whether he or she has been admitted to the hospital for food impaction. These assessments, plus an evaluation of the patient's nutritional status, help to determine how severe the dysphagia is and judge the need for surgical intervention, rather than more conservative (and usually less effective) methods of treating dysphagia.

Motility Disorders of the Pharyngoesophageal Segment

Disorders of the pharyngoesophageal phase of swallowing result from a discoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of the material from the oropharynx into the cervical esophagus. They can be categorized into one or a combination of the following abnormalities: (a) inadequate oropharyngeal bolus transport; (b) inability to pressurize the

pharynx; (c) inability to elevate the larynx; (d) discoordination of pharyngeal contraction and cricopharyngeal relaxation; and (e) decreased compliance of the pharyngoesophageal segment secondary to neuromuscular disease. The latter may result in incomplete anatomic relaxation of the cricopharyngeus and cervical esophagus.

Pharyngoesophageal swallowing disorders are usually congenital or due to acquired disease involving the central and peripheral nervous system. This includes cerebrovascular accidents, brain stem tumors, poliomyelitis, multiple sclerosis, Parkinson's disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Pure muscular diseases such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis are less common causes. Rarely, extrinsic compression by thyromegaly, cervical lymphadenopathy, or hyperostosis of the cervical spine can cause pharyngoesophageal dysphagia.

DIAGNOSTIC ASSESSMENT OF THE CRICOPHARYNGEAL SEGMENT

Abnormalities of pharyngoesophageal swallowing are difficult to assess with standard manometric techniques because of the rapidity of the oropharyngeal phase of swallowing, the elevation of the larynx, and the asymmetry of the cricopharyngeus. Video- or cineradiography is currently the most objective test to evaluate oropharyngeal bolus transport, pharyngeal compression, relaxation of the pharyngoesophageal segment, and the dynamics of airway protection during swallowing. It readily identifies a diverticulum (Fig. 25-48), stasis of the contrast medium in the valleculae, a cricopharyngeal bar, and/or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease, and result from the loss of muscle compliance in portions of the pharynx and esophagus composed of skeletal muscle.

A. Zenker's diverticulum, initially discovered 15 years ago and left untreated. **B.** Note its marked enlargement and evidence of laryngeal inlet aspiration on recent esophagogram. (Reproduced with permission from Waters PF, DeMeester TR: Foregut motor disorders and their surgical management. *Med Clin North Am* 65:1257, 1981. Copyright Elsevier.)

Careful analysis of video- or cineradiographic studies combined with manometry using specially designed catheters can identify the cause of a pharyngoesophageal dysfunction in most situations (Fig. 25-49). Motility studies may demonstrate inadequate pharyngeal pressurization, insufficient or lack of cricopharyngeal relaxation, marked discoordination of pharyngeal pressurization, cricopharyngeal relaxation and cervical esophageal contraction, or a hypopharyngeal bolus pressure suggesting decreased compliance of the skeletal portion of the cervical esophagus.

A. Schematic drawing of a pharyngeal pressure wave indicating the presence of the bolus pressure. **B.** Schematic drawing of the manometric recording typically seen during cricopharyngeal sphincter relaxation.

In many patients with cricopharyngeal dysfunction, including those with Zenker's diverticulum, it has been difficult to consistently demonstrate a motility abnormality or discoordination of pharyngoesophageal events. The abnormality most apt to be present is a loss of compliance in the pharyngoesophageal segment manifested by an increased bolus pressure. Cook and colleagues have demonstrated an increased resistance to the movement of a bolus through what appears on manometry to be a completely relaxed cricopharyngeal sphincter. Using simultaneous manometry and videofluoroscopy, they showed that, in these patients, the cricopharyngeus is only partially relaxed; that is, the sphincter is relaxed enough to allow a drop of its pressure to esophageal baseline on manometry, but insufficiently relaxed to allow unimpaired passage of the bolus into the esophagus. This incomplete relaxation is due to a loss of compliance of the muscle in the pharyngoesophageal segment, and may be associated with a cricopharyngeal bar or Zenker's diverticulum. This decreased compliance of the cricopharyngeal sphincter can be recognized on esophageal manometry by a "shoulder" on the pharyngeal pressure wave, the amplitude of which correlates directly with the degree of outflow obstruction (Fig. 25-50). Increasing the diameter of this noncompliant segment reduces the resistance imposed on the passage of a bolus. Consequently, patients with low pharyngeal pressure (i.e., poor piston function of the pharynx), or patients with increased resistance of the pharyngocervical esophageal segment from loss of skeletal muscle compliance, are improved by a pharyngocricocervical esophageal myotomy. This enlarges the pharyngoesophageal segment and reduces outflow resistance. Esophageal muscle biopsy specimens from patients with Zenker's diverticulum have shown histologic evidence of the restrictive myopathy in the pharyngoesophageal segment. These findings correlate well with the observation of a decreased compliance of the upper esophagus demonstrated by videoradiography and the findings on detailed manometric studies of the pharynx and cervical esophagus. They suggest that the diverticulum develops as a consequence of the outflow resistance to bolus transport through the noncompliant muscle of the pharyngoesophageal segment.

Pharyngeal shoulder pressures and diameter of the pharyngoesophageal segment in controls and patients with Zenker's diverticulum. UES = upper esophageal sphincter. (Data from Cook IJ, et al: Zenker's diverticulum: Evidence for a restrictive cricopharyngeal myopathy. *Gastroenterology* 96:A98, 1989.)

The requirements for a successful pharyngoesophageal myotomy are (a) adequate oropharyngeal bolus transport; (b) the presence of an intact swallowing reflex; (c) reasonable coordination of pharyngeal pressurization with cricopharyngeal relaxation; and (d) a cricopharyngeal bar, Zenker's diverticulum, or a narrowed pharyngoesophageal segment on videoesophagogram and/or the presence of excessive pharyngoesophageal shoulder pressure on motility study.

ZENKER'S DIVERTICULUM

In the past, the most common recognized sign of pharyngoesophageal dysfunction was the presence of a Zenker's diverticulum, originally described by Ludlow in 1769. The eponym resulted from Zenker's classic clinicopathologic descriptions of 34 cases published in 1878. Pharyngoesophageal diverticula have been reported to occur in 1 of 1000 routine barium examinations, and classically occur in elderly, white males. Zenker's diverticula tend to enlarge progressively with time due to the decreased compliance of the skeletal portion of the cervical esophagus that occurs with aging.

Presenting symptoms include dysphagia associated with the spontaneous regurgitation of undigested, bland material, often interrupting eating or drinking. On occasion, the dysphagia can be severe enough to cause debilitation and significant weight loss. Chronic aspiration and repetitive respiratory infection are common associated complaints. Once suspected, the diagnosis is established by a barium swallow. Endoscopy is usually difficult in the presence of a cricopharyngeal diverticulum, and potentially dangerous, owing to obstruction of the true esophageal lumen by the diverticulum and the attendant risk of diverticular perforation.

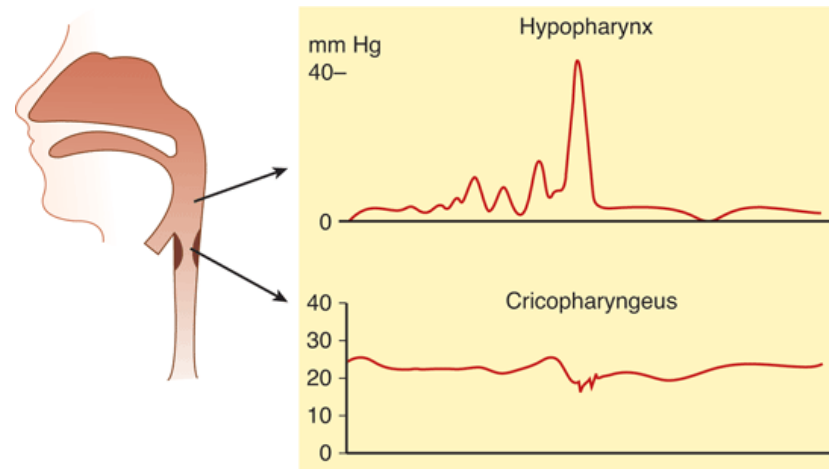

CRICOPHARYNGEAL MYOTOMY

The low morbidity and mortality associated with cricopharyngeal and upper esophageal myotomy have encouraged a liberal approach toward its use for almost any problem in the oropharyngeal phase of swallowing. This attitude has resulted in an overall success rate in the relief of symptoms of only 64%. When patients are selected for surgery using radiographic or motility markers of disease, a much higher proportion will benefit. Two methods of cricopharyngoesophageal myotomy are in common use, one using traditional surgical approaches, and one using rigid laryngoscopy and a linear cutting stapler.

OPEN CRICOPHARYNGEAL MYOTOMY, DIVERTICULOPEXY, AND DIVERTICULECTOMY

The myotomy can be performed under local or general anesthesia through an incision along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally, and the thyroid, trachea, and larynx medially (Fig. 25-51). When a pharyngoesophageal diverticulum is present, localization of the pharyngoesophageal segment is easy. The diverticulum is carefully freed from the overlying areolar tissue to expose its neck, just below the inferior pharyngeal constrictor and above the cricopharyngeus muscle. It can be difficult to identify the cricopharyngeus muscle in the absence of a diverticulum. A benefit of local anesthesia is that the patient can swallow and demonstrate an area of persistent narrowing at the pharyngoesophageal junction. Furthermore, before closing the incision, gelatin can be fed to the patient to ascertain whether the symptoms have been relieved, and to inspect the opening of the previously narrowed pharyngoesophageal segment. Under general anesthesia, and in the absence of a diverticulum, the placement of a nasogastric tube to the level of the manometrically determined cricopharyngeal sphincter helps in localization of the structures. The myotomy is extended cephalad by dividing 1 to 2 cm of inferior constrictor muscle of the pharynx, and caudad by dividing the cricopharyngeal muscle and the cervical esophagus for a length of 4 to 5 cm. The cervical wound is closed only when all oozing of blood has ceased, because a hematoma after this procedure is common, and is often associated with temporary dysphagia while the hematoma absorbs. Oral alimentation is started the day after surgery. The patient is usually discharged on the first or second postoperative day.

If a diverticulum is present and is large enough to persist after a myotomy, it may be sutured in the inverted position to the prevertebral fascia using a permanent suture (i.e., diverticulopexy) (Fig. 25-52). If the diverticulum is excessively large so that it would be redundant if suspended, or if its walls are thickened, a diverticulectomy should be performed. This is best performed under general anesthesia by placing a Maloney dilator (48F) in the esophagus, after controlling the neck of the diverticulum and after myotomy. A linear stapler is placed across the neck of the diverticulum and the diverticulum is excised distal to the staple line. The security of this staple line and effectiveness of the myotomy may be tested before hospital discharge with a water soluble contrast esophagogram. Postoperative complications include fistula formation, abscess, hematoma, recurrent nerve paralysis, difficulties in phonation, and Horner's syndrome. The incidence of the first two can be reduced by performing a diverticulopexy rather than diverticulectomy.

ENDOSCOPIC CRICOPHARYNGOTOMY

Endoscopic stapled cricopharyngotomy and diverticulotomy recently has been described. This procedure is most effective for larger diverticula (>2 cm), and may be impossible to perform for the small diverticulum. The procedure uses a specialized "diverticuloscope" with two retractable valves passed into the hypopharynx. The lips of the diverticuloscope are positioned so that one lip lies in the esophageal lumen and the other in the diverticular lumen. The valves of the diverticuloscope are retracted appropriately so as to visualize the septum interposed between the diverticulum and the esophagus. An endoscopic linear stapler is introduced into the diverticuloscope and positioned against the common septum with the anvil in the diverticulum and the cartridge in the esophageal lumen. Firing of the stapler divides the common septum between the posterior esophageal and the diverticular wall over a length of 30 mm, placing three rows of staples on each side. More than one stapler application may be needed, depending on the size of the diverticulum (Fig. 25-53). The patient is allowed to resume liquid feeds immediately, and is usually discharged the day after surgery. Complications are rare and may include perforation at the apex of the diverticulum, and failure to relieve dysphagia resulting from incomplete myotomy. The former complication can usually be treated with antibiotics, but may rarely require neck drainage.

The technique for transoral cricopharyngotomy and Zenker's diverticulotomy.

Recurrence of a Zenker's diverticulum occurs late, and is more common after diverticulectomy without myotomy, presumably due to persistence of the underlying loss of compliance of the cervical esophagus when a myotomy is not performed. After endoscopic cricopharyngotomy lateral residual "pouches" may be seen on radiographs, but are rarely responsible for residual or recurrent symptoms if the myotomy has been complete.

Postoperative motility studies have shown that the peak pharyngeal pressure generated on swallowing is not affected, the resting cricopharyngeal pressure is reduced but not eliminated, and the cricopharyngeal sphincter length is shortened. Consequently, after myotomy, there is protection against esophagopharyngeal regurgitation.

Motility Disorders of the Esophageal Body and Lower Esophageal Sphincter

Disorders of the esophageal phase of swallowing result from abnormalities in the propulsive pump action of the esophageal body or the relaxation of the LES. These disorders result from either primary esophageal abnormalities, or from generalized neural, muscular, or collagen vascular disease (Table 25-9). The use of standard and high-resolution esophageal manometry techniques has allowed specific primary esophageal motility disorders to be identified out of a pool of nonspecific motility abnormalities. Primary esophageal motor disorders include achalasia, DES, nutcracker esophagus, and the hypertensive LES. The manometric characteristics of these disorders are shown in Table 25-10.

Table 25-9 Esophageal Motility Disorders

Primary esophageal motility disorders

Achalasia, "vigorous" achalasia

Diffuse and segmental esophageal spasm

Nutcracker esophagus

Hypertensive lower esophageal sphincter
Nonspecific esophageal motility disorders
Secondary esophageal motility disorders
Collagen vascular diseases: progressive systemic sclerosis, polymyositis and dermatomyositis, mixed connective tissue disease, systemic lupus erythematosus, et al
Chronic idiopathic intestinal pseudo-obstruction
Neuromuscular diseases
Endocrine and metastatic disorders

Table 25-10 Manometric Characteristics of the Primary Esophageal Motility Disorders
Achalasia
Incomplete lower esophageal sphincter (LES) relaxation (<75% relaxation)
Aperistalsis in the esophageal body
Elevated LES pressure ≥ 26 mmHg
Increased intraesophageal baseline pressures relative to gastric baseline
Diffuse esophageal spasm (DES)
Simultaneous (nonperistaltic contractions) (>20% of wet swallows)
Repetitive and multipeaked contractions
Spontaneous contractions
Intermittent normal peristalsis
Contractions may be of increased amplitude and duration
Nutcracker esophagus
Mean peristaltic amplitude (10 wet swallows) in distal esophagus ≥ 180 mmHg
Increased mean duration of contractions (>7.0 s)
Normal peristaltic sequence
Hypertensive lower esophageal sphincter
Elevated LES pressure (≥ 26 mmHg)
Normal LES relaxation
Normal peristalsis in the esophageal body
Ineffective esophageal motility disorders
Decreased or absent amplitude of esophageal peristalsis (<30 mmHg)
Increased number of nontransmitted contractions

Source: Reproduced with permission from DeMeester TR, et al: Physiologic diagnostic studies, in Zuidema GD, Orringer MB (eds): *Shackelford's Surgery of the Alimentary Tract*, 3rd ed, Vol. 1. Philadelphia: W.B. Saunders, 1991, p 115. Copyright Elsevier.

The boundaries between the primary esophageal motor disorders are vague, and intermediate types exist, some of which may combine more than one type of motility pattern. These findings indicate that esophageal motility disorders should be looked at as a spectrum of abnormalities that reflects various stages of destruction of esophageal motor function.

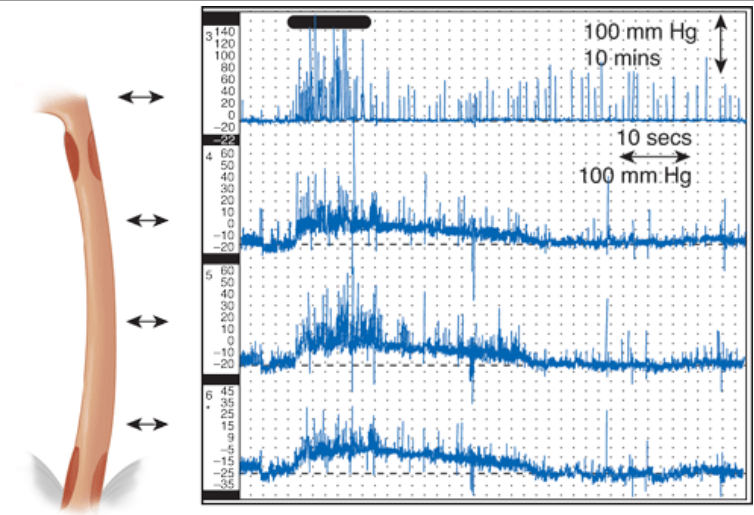

ACHALASIA

The best known and best understood primary motility disorder of the esophagus is achalasia, with an incidence of six per 100,000 population per year. Although complete absence of peristalsis in the esophageal body has been proposed as the major abnormality, present evidence indicates achalasia is a primary disorder of the LES. This is based on 24-hour outpatient esophageal motility monitoring, which shows that, even in advanced disease, up to 5% of contractions can be peristaltic. Simultaneous esophageal waves develop as a result of the increased resistance to esophageal emptying caused by the nonrelaxing LES. This conclusion is supported by experimental studies in which a band placed loosely around the GEJ in experimental models did not change sphincter pressures, but resulted in impaired relaxation of the LES and outflow resistance. This led to a markedly increased frequency of simultaneous waveforms and a decrease in contraction amplitude. The changes were associated with radiographic dilation of the esophagus and were reversible after removal of the band. Observations in patients with pseudoachalasia due to tumor infiltration, a tight stricture in the distal esophagus, or an antireflux

procedure that is too tight also provide evidence that dysfunction of the esophageal body can be caused by the increased outflow obstruction of a nonrelaxing LES. The observation that esophageal peristalsis can return in patients with classic achalasia following dilation or myotomy provides further support that achalasia is a primary disease of the LES.

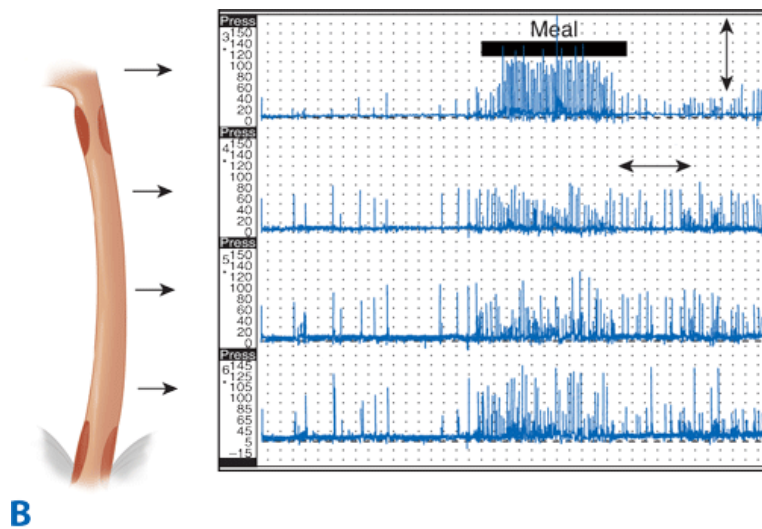

The pathogenesis of achalasia is presumed to be a neurogenic degeneration, which is either idiopathic or due to infection. In experimental animals, the disease has been reproduced by destruction of the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve. In patients with the disease, degenerative changes have been shown in the vagus nerve and in the ganglia in the myenteric plexus of the esophagus itself. This degeneration results in hypertension of the LES, a failure of the sphincter to relax on swallowing, elevation of intraluminal esophageal pressure, esophageal dilatation, and a subsequent loss of progressive peristalsis in the body of the esophagus. The esophageal dilatation results from the combination of a nonrelaxing sphincter, which causes a functional retention of ingested material in the esophagus, and elevation of intraluminal pressure from repetitive pharyngeal air swallowing (Fig. 25-54). With time, the functional disorder results in anatomic alterations seen on radiographic studies, such as a dilated esophagus with a tapering, "bird's beak"-like narrowing of the distal end (Fig. 25-55). There is usually an air-fluid level in the esophagus from the retained food and saliva, the height of which reflects the degree of resistance imposed by the nonrelaxing sphincter. As the disease progresses, the esophagus becomes massively dilated and tortuous.

A subgroup of patients with otherwise typical features of classic achalasia has simultaneous contractions of their esophageal body that can be of high amplitude. This manometric pattern has been termed *vigorous achalasia*, and chest pain episodes are a common finding in these patients. Differentiation of vigorous achalasia from DES can be difficult. In both diseases, videoradiographic examination may show a corkscrew deformity of the esophagus and diverticulum formation.

DIFFUSE AND SEGMENTAL ESOPHAGEAL SPASM

DES is characterized by substernal chest pain and/or dysphagia. DES differs from classic achalasia in that it is primarily a disease of the esophageal body, produces a lesser degree of dysphagia, causes more chest pain, and has less effect on the patient's general condition. Nonetheless, it is impossible to differentiate achalasia from DES on the basis of symptoms alone. Esophagogram and esophageal manometry are required to distinguish these two entities. True symptomatic DES is a rare condition, occurring about five times less frequently than achalasia.

The causation and neuromuscular pathophysiology of DES are unclear. The basic motor abnormality is rapid wave progression down the esophagus secondary to an abnormality in the latency gradient. Hypertrophy of the muscular layer of the esophageal wall and degeneration of the esophageal branches of the vagus nerve have been observed in this disease, although these are not constant findings. Manometric abnormalities in DES may be present over the total length of the esophageal body, but usually are confined to the distal two thirds. In *segmental esophageal spasm*, the manometric abnormalities are confined to a short segment of the esophagus.

The classic manometric findings in these patients are characterized by the frequent occurrence of simultaneous waveforms and multi peaked esophageal contractions, which may be of abnormally high amplitude or long duration. Key to the diagnosis of DES is that there remain some peristaltic waveforms in excess of those seen in achalasia. A criterion of 30% or more peristaltic waveforms out of 10 wet swallows has been used to differentiate DES from vigorous achalasia. However, this figure is arbitrary and often debated.

The LES in patients with DES usually shows a normal resting pressure and relaxation on swallowing. A hypertensive sphincter with poor relaxation may also be present. In patients with advanced disease, the radiographic appearance of tertiary contractions appears helical, and has been termed *corkscrew esophagus* or *pseudodiverticulosis* (Fig. 25-56). Patients with segmental or diffuse esophageal spasm can compartmentalize the esophagus and develop an epiphrenic or midesophageal diverticulum between two areas of high pressure occurring simultaneously (Fig. 25-57).

NUTCRACKER ESOPHAGUS

The disorder, termed *nutcracker* or *supersqueezer esophagus*, was recognized in the late 1970s. Other terms used to describe this entity are *hypertensive peristalsis* or *high-amplitude peristaltic contractions*. It is the most common of the primary esophageal motility disorders. By definition the so-called *nutcracker esophagus* is a manometric abnormality in patients who are characterized by peristaltic esophageal contractions with peak amplitudes greater than two SDs above the normal values in individual laboratories. Contraction amplitudes in these patients can easily be above 400 mmHg. At the lower end of peak pressure, it is unclear whether nutcracker esophagus causes any symptoms. In fact, chest pain symptoms in nutcracker esophagus patients may be related to GERD rather than intraluminal hypertension. Treatment in these patients should be aimed at the treatment of GERD. At the high end (peak pressures >300 mmHg) chest pain may be the result of the nutcracker physiology, as treatment directed at reducing intraluminal pressure is more effective than when used for those with lower peak pressures.

HYPERTENSIVE LOWER ESOPHAGEAL SPHINCTER

Hypertensive LES in patients with chest pain or dysphagia was first described as a separate entity by Code and associates. This disorder is characterized by an elevated basal pressure of the LES with normal relaxation and normal propulsion in the esophageal body. About one half of these patients, however, have associated motility disorders of the esophageal body, particularly hypertensive peristalsis and simultaneous waveforms. In the remainder, the disorder exists as an isolated abnormality. Dysphagia in these patients may be caused by a lack of compliance of the sphincter, even in its relaxed state. Myotomy of the LES may be indicated in patients not responding to medical therapy or dilation.

SECONDARY ESOPHAGEAL MOTILITY DISORDERS

Connective tissue disease, particularly scleroderma and the CREST syndrome, exhibits severe esophageal motility disorders. Additionally, patients treated as infants for esophageal atresia will often develop secondary motility disorders manifest later in life. Symptoms of these disorders are heartburn and dysphagia. The latter may be a result of a peptic stricture rather than the esophageal dysmotility. An esophageal motility study will usually show severely reduced or absent peristalsis with severely reduced or absent LES pressure. The role of antireflux surgery in these conditions is controversial, but, if performed, should be limited to partial fundoplication, as full (Nissen) fundoplication may result in severe dysphagia.

NONSPECIFIC ESOPHAGEAL MOTOR DISORDERS AND INEFFECTIVE ESOPHAGEAL MOTILITY

Many patients complaining of dysphagia or chest pain of noncardiac origin demonstrate a variety of wave patterns and contraction amplitudes on esophageal manometry that are clearly out of the normal range, but do not meet the criteria of a primary esophageal motility disorder. Esophageal motility in these patients frequently shows an increased number of multi peaked or repetitive contractions, contractions of prolonged duration, nontransmitted contractions, an interruption of a peristaltic wave at various levels of the esophagus, or contractions of low amplitude. These motility abnormalities have been termed *nonspecific esophageal motility disorders*. Their significance in the causation of chest pain or dysphagia is still unclear. Surgery plays no role in the treatment of these disorders unless there is an associated diverticulum.

A clear distinction between primary esophageal motility disorders and nonspecific esophageal motility disorders is often not possible. Patients diagnosed as having nonspecific esophageal motility abnormalities on repeated studies will occasionally show abnormalities consistent with nutcracker esophagus. Similarly, progression from a nonspecific esophageal motility disorder to classic DES has been demonstrated. Therefore, the finding of a nonspecific esophageal motility disorder may represent only a manometric marker of an intermittent, more severe esophageal motor abnormality. Combined ambulatory 24-hour esophageal pH and motility monitoring has shown that an increased esophageal exposure to gastric juice is common in patients diagnosed as having a nonspecific esophageal motility disorder. In some situations, the motor abnormalities may be induced by the irritation of refluxed gastric juice; in other situations, it may be a primary event unrelated to the presence of reflux. High-amplitude peristalsis (nutcracker esophagus) and low-amplitude peristalsis (ineffective esophageal motility) are frequently associated with GERD.

DIVERTICULA OF THE ESOPHAGEAL BODY

Diverticula of the esophagus may be characterized by their location in the esophagus (proximal, mid-, or distal esophagus), or by the nature of concomitant pathology. Diverticula associated with motor disorders are termed *pulsion diverticula* and those associated with inflammatory conditions are termed *traction diverticula*. Pulsion diverticula occur most commonly with nonspecific motility disorders, but can occur with all of the primary motility disorders. In the latter situation, the motility disorder is usually diagnosed before the development of the diverticulum. When associated with achalasia, the development of a diverticulum may temporarily alleviate the symptom of dysphagia by becoming a receptacle for ingested food, and substitute the symptom of dysphagia for postprandial pain and regurgitation of undigested food. If a motility abnormality of the esophageal body or LES cannot be identified, a traction or congenital cause for the diverticulum should be considered.

Because development in radiology preceded development in motility monitoring, diverticula of the esophagus were considered historically to be a primary abnormality, the cause, rather than the consequence, of motility disorders. Consequently, earlier texts focused on them as specific entities based upon their location.

Epiphrenic diverticula arise from the terminal third of the thoracic esophagus and are usually found adjacent to the diaphragm. They have been associated with distal esophageal muscular hypertrophy, esophageal motility abnormalities, and increased luminal pressure. They are "pulsion" diverticula, and are associated with diffuse spasm, achalasia, or nonspecific motor abnormalities in the body of the esophagus.

Whether the diverticulum should be surgically resected or suspended depends on its size and proximity to the vertebral body. When diverticula are associated with esophageal motility disorders, esophageal myotomy from the distal extent of the diverticulum to the stomach should be combined with diverticulectomy. If diverticulectomy alone is performed, one can expect a high incidence of suture line rupture due to the same intraluminal pressure that initially gave rise to the diverticulum. If the diverticulum is suspended to the prevertebral fascia of the thoracic vertebra, a myotomy is begun at the neck of the diverticulum and extended across the LES. If the diverticulum is excised by dividing the neck, the muscle is closed over the excision site and a myotomy is performed on the opposite esophageal wall, starting at the level of diverticulum. If complete, the myotomy will cross the LES, reducing distal esophageal peak pressure, and will increase the likelihood that dysphagia will be replaced with GERD symptoms. Increasingly, partial fundoplication (anterior or posterior) is performed after LES myotomy to decrease the frequency of disabling GERD developing after myotomy and diverticulectomy. When a large diverticulum is associated with a hiatal hernia, then hiatal hernia repair is added. All these procedures may be performed with traditional or minimally invasive techniques.

Midesophageal or traction diverticula were first described in the nineteenth century (Fig. 25-58). At that time, they were frequently noted in patients who had mediastinal LN involvement with tuberculosis. It was theorized that adhesions formed between the inflamed mediastinal nodes and the esophagus. By contraction, the adhesions exerted traction on the esophageal wall and led to a localized diverticulum (Fig. 25-59). This theory was based on the findings of early dissections, where adhesions between diverticula and LNs were commonly found. Other conditions associated with mediastinal lymphadenopathy, such as pulmonary fungal infections (e.g., aspergillosis), lymphoma, or sarcoid, may create traction esophageal diverticula after successful treatment. Rarely, when no underlying inflammatory pathology is identified, a motility disorder may be identified.

Illustration of the pathophysiology of mid-esophageal diverticulum showing traction on the esophageal wall from adhesions to inflamed subcarinal lymph nodes.

Most mid-esophageal diverticula are asymptomatic and incidentally discovered during investigation for non-esophageal complaints. In such patients, the radiologic abnormality may be ignored. Patients with symptoms of dysphagia, regurgitation, chest pain, or aspiration, in whom a diverticulum is discovered, should be thoroughly investigated for an esophageal motor abnormality. Occasionally, a patient will present with a bronchoesophageal fistula manifested by a chronic cough on ingestion of meals. The diverticulum in such patients is most likely to have an inflammatory etiology.

The indication for surgical intervention is dictated by the degree of symptomatic disability. Usually, mid-esophageal diverticula can be suspended due to their proximity to the spine. If a motor abnormality is documented, a myotomy should be performed as described for an epiphrenic diverticulum.

OPERATIONS FOR ESOPHAGEAL MOTOR DISORDERS AND DIVERTICULA

Long Esophageal Myotomy for Motor Disorders of the Esophageal Body

A long esophageal myotomy is indicated for dysphagia caused by any motor disorder characterized by segmental or generalized simultaneous waveforms in a patient whose symptoms are not relieved by medical therapy. Such disorders include diffuse and segmental esophageal spasm, vigorous achalasia, and nonspecific motility disorders associated with a mid- or epiphrenic esophageal diverticulum. However, the decision to operate must be made by a balanced evaluation of the patient's symptoms, diet, lifestyle adjustments, and nutritional status, with the most important factor being the possibility of improving the patient's swallowing disability. The symptom of chest pain alone is not an indication for a surgical procedure.

The identification of patients with symptoms of dysphagia and chest pain who might benefit from a surgical myotomy is difficult. Ambulatory motility studies have shown that when the prevalence of "effective contractions" (i.e., peristaltic waveforms consisting of contractions with an amplitude above 30 mmHg) drops below 50% during meals, the patient is likely to experience dysphagia (Fig. 25-60). This would suggest that relief from the symptom can be expected with an improvement of esophageal contraction amplitude or amelioration of nonperistaltic waveforms. Prokinetic agents may increase esophageal contraction amplitude, but do not alter the prevalence of simultaneous waveforms. Patients in whom the efficacy of esophageal propulsion is severely compromised because of a high prevalence of simultaneous waveforms usually receive little benefit from medical therapy. In these patients, a surgical myotomy of the esophageal body can improve the patients' dysphagia, provided the loss of contraction amplitude in the remaining peristaltic waveforms, caused by the myotomy, has less effect on swallowing function than the presence of the excessive simultaneous contractions. This situation is reached when the prevalence of effective waveforms during meals drops below 30%, (i.e., 70% of esophageal waveforms are ineffective).

Fig. 25-60.

Prevalence of effective contractions, (i.e., peristaltic contractions with an amplitude >30 mmHg) during meal periods in individual normal volunteers, patients (Pat) without dysphagia, and patients with nonobstructive dysphagia.

In patients selected for surgery, preoperative manometry is essential to determine the proximal extent of the esophageal myotomy. Most surgeons extend the myotomy distally across the LES to reduce outflow resistance. Consequently, some form of antireflux protection is needed to avoid gastroesophageal reflux if there has been extensive dissection of the cardia. In this situation, most authors prefer a partial, rather than a full, fundoplication, in order not to add back-resistance that will further interfere with the ability of the myotomized esophagus to empty (Fig. 25-61). If the symptoms of reflux are present preoperatively, 24-hour pH monitoring is required to confirm its presence.

Fig. 25-61.

Esophageal (Eso.) diameter, dysphagia, and esophageal retention in patients with achalasia treated with myotomy and Nissen fundoplication, 10 years after treatment (Rx).
(Based on Topart P, et al: Long-term effect of total fundoplication on the myotomized esophagus. *Ann Thorac Surg* 54:1046, 1992.)

The procedure may be performed either open or via thoracoscopy. The open technique is performed through a left thoracotomy in the sixth intercostal space (Fig. 25-62). An incision is made in the posterior mediastinal pleura over the esophagus, and the left lateral wall of the esophagus is exposed. The esophagus is not circumferentially dissected unless necessary. A 2-cm incision is made into the abdomen

through the parietal peritoneum at the midportion of the left crus. A tongue of gastric fundus is pulled into the chest. This exposes the GEJ and its associated fat pad. The latter is excised to give a clear view of the junction. A myotomy is performed through all muscle layers, extending distally over the stomach 1 to 2 cm below the GEJ, and proximally on the esophagus over the distance of the manometric abnormality. The muscle layer is dissected from the mucosa laterally for a distance of 1 cm. Care is taken to divide all minute muscle bands, particularly in the area of the GEJ. The gastric fundic tongue is sutured to the margins of the myotomy over a distance of 3 to 4 cm and replaced into the abdomen. This maintains separation of the muscle and acts as a partial fundoplication to prevent reflux.

Technique of long myotomy: **A.** Exposure of the lower esophagus through the left sixth intercostal space and incision of the mediastinal pleura in preparation for surgical myotomy. **B.** Location of a 2-cm incision made through the phrenoesophageal membrane into the abdomen along the midlateral border of the left crus. **C.** Retraction of tongue of gastric fundus into the chest through the previously made incision. **D.** Removal of the gastroesophageal fat pad to expose the gastroesophageal junction. **E.** A myotomy down to the mucosa is started on the esophageal body. **F.** Completed myotomy extending over the stomach for 1 cm. **G.** Reconstruction of the cardia after a myotomy, illustrating the position of the sutures used to stitch the gastric fundic flap to the margins of the myotomy. **H.** Reconstruction of the cardia after a myotomy, illustrating the intra-abdominal position of the gastric tongue covering the distal 4 cm of the myotomy.

If an epiphrenic diverticulum is present, it is excised by dividing the neck with a stapler sized for the thickness of the diverticulum (2.0- to 4.8-mm staple leg length) followed by a closure of the muscle over the staple line, when possible. The myotomy is then performed on the opposite esophageal wall. If a midesophageal diverticulum is present, the myotomy is made so that it includes the muscle around the neck, and the diverticulum is suspended by attaching it to the paravertebral fascia of the thoracic vertebra above the level of the diverticular neck. Before performing any operation for an esophageal diverticulum, it is wise to endoscope the patient to wash all food and other debris from the diverticulum.

The results of myotomy for motor disorders of the esophageal body have improved in parallel with the improved preoperative diagnosis afforded by manometry. Previous published series report between 40 and 92% improvement of symptoms, but interpretation is difficult due to the small number of patients involved and the varying criteria for diagnosis of the primary motor abnormality. When myotomy is accurately done, 93% of the patients have effective palliation of dysphagia after a mean follow-up of 5 years, and 89% would have the procedure again, if it was necessary. Most patients gain or maintain rather than lose weight after the operation. Postoperative motility studies show that the myotomy reduces the amplitude of esophageal contractions to near zero and eliminates simultaneous peristaltic waves. If the benefit of obliterating the simultaneous waves exceeds the adverse effect on bolus propulsion caused by the loss of peristaltic waveforms, the patient's dysphagia is likely to be improved by the procedure. If not, the patient is likely to continue to complain of dysphagia and to have little improvement as a result of the operation.

The thoracoscopic technique is complicated by the fact that it requires complete retraction of the lung anteriorly to expose the esophagus. Proper positioning of the patient is critical to achieving this exposure. A prone position is ideal, allowing the left lung to fall forward away from the esophagus. Because of the possibility of open thoracotomy, however, it is best to place the patient in the right lateral decubitus position with the left thorax up, and then to roll the patient anteriorly 45° toward prone. A beanbag secured to the table is used to hold the patient. The table can be rotated a further 30 to 40° so that the patient ends up nearly prone. Should thoracotomy become necessary, the table can be rotated back to the horizontal position and a thoracotomy performed without difficulty. Prone positioning is the key element in providing exposure for long myotomy. Four thoracoscopic ports in the left chest are used. With suitable lung retraction, the myotomy is performed through all esophageal muscle layers, extending distally to the endoscopic GEJ, and proximally over the distance of the manometric abnormality.

Few reports exist concerning the minimally invasive technique for performing long esophageal myotomy. Cuschieri has reported a preliminary experience with a thoracoscopically performed long esophageal myotomy for the treatment of nutcracker esophagus. Three patients with symptoms of chest pain and high-amplitude esophageal contractions and peristaltic waveforms were operated on. No major morbidity was encountered. Nasogastric tubes were removed the first postoperative day and oral feeding was started on the second postoperative day. Two patients were discharged on postoperative day 4 and one patient on day 5. All had symptomatic relief on short-term follow-up.

Epiphrenic diverticula are more frequently addressed with laparoscopic access, in combination with a laparoscopic division of the LES (Heller myotomy) (Fig. 25-63). If the diverticulum can be completely mobilized through the hiatus, it may be safely excised from below. The neck of the diverticulum is transected with a GIA stapler after passage of a 48F dilator. Not infrequently, the diverticulum is sufficiently large that access to the neck of the diverticulum across the hiatus is quite difficult. Additionally, the inflammatory reaction to the diverticulum may further make the transhiatal dissection difficult. Under these circumstances, it is safer to perform the diverticulectomy through a right thoracoscopic approach either at the time of the initial procedure or at a later date, depending upon the frailty of the patient. Following diverticulectomy, it is critical that the esophageal staple line be treated with a great deal of care. Closure of the muscle over the staple line is preferable. Additionally, the patient kept NPO for 3 to 5 days and obtained a contrast study before initiating clear liquids. Solid foods are withheld for 2 weeks to decrease the likelihood of staple line leak. Buttressing or sealing the staple line with fibrin glue is also an attractive option.

Myotomy of the Lower Esophageal Sphincter (Heller Myotomy)

Second only to reflux disease, achalasia is the most common functional disorder of the esophagus to require surgical intervention. The goal of treatment is to relieve the functional outflow obstruction secondary to the loss of relaxation and compliance of the LES. This requires disrupting the LES muscle. When performed adequately (i.e., reducing sphincter pressure to <10 mmHg), and done early in the course of disease, LES myotomy results in symptomatic improvement with the occasional return of esophageal peristalsis. Reduction in LES resistance can be accomplished intraluminally by hydrostatic balloon dilation, which ruptures the sphincter muscle, by botulinum toxin injection, or by a surgical myotomy that cuts the sphincter. The difference between these three methods appears to be the greater likelihood of reducing sphincter pressure to <10 mmHg by surgical myotomy as compared with hydrostatic balloon dilation. However, patients whose sphincter pressure has been reduced by hydrostatic balloon dilation to <10 mmHg have an outcome similar to those after surgical myotomy (Fig. 25-64). Botulinum toxin injection may achieve similar results, but has a duration of action that may be measured in weeks or months, rather than years. Botulinum toxin injection may best be used as a diagnostic tool, when it is not clear whether a hypertensive LES is the primary cause of dysphagia. Responsiveness to botulinum toxin injection may predict a good response to Heller myotomy.

Prevalence of clinical remission in 122 patients stratified according to postdilatation lower esophageal sphincter (LES) pressures greater than or <10 mmHg.

(Reproduced with permission from Ponce J, Garrigues V, Pertejo V, et al: Individual prediction of response to pneumatic dilation in patients with achalasia. *Dig Dis Sci* 41:2138, 1996. With kind permission from Springer Science+Business Media.)

The therapeutic decisions regarding the treatment of patients with achalasia center around four issues. The first issue is the question of whether newly diagnosed patients should be treated with pneumatic dilation or a surgical myotomy. Long-term follow-up studies have shown that pneumatic dilation achieves adequate relief of dysphagia and pharyngeal regurgitation in 50 to 60% of patients (Fig. 25-65). Close follow-up is required, and if dilation fails, myotomy is indicated. For those patients who have a dilated and tortuous esophagus or an associated hiatal hernia, balloon dilation is dangerous and surgery is the better option. The outcome of the one controlled randomized study (38 patients) comparing the two modes of therapy suggests that surgical myotomy as a primary treatment gives better long-term results. Several randomized trials comparing laparoscopic cardiomyotomy with balloon dilation or botulinum toxin injection have favored the surgical approach as well. Although it has been reported that a myotomy after previous balloon dilation is more difficult, this has not been the experience of these authors unless the cardia has been ruptured in a sawtooth manner. In this situation, operative intervention, either immediately or after healing has occurred, can be difficult. Similarly, myotomy after botulinum toxin injection has reported to be more difficult, but this is largely a function of the submucosal inflammatory response, which may be a bit unpredictable, and is most intense in the first 6 to 12 weeks after injection. It is important to wait at least 3 months after botulinum toxin injection to perform cardiomyotomy to minimize the risk of encountering dense inflammation.

The second issue is the question of whether a surgical myotomy should be performed through the abdomen or the chest. Myotomy of the LES can be accomplished via either an abdominal or thoracic approach. In the absence of a previous upper abdominal surgery, most surgeons prefer the abdominal approach to LES myotomy as laparoscopy results in less pain and a shorter length of stay than thoracoscopy. In addition, it is a bit easier to assure a long gastric myotomy when the approach is transabdominal.

The third issue—and one that has been long debated—is the question of whether an antireflux procedure should be added to a surgical myotomy. Excellent results have been reported following meticulously performed myotomy without an antireflux component. Retrospective studies, with long-term follow-up of large cohorts of patients undergoing Heller myotomy demonstrated that, after 10 years, more than 50% of patients had reflux symptoms without a fundoplication. In a recent randomized clinical trial, 7% of patients undergoing Dor fundoplication following LES myotomy had abnormal 24-hour pH probes, and 42% of patients with a myotomy only had abnormal reflux profiles. If an antireflux procedure is used as an adjunct to esophageal myotomy, a complete 360° fundoplication should be avoided. Rather, a 270° Belsey fundoplication, a Toupet posterior 180° fundoplication, or a Dor anterior 180° fundoplication should be used to avoid the long-term esophageal dysfunction secondary to the outflow obstruction afforded by the fundoplication itself.

The fourth issue centers on whether or not a cure of this disease is achievable. Long-term follow-up studies after surgical myotomy have shown that late deterioration in results occurs after this procedure, regardless of whether an antireflux procedure is done, and also after balloon dilation, even when the sphincter pressure is reduced to below 10 mmHg. It may be that, even though a myotomy or balloon rupture of the LES muscle reduces the outflow obstruction at the cardia, the underlying motor disorder in the body of the esophagus persists and deteriorates further with the passage of time, leading to increased impairment of esophageal emptying. The earlier an effective reduction in outflow resistance can be accomplished, the better the outcome will be, and the more likely some esophageal body function can be restored.

In performing a surgical myotomy of the LES, there are four important principles: (a) complete division of all circular and collar-sling muscle fibers, (b) adequate distal myotomy to reduce outflow resistance, (c) "undermining" of the muscularis to allow wide separation of the esophageal muscle, and (d) prevention of postoperative reflux. In the past, the drawback of a surgical myotomy was the need for an open procedure, which often deterred patients from choosing the best treatment option for achalasia. With the advent of minimally invasive surgical techniques two decades ago, laparoscopic cardiomyotomy (Heller myotomy) has become the treatment of choice for most patients with achalasia.

Open Esophageal Myotomy

Open techniques of distal esophageal myotomy are rarely used outside of reoperations. Primary procedures can almost always be successfully completed via laparoscopy. A modified Heller myotomy can be performed through a left thoracotomy incision in the sixth intercostal space along the upper border of the seventh rib. The esophagus and a tongue of gastric fundus are exposed as described for a long myotomy. A myotomy through all muscle layers is performed, extending distally over the stomach to 1 to 2 cm below the junction, and proximally on the esophagus for 4 to 5 cm. The cardia is reconstructed by suturing the tongue of gastric fundus to the margins of the myotomy, to prevent rehealing of the myotomy site, and to provide reflux protection in the area of the divided sphincter. If an extensive dissection of the cardia has been done, a more formal Belsey repair is performed. The tongue of gastric fundus is allowed to retract into the abdomen. Traditionally, nasogastric drainage is maintained for 6 days to prevent distention of the stomach during healing. An oral diet is resumed on the seventh day, after a barium swallow study shows unobstructed passage of the bolus into the stomach without extravasation.

In a randomized, long-term follow-up by Csendes and colleagues of 81 patients treated for achalasia, either by forceful dilation or by surgical myotomy, myotomy was associated with a significant increase in the diameter at the GEJ and a decrease in the diameter at the middle third of the esophagus on follow-up radiographic studies. There was a greater reduction in sphincter pressure and improvement in the amplitude of esophageal contractions after myotomy. Thirteen percent of patients regained some peristalsis after dilation, compared with 28% after surgery. These findings were shown to persist over a 5-year follow-up period, at which time 95% of those treated with surgical myotomy were doing well. Of those who were treated with dilation, only 54% were doing well, while 16% required redilation and 22% eventually required surgical myotomy to obtain relief.

If simultaneous esophageal contractions are associated with the sphincter abnormality, the so-called *vigorous achalasia*, then the myotomy should extend over the distance of the abnormal motility as mapped by the preoperative motility study. Failure to do this will result in continuing dysphagia and a dissatisfied patient. The best objective evaluation of improvement in the patient following either balloon

dilation or myotomy is a scintigraphic measurement of esophageal emptying time. A good therapeutic response improves esophageal emptying toward normal. However, some degree of dysphagia may persist despite improved esophageal emptying, due to disturbances in esophageal body function. When an antireflux procedure is added to the myotomy, it should be a partial fundoplication. A 360° fundoplication is associated with progressive retention of swallowed food, regurgitation, and aspiration to a degree that exceeds the patient's preoperative symptoms.

Laparoscopic Cardiomyotomy

More commonly known as a *laparoscopic Heller myotomy*, after Ernst Heller, a German surgeon who described a "double myotomy" in 1913, the laparoscopic approach is similar to the Nissen fundoplication in terms of the trocar placement and exposure and dissection of the esophageal hiatus (Fig. 25-66). The procedure begins by division of the short gastric vessels in preparation for fundoplication. Exposure of the GEJ via removal of the gastroesophageal fat pad follows. The anterior vagus nerve is swept right laterally along with the fat pad. Once completed, the GEJ and distal 4 to 5 cm of esophagus should be bared of any overlying tissue, and generally follows dissection of the GEJ. A distal esophageal myotomy is performed. It is generally easiest to begin the myotomy 1 to 2 cm above the GEJ, in an area above that of previous botulinum toxin injections or balloon dilation. Either scissors or a hook-type electrocautery can be used to initiate the incision in the longitudinal and circular muscle. Distally, the myotomy is carried across the GEJ and onto the proximal stomach for approximately 2 to 3 cm. After completion, the muscle edges are separated bluntly from the esophageal mucosa for approximately 50% of the esophageal circumference. An antireflux procedure follows completion of the myotomy. Either an anterior hemifundoplication augmenting the angle of His (Dor) or posterior partial fundoplication (Toupet) can be performed. The Dor type fundoplication is slightly easier to perform, and does not require disruption of the normal posterior gastroesophageal attachments (a theoretical advantage in preventing postoperative reflux).

A. Longitudinal muscle is divided. **B.** Mechanical disruption of lower esophageal sphincter muscle fibers. **C.** Myotomy must be carried across gastroesophageal junction. **D.** Gastric extension should equal 2 to 3 cm. **E.** Anterior (Dor) fundoplication is sutured to the diaphragmatic arch. **F.** Posterior (Toupet) fundoplication is sutured to cut edges of myotomy. EG jct = esophagogastric junction.

Outcome Assessment of the Therapy for Achalasia

Critical analysis of the results of therapy for motor disorders of the esophagus requires objective measurement. The use of symptoms alone as an endpoint to evaluate therapy for achalasia may be misleading. The propensity for patients to unconsciously modify their diet to avoid difficulty swallowing is underestimated, making an assessment of results based on symptoms unreliable. Insufficient reduction in outflow resistance may allow progressive esophageal dilation to develop slowly, giving the impression of improvement because the volume of food able to be ingested with comfort increases. A variety of objective measurements may be used to assess success, including LES pressure, esophageal baseline pressure, and scintigraphic assessment of esophageal emptying time. Esophageal baseline pressure is usually negative when compared to gastric pressure. Given that the goal of therapy is to eliminate the outflow resistance of a nonrelaxing sphincter, measurement of improvements in esophageal baseline pressure and scintigraphic transit time may be better indicators of success, but are rarely reported.

Eckardt and associates investigated whether the outcome of pneumatic dilation in patients with achalasia could be predicted on the basis of objective measurements. Postdilation LES pressure was the most valuable measurement for predicting long-term clinical response. A postdilatation sphincter pressure <10 mmHg predicted a good response. Fifty percent of the patients studied had postdilatation sphincter pressures between 10 and 20 mmHg, with a 2-year remission rate of 71%. Importantly, 16 of 46 patients were left with a postdilatation sphincter pressure of >20 mmHg, and had an unacceptable outcome. Overall, only 30% of patients dilated remained in symptomatic remission at 5 years.

Bonavina and colleagues reported good to excellent results with transabdominal myotomy and Dor fundoplication in 94% of patients after a mean follow-up of 5.4 years. No operative mortality occurred in either of these series, attesting to the safety of the procedure. Malthaner and Pearson reported the long-term clinical results in 35 patients with achalasia, having a minimum follow-up of 10 years (Table 25-11). Twenty-two of these patients underwent primary esophageal myotomy and Belsey hemifundoplication at the Toronto General Hospital. Excellent to good results were noted in 95% of patients at 1 year, declining to 68, 69, and 67% at 10, 15, and 20 years, respectively. Two patients underwent early reoperation for an incomplete myotomy, and three underwent an esophagectomy for progressive disease. They concluded that there was a deterioration of the initially good results after surgical myotomy and hiatal repair for achalasia, which is due to late complications of gastroesophageal reflux.

Table 25-11 Reasons for Failure of Esophageal Myotomy

Author, Procedure (n)	

Reason	Ellis, Myotomy Only (n = 81)	Goulbourne, Myotomy Only (n = 65)	Malthaner, Myotomy + Antireflux (n = 22)
Reflux	4%	5%	18%
Inadequate myotomy	2%	—	9%
Megaesophagus	2%	—	—
Poor emptying	4%	3%	—
Persistent chest pain	1%	—	—

Source: Data from Malthaner RA, et al: Long-term results in surgically managed esophageal achalasia. *Ann Thorac Surg* 58:1343, 1994; Ellis FH Jr.: Oesophagomyotomy for achalasia: A 22-year experience. *Br J Surg* 80:882, 1993; and Goulbourne IA, et al: Long-term results of Heller's operation for achalasia. *J Royal Coll Surg* 30, 1985.

Ellis reported his lifetime experience with transthoracic short esophageal myotomy without an antireflux procedure. One hundred seventy-nine patients were analyzed at a mean follow-up of 9 years, ranging from 6 months to 20 years. Overall, 89% of patients were improved at the 9-year mark. He also observed that the level of improvement deteriorated with time, with excellent results (patients continuing to be symptom free) decreasing from 54% at 10 years to 32% at 20 years. He concluded that a short transthoracic myotomy without an antireflux procedure provides excellent long-term relief of dysphagia, and, contrary to Malthaner and Pearson's experience, does not result in complications of gastroesophageal reflux. Both studies document nearly identical results 10 to 15 years following the procedure, and both report deterioration over time, probably due to progression of the underlying disease. The addition of an antireflux procedure if the operation is performed transthoracically has no significant effect on the outcome.

The outcome of laparoscopic myotomy and hemifundoplication has been well documented. Two reports of over 100 patients have documented relief of dysphagia in 93% of patients. Richter and coworkers reviewed published reports to date, including 254 patients with an average success rate of 93% at 2.5 years. Conversion to an open procedure occurs in 0 to 5% of patients. Complications are uncommon, occurring in <5% of patients. Intraoperative complications consist largely of mucosal perforation, and have been more likely to occur after botulinum toxin injection. The incidence of objective reflux disease as evidenced by abnormal acid exposure is <10%.

A number of randomized clinical trials in the past decade have compared the outcomes of laparoscopic Heller myotomy to pneumatic dilation and to botulinum toxin injection. In each of these trials, laparoscopic Heller myotomy and partial fundoplication was superior to the alternative treatment. Lastly, a randomized clinical trial examining the need for fundoplication following Heller myotomy demonstrated a great deal more reflux in patients without fundoplication, and no better swallowing in the Heller-only group. The best treatment for achalasia is a laparoscopic Heller myotomy and partial fundoplication.

Esophageal Resection for End-Stage Motor Disorders of the Esophagus

Patients with dysphagia and long-standing benign disease, whose esophageal function has been destroyed by the disease process or multiple previous surgical procedures, are best managed by esophagectomy. Fibrosis of the esophagus and cardia can result in weak contractions and failure of the distal esophageal sphincter to relax. The loss of esophageal contractions can result in the stasis of food, esophageal dilatation, regurgitation, and aspiration. The presence of these abnormalities signals end-stage motor disease. In these situations esophageal replacement is usually required to establish normal alimentation. Before proceeding with esophageal resection for patients with end-stage benign disease, the choice of the organ to substitute for the esophagus (i.e., stomach, jejunum, or colon) should be considered. The choice of replacement is affected by a number of factors, as described later in the section on Techniques of Esophageal Reconstruction.

CARCINOMA OF THE ESOPHAGUS

Squamous carcinoma accounts for the majority of esophageal carcinomas worldwide. Its incidence is highly variable, ranging from approximately 20 per 100,000 in the United States and Britain, to 160 per 100,000 in certain parts of South Africa and the Honan Province of China, and even 540 per 100,000 in the Guriev district of Kazakhstan. The environmental factors responsible for these localized high-incidence areas have not been conclusively identified, though additives to local foodstuffs (nitroso compounds in pickled vegetables and smoked meats) and mineral deficiencies (zinc and molybdenum) have been suggested. In Western societies, smoking and alcohol consumption are strongly linked with squamous carcinoma. Other definite associations link squamous carcinoma with long-standing achalasia, lye strictures, tylosis (an autosomal dominant disorder characterized by hyperkeratosis of the palms and soles), and human papillomavirus.

Adenocarcinoma of the esophagus, once an unusual malignancy, is diagnosed with increasing frequency (Fig. 25-67), and now accounts for more than 50% of esophageal cancer in most Western countries. The shift in the epidemiology of esophageal cancer from predominantly squamous carcinoma seen in association with smoking and alcohol, to adenocarcinoma in the setting of BE, is one of the most dramatic changes that have occurred in the history of human neoplasia. Although esophageal carcinoma is a relatively uncommon malignancy, its prevalence is exploding, largely secondary to the well-established association between gastroesophageal reflux, BE, and esophageal adenocarcinoma. Once a nearly uniformly lethal disease, survival is improving because of advances in the understanding of its molecular biology, screening and surveillance practices, improved staging, minimally invasive surgical techniques, and neoadjuvant therapy.

Incidence and mortality rate trends for esophageal cancer. NCI = National Cancer Institute.

(Reproduced with permission from the National Cancer Institute. Last updated September, 2008.)

Furthermore, the clinical picture of esophageal adenocarcinoma is changing. It now occurs not only considerably more frequently, but in younger patients, and is often detected at an earlier stage. These facts support rethinking the traditional approach of assuming palliation is appropriate in all patients. The historical focus on palliation of dysphagia in an elderly patient with comorbidities should change when dealing with a young patient with dependent children and a productive life ahead. The potential for cure becomes of paramount importance.

The gross appearance resembles that of squamous cell carcinoma. Microscopically, adenocarcinoma almost always originates in metaplastic Barrett's mucosa, and resembles gastric cancer. Rarely, it arises in the submucosal glands, and forms intramural growths that resemble the mucoepidermal and adenoid cystic carcinomas of the salivary glands.

The most important etiologic factor in the development of primary adenocarcinoma of the esophagus is a metaplastic columnar-lined or Barrett's esophagus, which occurs as a complication in approximately 10 to 15% of patients with GERD. When studied prospectively, the incidence of adenocarcinoma in a patient with BE is one in 100 to 200 patient-years of follow-up (i.e., for every 100 patients with BE followed for 1 year, one will develop adenocarcinoma). Although this risk appears to be small, it is at least 40 to 50 times that expected for a similar population without BE. This risk is similar to the risk for developing lung cancer in a person with a 20-pack-per-year history of smoking. Endoscopic surveillance for patients with BE is recommended for two reasons: (a) At present there is no reliable evidence that medical therapy removes the risk of neoplastic transformation, and (b) malignancy in BE is curable if detected at an early stage.

Clinical Manifestations

Esophageal cancer generally presents with dysphagia, although increasing numbers of relatively asymptomatic patients are now identified on surveillance endoscopy, or present with nonspecific upper GI symptoms and undergo upper endoscopy. Extension of the primary tumor into the tracheobronchial tree can cause stridor, and, if a tracheoesophageal fistula develops, coughing, choking, and aspiration pneumonia result. Rarely, severe bleeding from the primary tumor or from erosion into the aorta or pulmonary vessels occurs. Either vocal cord may be invaded, causing paralysis, but most commonly, paralysis is caused by invasion of the left recurrent laryngeal nerve by the primary tumor or LN metastasis. Systemic organ metastases are usually manifested by jaundice or bone pain. The situation is different in high-incidence areas where screening is practiced. In these communities, the most prominent early symptom is pain on swallowing rough or dry food.

Dysphagia usually presents late in the natural history of the disease, because the lack of a serosal layer on the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough for the patient to seek medical advice only when more than 60% of the esophageal circumference is infiltrated with cancer. Consequently, the disease is usually advanced if symptoms herald its presence. Tracheoesophageal fistula may be present in some patients on their first visit to the hospital, and more than 40% will have evidence of distant metastases. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia. The physical signs of esophageal tumors are those associated with the presence of distant metastases.

General Approach to Esophageal Cancer

Therapy of esophageal cancer is dictated by the stage of the cancer at the time of diagnosis. Put simply, one needs to determine if the disease is confined to the esophagus, (T1–T2, N0), locally advanced (T1–3, N1), or disseminated (any T, any N, M1). If cancer is confined to the esophagus, removal of the tumor with adjacent LNs may be curative. Very early tumors confined to the mucosa (T in situ, T1a, intramucosal cancer) may be addressed with endoscopic treatment. When the tumor is locally aggressive, modern therapy dictates a multimodality approach in a surgically fit patient. Multimodality therapy is either chemotherapy followed by surgery or radiation and chemotherapy followed by surgery. When given before surgery, these treatments are referred to as *neoadjuvant* or *induction therapy*. For disseminated cancer, treatment is aimed at palliation of symptoms. If the patient has dysphagia, as many do, the most rapid form of palliation is the placement of an expandable esophageal stent, endoscopically. For palliation of GEJ cancer, radiation may be the first choice, as stents placed across the GEJ create a great deal of gastroesophageal reflux.

Staging of Esophageal Cancer

Choosing the best therapy for an individual patient requires accurate staging. Staging starts with the history and physical. LN disease remote from the tumor, particularly in the cervical region, may be palpable on neck examination and generally indicates cancer dissemination. This is often referred to as *M1a disease*, indicating that these patients should not be treated with therapy directed toward locally advanced cancer. Other metastatic LNs are rarely palpable but are equally ominous, especially the umbilical LN in GEJ cancer.

Chest x-ray is the first step of staging, but is rarely informative. Computed tomographic (CT) scanning of the chest, abdomen, and pelvis provides information on local invasion of the primary cancer, LN involvement, or disseminated disease. The most common sites of esophageal cancer metastases are lung, liver, and peritoneal surfaces, including the omentum and small bowel mesentery. If masses are identified that are not characteristic for cancer or are in a location that precludes resection with the cancer specimen, positron emission tomography (PET) scanning may be able to tell whether the masses are metabolically active (likely to be cancer) or not. A PET active focus corresponding to a mass on CT scan outside of the field of esophageal resection should be biopsied before resection is performed.

The introduction of endoscopic ultrasound (EUS) has made it possible to identify patients who are potentially curable before surgical therapy. Using an endoscope, the depth of the wall penetration by the tumor and the presence of LN metastases can be determined with 80% accuracy. A curative resection should be encouraged if EUS indicates that the tumor has not invaded adjacent organs (T4), and/or fewer than five enlarged LNs are imaged. Thoracoscopic and laparoscopic staging of esophageal cancer may add benefit when the nature of enlarged LNs remote from the cancer cannot be determined, or when advanced imaging systems (PET and high-resolution spiral CT) are not available.

Occasionally, diagnostic laparoscopy and jejunostomy tube placement may proceed induction chemoradiation in the patient with severe dysphagia and weight loss from a locally advanced cancer. In summary, esophageal cancer is diagnosed with endoscopic biopsy and is staged with CT scanning of the chest and abdomen, EUS, and PET scan for all patients with CT or EUS evidence of advanced disease (T2 or greater, N1 or NX). Experience with esophageal resections in patients with early disease has identified characteristics of esophageal cancer that are associated with improved survival. A number of studies suggest that only metastasis to LNs and tumor penetration of the esophageal wall have a significant and independent influence on prognosis. Factors known to be important in the survival of patients with advanced disease, such as cell type, degree of cellular differentiation, or location of tumor in the esophagus, have no effect on survival of patients who have undergone resection for early disease. Studies also showed that patients having five or fewer LN metastases have a better outcome. Using these data, Skinner developed the wall penetration, LN, and distant organ metastases system for staging.

The wall penetration, LN, and distant organ metastases system differed somewhat from the previous efforts to develop a satisfactory staging criteria for carcinoma of the esophagus. Most surgeons agreed that the 1983 tumor, nodes, and metastasis system left much to be desired. In the third edition of the manual for Staging of Cancer of the American Joint Committee on Cancer in 1988, an effort was made to provide a finer discrimination between stages than had been contained in the previous edition in 1983. Table 25-12 shows the definitions for the primary tumor, regional LNs, and distant metastasis, as listed in the 1988 manual. Further refinements of the staging system of esophageal cancer are underway and likely to be approved by the American Joint Committee on Cancer, recognizing the difference in survival afforded by resection of limited LN disease adjacent to the tumor, as compared to multilevel LN disease and positive LNs remote from the primary. In addition, the difference between intramucosal cancer and cancer extending to the submucosa (both currently T1 cancer) will be recognized.

Table 25-12 Staging of Cancer of the Esophagus and Cardia (AJCC 1988)						
Stage	Classification			No. of Patients	% 5-Year Survival	P Value
0	Tis	N ₀	M ₀	16	100	NS
I	T ₁	N ₀	M ₀	22	78.9	.0021
IIA	T ₂	N ₀	M ₀	80	37.9	
	T ₃	N ₀	M ₀			
IIB	T	N	M	39	27.3	NS

	1	1	0			
	T ₂	N ₁	M ₀			
III	T ₃	N ₁	M ₀	218	13.7	NS
	T4	Any N	M ₀			
IV	Any T	Any N	M ₁	33/408	0	.0001

Clinical Approach to Carcinoma of the Esophagus and Cardia

The selection of a curative vs. a palliative operation for cancer of the esophagus is based on the location of the tumor, the patient's age and health, the extent of the disease, and preoperative staging.

Figure 25-68 shows an algorithm of the clinical decisions important in the selection of curative or palliative therapy.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

TUMOR LOCATION

The selection of surgical therapy for patients with carcinoma of the esophagus depends not only on the anatomic stage of the disease and an assessment of the swallowing capacity of the patient, but also on the location of the primary tumor.

It is estimated that 8% of the primary malignant tumors of the esophagus occur in the cervical portion (Fig. 25-69). They are almost always squamous cell lesions, with a rare adenocarcinoma arising from a congenital inlet patch of columnar lining. These tumors, particularly those in the postcricoid area, represent a separate pathologic entity for two reasons: (a) They are more common in females and appear to be a unique entity in this regard; and (b) The efferent lymphatics from the cervical esophagus drain completely differently from those of the thoracic esophagus. The latter drain directly into the paratracheal and deep cervical or internal jugular LNs with minimal flow in a longitudinal direction. Except in advanced disease, it is unusual for intrathoracic LNs to be involved.

Fig. 25-69.

Cervical esophageal cancer is frequently unresectable because of early invasion of the larynx, great vessels, or trachea. Radical surgery including esophagolaryngectomy may occasionally be performed for these lesions, but the ensuing morbidity makes this a less than desirable approach in the face of uncertain cure. Thus, for most patients with cervical esophageal cancer, stereotactic radiation with concomitant chemotherapy is the most desirable treatment.

Tumors that arise within the middle third of the esophagus are squamous carcinomas most commonly and are frequently associated with LN metastasis, which are usually in the thorax but may be in the neck or abdomen, and may skip areas in between. Although it is generally felt that individuals with midthoracic cancer and abdominal LN metastases are incurable with surgery, there are some emerging data that suggest that cervical LN metastases, if isolated, can be resected with benefit. Generally, T1 and T2 cancers without LN metastases are treated with resection only, but there is more and more data to suggest that LN involvement or transmural cancer (T3) warrants treatment with neoadjuvant chemoradiation therapy followed by resection. Although some surgeons prefer a transhiatal esophagectomy for all tumor locations, most surgeons believe that resection of midesophageal cancer should be performed under direct vision with either thoracoscopy [video-assisted thoracic surgery (VATS)] or with thoracotomy.

Tumors of the lower esophagus and cardia are usually adenocarcinomas. Unless preoperative and intraoperative staging clearly demonstrate an incurable lesion, resection in continuity with a LN dissection should be performed. Because of the propensity of GI tumors to spread for long distances submucosally, long lengths of grossly normal GI tract should be resected. The longitudinal lymph flow in the esophagus can result in skip areas, with small foci of tumor above the primary lesion, which underscores the importance of a wide resection of esophageal tumors. Wong has shown that local recurrence at the anastomosis can be prevented by obtaining a 10-cm margin of normal esophagus above the tumor. Anatomic studies have also shown that there is no submucosal lymphatic barrier between the esophagus and the stomach at the cardia, and Wong has shown that 50% of the local recurrences in patients with esophageal cancer who are resected for cure occur in the intrathoracic stomach along the line of the gastric resection. Considering that the length of the esophagus ranges from 17 to 25 cm, and the length of the lesser curvature of the stomach is approximately 12 cm, a curative resection requires a cervical division of the esophagus and a >50% proximal gastrectomy in most patients with carcinoma of the distal esophagus or cardia.

AGE

Resection for cure of carcinoma of the esophagus in a patient older than 80 years is rarely indicated, because of the additional operative risk and the shorter life expectancy. Despite this general guideline, octogenarians with a high performance status and excellent cardiopulmonary reserve may be considered candidates for esophagectomy. It is in this group of patients that the lesser physiologic impact of

minimally invasive surgery may reduce the morbidity and mortality associated with open two- or three-field esophagectomy.

CARDIOPULMONARY RESERVE

Patients undergoing esophageal resection should have sufficient cardiopulmonary reserve to tolerate the proposed procedure. The respiratory function is best assessed with the forced expiratory volume in 1 second, which ideally should be 2 L or more. Any patient with a forced expiratory volume in 1 second of <1.25 L is a poor candidate for thoracotomy, because he or she has a 40% risk of dying from respiratory insufficiency within 4 years. In patients with poor pulmonary reserve, the transhiatal esophagectomy should be considered, as the pulmonary morbidity of this operation is less than is seen following thoracotomy. Clinical evaluation and electrocardiogram are not sufficient indicators of cardiac reserve. Echocardiography and dipyridamole thallium imaging provide accurate information on wall motion, ejection fraction, and myocardial blood flow. A defect on thallium imaging may require further evaluation with preoperative coronary angiography. A resting ejection fraction of <40%, particularly if there is no increase with exercise, is an ominous sign. In the absence of invasive testing, observed stair-climbing is an economical (albeit not quantitative) method of assessing cardiopulmonary reserve. Most individuals who can climb three flights of stairs without stopping will do well with two-field open esophagectomy, especially if an epidural catheter is used for postoperative pain relief.

NUTRITIONAL STATUS

The factor most predictive of postoperative complication is the nutritional status of the patient. Profound weight loss, more than 20 lb, associated with hypoalbuminemia (albumin <3.5 g/dL) is associated with a much higher rate of complications and mortality than patients who enter curative surgery in better nutritional condition. Because malnourished patients generally have locally advanced esophageal cancer, if not metastatic disease, one should consider the placement of a feeding tube before the beginning of induction chemoradiation therapy. Although mild amounts of dysphagia are improved by induction chemoradiation therapy, more pronounced dysphagia and associated malnutrition should be addressed before the initiation of chemoradiation. A laparoscopic jejunostomy tube can be placed prior to induction therapy or at the time of esophagectomy. There are emerging data that 5 days' pretreatment with immune-enhancing nutrition, rich in fish oils, decreases cardiac and other complications, following esophagectomy.

CLINICAL STAGING

Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner's syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation, and malignant pleural effusion. Factors that make surgical cure unlikely include a tumor >8 cm in length, abnormal axis of the esophagus on a barium radiogram, more than four enlarged LNs on CT, a weight loss more than 20%, and loss of appetite. Studies indicate that there are several favorable parameters associated with tumors <4 cm in length, there are fewer with tumors between 4 and 8 cm, and there are no favorable criteria for tumors >8 cm in length. Consequently, the finding of a tumor >8 cm in length should exclude curative resection; the finding of a smaller tumor should encourage an aggressive approach.

PREOPERATIVE STAGING WITH ADVANCED IMAGING

For years, clinical staging, contrast radiography, endoscopy, and CT scanning formed the backbone of esophageal cancer staging. More recently, preoperative decision making is guided by endoscopic ultrasonography and PET scanning.

EUS provides the most reliable method of determining depth of cancer invasion. In the absence of enlarged LNs, the degree of wall invasion dictates surgical therapy. If a small focus of esophageal cancer is seen to be confined to the mucosa, endoscopic mucosal resection (EMR) is a preferable option. If the tumor invades the submucosa, without visible lymph node involvement, most individuals would suggest esophagectomy with LN dissection, as positive nodes can be found in 20 to 25% of those with cancer limited to the mucosa and submucosa. If EUS demonstrates spread through the wall of the esophagus, especially if LNs are enlarged, then induction chemoradiation therapy (neoadjuvant therapy) should be strongly considered. Lastly, when the EUS demonstrates invasion of the trachea, bronchus, aorta, or pleura, especially with a pleural effusion, then surgical resection is rarely indicated. Thus, it can be seen that the therapy of esophageal cancer is largely driven by the finding of an endoscopic ultrasonography. It is difficult to provide modern treatment of esophageal cancer without access to this modality.

PET scanning, usually combined with an axial CT scan (CT-PET), usually is performed on patients with locally advanced cancer or questionable lesions on CT scan to determine whether metastases are present. The PET scan uses the injection of radiolabeled deoxyglucose, which is taken up in metabolically active tissues such as cancer. PET-positive areas must be correlated with the CT scan findings to assess the significance of "hot spots." CT-PET scanning has been especially useful before the initiation of chemoradiation therapy. An early response to chemoradiotherapy, by PET scan, improves the prognosis whether or not resection is ultimately performed. Conversely, if a PET-avid tumor shows no change in metabolic activity after 2 weeks of induction chemoradiation therapy, it is unlikely that further chemo or radiation therapy will be of any benefit. These patients have a worse prognosis, and may be referred for resection or palliation without incurring the morbidity or expense of a full course of chemo- and radiation therapy.

Palliation of Esophageal Cancer

Palliation of esophageal cancer is indicated for individuals with metastatic esophageal cancer or cancer invading adjacent organs (T4) who are unable to swallow, or individuals with fistulae into the

tracheobronchial tree. Aortic esophageal fistulas are extremely rare and nearly 100% lethal. Dysphagia as a result of esophageal cancer can be graded from grade I, eating normally, to grade VI, unable to swallow saliva (Table 25-13). Grades I–III often can be managed with radiation therapy, usually in combination with chemotherapy. When surgical resection is not anticipated in the future, this is termed *definitive chemoradiation therapy* and usually is palliative. Radiation dose is increased from 45 Gy to 60 Gy administered over 8 weeks, rather than the 4 weeks given for chemoradiation induction therapy. In a small percentage of patients, a complete response to chemoradiation therapy will not only palliate the symptoms, but leave the patient with undetectable cancer of the esophagus. Although some of these patients are truly cured, cancer will recur in many either locally or systemically 1 to 5 years following definitive chemoradiation. In a few patients, definitive chemoradiation will be successful in all sites but the esophagus. After a 12-month wait from initial treatment and no other sites of tumor detectable except the esophagus, some of these patients may be candidates for salvage esophagectomy.

Table 25-13 Functional Grades of Dysphagia		
Grade	Definition	Incidence at Diagnosis (%)
I	Eating normally	11
II	Requires liquids with meals	21
III	Able to take semisolids but unable to take any solid food	30
IV	Able to take liquids only	40
V	Unable to take liquids, but able to swallow saliva	7
VI	Unable to swallow saliva	12

Source: Modified with permission from Takita H, et al: Squamous cell carcinoma of the esophagus: A study of 153 cases. *J Surg Oncol* 9:547, 1977.

For individuals with dysphagia grades IV and higher, additional treatment generally is necessary. The mainstay of therapy is indwelling esophageal stents. Covered removable stents may be used to seal fistulae or when stent removal becomes desirable in the future. When large, locally invasive tumors or metastatic esophageal cancer precludes any future hope of resection, uncovered expandable metal stents are the treatment of choice. The major limitations to stenting exist in cancers at the GEJ. A stent placed across the GEJ will result in severe gastroesophageal reflux and heartburn that can be quite disabling. In cancers at this level, radiation therapy alone may be preferable. If feeding access is desirable, a laparoscopic jejunostomy is usually the procedure of choice.

Surgical Treatment

The surgical treatment of esophageal cancer is dependent upon the location of the cancer, the depth of invasion, LN metastases, the fitness of the patient for operation, and the culture and beliefs of the individuals and institutions in which the treatment is performed. In an ideal world, there would be a single, stage-specific method of treating esophageal cancer, because the evidence would be unassailable and noncontroversial. Randomized clinical trials and meta-analyses would prove beyond a shadow of a doubt the value of surgery vs. nonoperative therapy and would dictate the type and extent of surgery that would optimally balance immediate morbidity and mortality with duration and quality of life conferred by the procedure and the perioperative management of the esophagectomy patient. Despite many noble attempts to establish this high level of evidence, many questions relating to the appropriate therapy of esophageal cancer remain controversial. About the only area of complete agreement is that esophagectomy should not be performed if an R0 resection is not possible. In other words, if the surgeon does not believe he or she can remove all LNs invaded by cancer and provide a tumor-free radial margin and esophagus and stomach margins that are tumor free, then a resection should not be performed.

MUCOSALLY BASED CANCER

In patients with BE, and especially those with high-grade dysplasia, subcentimeter nodules are frequently discovered. Nodules should be resected in entirety, as they often harbor adenocarcinoma. Five years ago, such resection was performed with a transhiatal esophagectomy, but greater comfort by therapeutic endoscopists with EMR offers another method for removing intramucosal cancer. Ideally, EMR starts with a very high-resolution EUS that can differentiate between nodules invading the submucosa and those confined to the mucosa. Tumors invading the submucosa are generally not felt amenable to endoscopic mucosal resection because of the high-frequency (20 to 25%) concurrent finding of positive LNs, which cannot be removed without esophagectomy. On the other hand, intramucosal cancers have little risk of spreading to regional LNs, as the esophageal lymphatics reach only to the level of the submucosa.

For this reason, small intramucosal carcinomas may be removed with EMR in the following manner: The area beneath the nodule is infiltrated with saline through a sclerotherapy needle. A specialized suction cap is mounted on the end of the endoscope and the nodule is drawn up into the cap, following which a snare is applied to resect the tissue. Alternatively, a rubber band can be delivered and the snare can be used to resect above the level of the rubber band. This specimen is then removed and sent to pathology. As long as the tumor is found to be confined to the mucosa and all margins are negative, the resection is complete. A positive margin or involvement of the submucosa warrants esophagectomy. Most importantly, these patients are at high risk for developing small nodular carcinomas elsewhere in their Barrett's segment, and routine surveillance on a 3- to 6-month basis must be continued indefinitely. Alternatively, one can consider radiofrequency ablation of the remainder of the high-grade dysplasia after careful surveillance biopsies demonstrate no further sign of cancer. This approach to the early esophageal cancer should not be used when there is any suspicion of mediastinal or abdominal

lymphadenopathy. Although it is currently rare that EMR provides definitive therapy of small nodular esophageal cancers, this may become more of the norm as greater surveillance reveals earlier cancers, and proficiency of the technique by surgeons and gastroenterologists increases. In addition, EMR allows a "large-particle biopsy," which may be helpful in directing surgical therapy, and targeted therapies "personalized" for the genotype and phenotype of each individual tumor.

MINIMALLY INVASIVE TRANSHIATAL ESOPHAGECTOMY

Minimally invasive transhiatal esophagectomy is an increasingly popular procedure; however, the number of these operations performed around the world remains small. Mini-invasive surgery (MIS) transhiatal esophagectomy was first performed by Aureo DePaula in Brazil and has been modified and adopted by many individuals around the world. This operation combines the advantages of transhiatal esophagectomy at minimizing pulmonary complications with the advantages of laparoscopy (less pain, quicker rehabilitation). Several variations of MIS transhiatal esophagectomy have been developed. For the earliest lesions, such as high-grade dysplasia or intramucosal carcinoma, a vagal sparing procedure can be entertained. In such a procedure, the vagal trunks are separated from the esophagus at the level of the diaphragm and the lesser curvature dissection of the stomach allows the vagus and left gastric pedicle to remain intact. Clearly, this dissection, which hugs the stomach and esophagus, provides no LN staging and is thus inadequate for all high-grade dysplasia and intramucosal cancer.

MIS transhiatal esophagectomy is usually performed through five or six small incisions in the upper abdomen and a transverse cervical incision for removing the specimen and performing the cervical esophagogastrostomy. To remove the esophagus from the posterior mediastinum, especially the area behind the pulmonary vessels and the tracheal bifurcation, which cannot be visualized even with a long laparoscope placed in the posterior mediastinum, it is preferred to use a vein stripping "inversion" technique (Fig. 25-70A). The details of this operation are too lengthy to include in this text, but include the laparoscopic creation of a 4-cm neoesophagus (gastric conduit) along the greater curvature of the stomach using the right gastroepiploic artery as the primary vascular pedicle. The conduit can be created through a mini-laparotomy or laparoscopically. A Kocher maneuver releases the duodenum, and a pyloroplasty may be performed (optional). Retrograde esophageal stripping is performed by dividing the esophagus below the GEJ and sliding a vein stripper from the neck down into the abdomen followed by an inversion of the esophagus in the posterior mediastinum and removal through the neck (Fig. 25-70B). This technique is reserved for patients with high-grade dysplasia and only microscopically detectable cancer. For small cancers at the GEJ, the esophagus can be stripped in an antegrade fashion by sliding the vein stripper down from the cervical incision and out the tail of the lesser curvature (Fig. 25-70C). The tail of the lesser curvature is pulled out a port site high in the epigastrium and used as a wound protector while the esophagus is inverted on itself. For GEJ cancers, a wide celiac access LN dissection, splenic artery, hepatic artery, and posterior mediastinal LN dissection can be performed as well or better than through a laparotomy. The gastric conduit is pulled up to the neck with a chest tube and anastomosed to the cervical esophagus in an end-to-side fashion using a surgical stapler or with a handsewn anastomosis. This method of esophagogastrrectomy may mitigate the need for intensive care unit care, and shorten the hospitalization to the time necessary for anatomic healing. Complications of this technique have been rare and primarily limited to leak from the esophagogastric anastomosis, which is self-limited and usually heals within 1 to 3 weeks, spontaneously.

OPEN TRANSHIATAL ESOPHAGECTOMY

Transhiatal esophagectomy, also known as *blunt esophagectomy* or *esophagectomy without a thoracotomy*, was first performed in 1933 by a British surgeon, but was popularized in the last quarter of the twentieth century by Mark Orringer from the University of Michigan. Although this operation may violate many of the principles of cancer resection, including extended radical LN dissection, this operation has performed as well as any of the more radical procedures in randomized trials, and in large database analyses. With transhiatal esophagectomy, the elements of dissection are similar to that described in the section entitled Minimally Invasive Transhiatal Esophagectomy including the creation of the gastric tube and the posterior mediastinal dissection through the hiatus. Because this dissection is performed with the fingertips rather than under direct vision with surgical instruments, it requires an enlargement of the diaphragmatic hiatus. The lower mediastinal LN basins can be resected as can the upper abdominal LNs, making this an attractive option for GEJ cancers. The mediastinal LNs above the inferior pulmonary vein are not removed with this technique, but rarely result in a point of isolated cancer recurrence.

Of all procedures for esophageal cancer, this operation is the quickest to perform in experienced hands and lies in an intermediate position between minimally invasive esophagectomy and the Ivor Lewis procedure with respect to complications and recovery.

MINIMALLY INVASIVE TWO- AND THREE-FIELD ESOPHAGECTOMY

After a rocky start, minimally invasive esophagectomy using a thoracic dissection through VATS has become reasonably popular. In general, this operation is performed with an anastomosis created in the neck (three-field), but may be performed with the anastomosis stapled in the high thorax (two-field). Both procedures will be described.

With a minimally invasive three-field esophagectomy, the patient is placed in the left lateral decubitus position. Double lumen intubation is required. Videoscopic access to the thorax is obtained in the midaxillary line in the ninth intercostal space and an angled telescope illuminates the chest superiorly. A mini-thoracotomy at about the sixth intercostal space anteriorly allows introduction of conventional surgical instruments, and a high trocar allows retraction of the lung away from the esophagus. In a three-field approach, the esophagus is dissected out along its length to include division of the azygos vein and harvesting of the LNs in the upper, middle, and lower posterior mediastinum. Hilar, aortopulmonary window, and posterior mediastinal nodes are all removed and sent with the specimen or individually. The thoracic duct is divided at the level of the diaphragm and removed with the specimen.

Following complete intrathoracic dissection, the patient is placed in the supine position and five laparoscopic ports are placed as with the MIS transhiatal esophagectomy. The abdominal portions of the operation are identical to those described previously in the section entitled Minimally Invasive Transhiatal Esophagectomy, and the gastric conduit is then sewn to the tip of the fully mobilized GEJ and lesser curvature sleeve. A feeding tube is placed and the pyloroplasty may be performed laparoscopically if the surgeon feels so inclined. A transverse cervical incision and dissection between the sternomastoid and

the anterior strap muscles allows access to the cervical esophagus. Great care is made to avoid stretching the recurrent laryngeal nerve. The esophagus and proximal stomach is then pulled up into the neck with the gastric conduit following. Cervical anastomosis is then performed.

The MIS transthoracic two-field esophagectomy is slightly different. In this operation, the abdominal portions of the operation are done first, including placement of the feeding tube, the creation of the conduit, and the sewing of the tip of the conduit to the fully dissected GEJ. The patient is then rolled into the left lateral decubitus position and, through right thoracoscopy, the esophagus is dissected out and divided 10 cm above the tumor. Once freed, the specimen is pulled out through the mini-thoracotomy and an end-to-end anastomosis stapler is introduced through the high corner of the gastric conduit and out a stab wound along the greater curvature. The anvil of the stapler is placed in the proximal esophagus and held with a purse-string, the stapler is docked, the anastomosis is created, and a gastrotomy is then closed with another firing of the GIA stapler. The three-field esophagectomy has the advantage of placing the anastomosis in the neck where leakage is unlikely to create a severe systemic consequence. On the other hand, placement of the anastomosis in the high chest minimizes the risks of injury to structures in the neck, particularly the recurrent laryngeal nerve. Although the leak of the intrathoracic anastomosis may be more likely to bear septic consequences, the incidence of leak is diminished. Other complications of this approach relate to pulmonary and cardiac status. In many series, the most common complication is pneumonia, the second is atrial fibrillation, and the third is anastomotic leak.

IVOR LEWIS (EN BLOC) ESOPHAGECTOMY

The theory behind radical transthoracic esophagectomy is that greater removal of LNs and periesophageal tissues diminishes the chance of a positive radial margin and LN recurrence. Although there are no randomized data demonstrating this to be superior to other forms of esophagectomy, there are many retrospective data demonstrating improved survival with greater numbers of LNs harvested. A recent study from Sloan-Kettering demonstrates a direct relationship between the number of negative nodes harvested and long-term survival. Although such a survival advantage may be related to the completeness of resection, extended radical resections may also be a surrogate for experienced surgeons working in great institutions. As a time-honored operation, there is no doubt that en bloc esophagectomy is the standard to which less radical techniques must be compared.

Generally, this operation is started in the abdomen with an upper midline laparotomy and extensive LN dissection in and about the celiac access and its branches, extending into the porta hepatis and along the splenic artery to the tail of the pancreas. All LNs are removed en bloc with the lesser curvature of the stomach. Unless the tumor extends into the stomach, reconstruction is performed with a greater curvature gastric tube. For GEJ cancers extending significantly into the gastric cardia or fundus, the proximal stomach is removed and reconstruction is performed with an isoperistaltic section of left colon between the upper esophagus and the remnant stomach, or the colon is connected to a Roux-en-Y limb of jejunum, if total gastrectomy is necessary. In the majority of cases, colon interposition is unnecessary, and a 4-cm gastric conduit is used.

Following closure of the abdominal incision, the patient is placed in the left lateral decubitus position and an anterolateral thoracotomy is performed through the sixth intercostal space. The azygos vein is divided and the posterior mediastinum is entirely cleaned out to include the thoracic duct, all periaortic tissues, and all tissue in the upper mediastinum along the course of the current laryngeal nerves and in the peribronchial, hilar, and tracheal LN stations. The proximal stomach is pulled up into the thorax where a conduit is created (if not performed previously) and a handsewn or stapled anastomosis is made between the upper thoracic esophagus and the gastric conduit or transverse colon. Chest tubes are placed, and the patient is taken to the intensive care unit.

Because this is the most radical of dissections, complications are most common, including pneumonia, respiratory failure, atrial fibrillation, chylothorax, anastomotic leak, conduit necrosis, gastrocutaneous fistula, and, if dissection is too near the recurrent laryngeal nerves, hoarseness or other vocal cord dysfunction. Tracheobronchial injury resulting in fistulas between the bronchus and conduit may also occur, however rarely. Although this procedure and three-field esophagectomy are fraught with the highest complication rate, the long-term outcome of this procedure provides the greatest survival in many single-center series and retrospective reviews.

THREE-FIELD OPEN ESOPHAGECTOMY

Three-field open esophagectomy is very similar to a minimally invasive three-field except that all access is through open incisions. This procedure is preferred by certain Japanese surgeons and LN counts achieved through this kind of operation may run from 45 to 60 LNs. Most Western surgeons question the benefit of such radical surgery when it is hard to define a survival advantage. Nonetheless, high intrathoracic cancers probably deserve such an aggressive approach if cure is the goal.

SALVAGE ESOPHAGECTOMY

"Salvage esophagectomy" is the nomenclature applied to esophagectomy performed after failure of definitive radiation and chemotherapy. The most frequent scenario is one in which distant disease (bone, lung, brain, or wide LN metastases) renders the patient nonoperable at initial presentation. Then, systemic chemotherapy, usually with radiation of the primary tumor, destroys all foci of metastasis, as demonstrated by CT and CT-PET, but the primary remains present and symptomatic. Following a period of observation, to make sure no new disease will "pop up," salvage esophagectomy is performed, usually with an open two-field approach. Surprisingly, the cure rate of salvage esophagectomy is not inconsequential. One in four patients undergoing this operation will be disease free 5 years later, despite the presence of residual cancer in the operative specimen. Because of the dense scarring created by radiation treatment, this procedure is the most technically challenging of all esophagectomy techniques.

Comparative Studies of Esophagectomy Technique

TRANSTHORACIC VS. TRANSHIATAL ESOPHAGECTOMY

There has been a great debate as to whether en bloc esophagectomy will provide a greater long-term benefit and cure rate in esophageal cancer than transhiatal esophagectomy. In a recent 7-year follow-up of a Dutch study addressing GEJ and lower esophageal cancers, there does not appear to be any benefit to the more extensive dissection despite higher morbidity and mortality. In a subgroup analysis of those with one to eight positive LNs, it did appear that the en bloc transthoracic resection may add to longevity. In another large database analysis of the Surveillance, Epidemiology, and End Results database, transthoracic and transhiatal esophagectomy were compared. In this study, the transhiatal esophagectomy had a greater long-term survival, but, when adjusted by cancer stage, this survival benefit disappeared. The mortality and morbidity after transhiatal esophagectomy appeared to be less. Suffice it to say that this debate over the best procedure for esophagectomy remains an open question.

The role of the minimally invasive surgical procedures for a cancer cure will require further study and longer follow-up. It would appear from preliminary analysis that the transhiatal esophagectomy, like its open cousin, may be performed with less morbidity and mortality than the VATS procedure. Long-term survival analyses will require careful follow-up for at least 5 to 10 years after cancer treatment.

Alternative Therapies

RADIATION THERAPY

Primary treatment with radiation therapy does not produce results comparable with those obtained with surgery. Currently, the use of radiotherapy is restricted to patients who are not candidates for surgery, and is usually combined with chemotherapy. Radiation alone is used for palliation of dysphagia but the benefit is short lived, lasting only 2 to 3 months. Furthermore, the length and course of treatment are difficult to justify in patients with a limited life expectancy.

ADJUVANT CHEMOTHERAPY

The proposal to use adjuvant chemotherapy in the treatment of esophageal cancer began when it became evident that most patients develop postoperative systemic metastasis without local recurrence. This observation led to the hypothesis that undetected systemic micrometastasis had been present at the time of diagnosis, and, if effective systemic therapy was added to local regional therapy, survival should improve.

Recently, this hypothesis has been supported by the observation of epithelial tumor cells in the bone marrow in 37% of patients with esophageal cancer who were resected for cure. These patients had a greater prevalence of relapse at 9 months after surgery compared to those patients without such cells. Such studies emphasize that hematogenous dissemination of viable malignant cells occurs early in the disease, and that systemic chemotherapy may be helpful if the cells are sensitive to the agent. On the other hand, systemic chemotherapy may be a hindrance, because of its immunosuppressive properties, if the cells are resistant. Unfortunately, current technology is not able to test tumor cell sensitivity to chemotherapeutic drugs. This requires that the choice of drugs be made solely on the basis of their clinical effectiveness against grossly similar tumors.

The decision to use preoperative rather than postoperative chemotherapy was based on the ineffectiveness of chemotherapeutic agents when used after surgery, and animal studies suggesting that agents given before surgery were more effective. The claim that patients who receive chemotherapy before resection are less likely to develop resistance to the drugs is unsupported by hard evidence. The claim that drug delivery is enhanced because blood flow is more robust before patients undergo surgical dissection is similarly flawed, due to the fact that if enough blood reaches the operative site to heal the wound or anastomosis, then the flow should be sufficient to deliver chemotherapeutic drugs. There are, however, data supporting the claim that preoperative chemotherapy in patients with esophageal carcinoma can, if effective, facilitate surgical resection by reducing the size of the tumor. This is particularly beneficial in the case of squamous cell tumors above the level of the carina. Reducing the size of the tumor may provide a safer margin between the tumor and the trachea, and allow an anastomosis to a tumor-free cervical esophagus just below the cricopharyngeus. Involved margin at this level usually requires a laryngectomy to prevent subsequent local recurrence.

PREOPERATIVE CHEMOTHERAPY

Eight randomized prospective studies of neoadjuvant chemotherapy vs. surgery alone have demonstrated mixed results. For adenocarcinomas of the distal esophagus and proximal stomach, preoperative neoadjuvant 5-fluorouracil (5-FU) and cisplatin chemotherapy has been shown to provide a survival advantage over surgery alone in a well-powered study from the United Kingdom (MRC trial). This trial is one of the few to include enough patients (800) to detect small differences. The trial had a 10% absolute survival benefit at 2 years for the neoadjuvant chemotherapy group. In a second trial from the United Kingdom (MAGIC trial) of distal esophageal and proximal gastric adenocarcinomas, the use of epirubicin in combination with cisplatin and 5-FU also demonstrated a survival advantage for the induction chemotherapy arm with 4 years median follow-up. As a result of these two trials, standard treatment of locally advanced adenocarcinoma in Europe calls for neoadjuvant chemotherapy with one of these two regimens. Most failures are due to distant metastatic disease, underscoring the need for improved systemic therapy. Postoperative septic and respiratory complications may be more common in patients receiving chemotherapy.

PREOPERATIVE COMBINATION CHEMO- AND RADIOTHERAPY

Preoperative chemoradiotherapy using cisplatin and 5-FU in combination with radiotherapy has been reported by several investigators to be beneficial in both adenocarcinoma and squamous cell carcinoma of the esophagus. There have been 10 randomized prospective studies (Table 25-14). A recent meta-analysis of these trials demonstrates a 13% survival advantage for neoadjuvant chemoradiation therapy, which is more pronounced for patients with adenocarcinoma than for those with squamous carcinoma (Table 25-15). It was also observed that the benefit for chemotherapy alone (7%) was not as dramatic as for chemoradiotherapy used in the neoadjuvant setting. Additionally, other work has demonstrated the importance of obtaining an R0 (tumor-free) resection as the most important variable determining long-term survival. Although there are not direct, randomized comparisons between chemotherapy and chemoradiation therapy, it appears that the addition of radiation may improve local response of the tumor, and may allow a greater opportunity for the surgeon to obtain an R0 resection.

Table 25-14 Randomized Trials of Neoadjuvant Chemoradiotherapy vs. Surgery, or Neoadjuvant Chemotherapy vs. Surgery						
Year Activated	Treatment Schedule (Radiotherapy)	Treatment Schedule (Chemotherapy)	Concurrent or Sequential	Tumor Type	Sample Size	Median Follow-Up (Mo)
Chemoradiotherapy						
1983	35 Gy, 1.75 Gy/fraction over 4 wk	Two cycles: cisplatin 20 mg/m ² d 1–5; bleomycin 5 mg/m ² d 1–5	Sequential	SCC	78	18 ^a

The timing of surgery after chemoradiation induction is generally felt to be optimal between 6 and 8 weeks following the completion of induction therapy. Earlier than this time, active inflammation may make the resection hazardous, and the patients have not had time to recover fully from the chemoradiation. After 8 weeks, edema in the periesophageal tissue starts to turn to scar tissue, making dissection more difficult.

With chemoradiation, the complete response rates for adenocarcinoma range from 17 to 24% (Table 25-16). No tumor is detected in the specimen after esophagectomy. Patients demonstrating a complete response to chemoradiation have a better survival rate than those without complete response, but distant failure remains common.

Table 25-16 Results of Neoadjuvant Therapy in Adenocarcinoma of the Esophagus					
Institution	Year	No. of Patients	Regimen	Complete Pathologic Response (%)	Survival

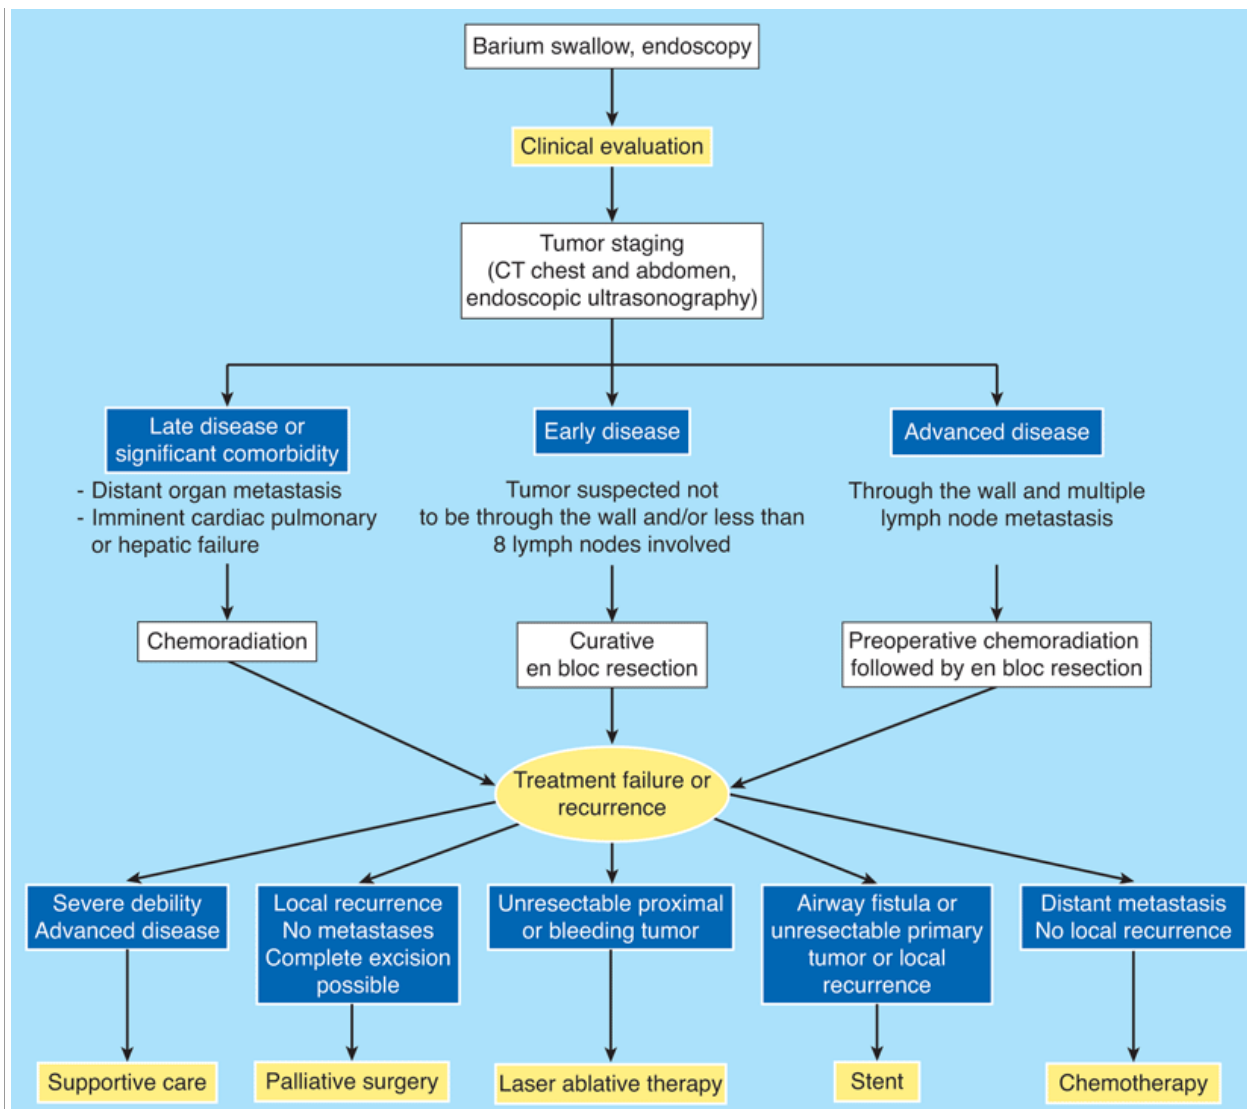

M. D. Anderson	1990	35	P, E, 5-FU	3	42% at 3 y

At present, the strongest predictors of outcome of patients with esophageal cancer are the anatomic extent of the tumor at diagnosis and the completeness of tumor removal by surgical resection. After incomplete resection of an esophageal cancer, the 5-year survival rates are 0 to 5%. In contrast, after complete resection, independent of stage of disease, 5-year survival ranges from 15 to 40%, according to selection criteria and stage distribution. The importance of early recognition and adequate surgical resection cannot be overemphasized. Figure 25-71 is a global algorithm for the management of esophageal carcinoma.

Suggested global algorithm for the management of carcinoma of the esophagus. CT = computed tomography.

SARCOMA OF THE ESOPHAGUS

Sarcomas and carcinosarcomas are rare neoplasms, accounting for approximately 0.1 to 1.5% of all esophageal tumors. They present with the symptom of dysphagia, which does not differ from the dysphagia associated with the more common epithelial carcinoma. Tumors located within the cervical or high thoracic esophagus can cause symptoms of pulmonary aspiration secondary to esophageal obstruction. Large tumors originating at the level of the tracheal bifurcation can produce symptoms of airway obstruction and syncope by direct compression of the tracheobronchial tree and heart (Fig. 25-72). The duration of dysphagia and age of the patients affected with these tumors are similar to those with carcinoma of the esophagus.

A. Computed tomographic scan of a leiomyosarcoma (black arrow) that caused compression of the heart and symptoms of syncope. **B.** Surgical specimen of leiomyosarcoma shown in **A** with a

pedunculated luminal lesion (*white arrow*) and a large extraesophageal component (*black arrow*). There was no evidence of lymph node metastasis at the time of operation.

A barium swallow usually shows a large polypoid intraluminal esophageal mass, causing partial obstruction and dilatation of the esophagus proximal to the tumor (Fig. 25-73). The smooth polypoid nature of the lesion, although not diagnostic, is distinctive enough to suggest the presence of a sarcoma rather than the more common ulcerating, stenosing carcinoma.

Fig. 25-73.

A. Barium swallow showing a large polypoid intraluminal esophageal mass causing partial obstruction and dilation of the proximal esophagus. **B.** Operative specimen showing 9-cm polypoid leiomyoblastoma.

Esophagoscopy commonly shows an intraluminal necrotic mass. When biopsy is attempted, it is important to remove the necrotic tissue until bleeding is seen on the tumor's surface. When this is not done, the biopsy specimen will show only tissue necrosis. Even when viable tumor is obtained on biopsy, it has been these authors' experience that it cannot be definitively identified as carcinoma, sarcoma, or carcinosarcoma on the basis of the histology of the portion biopsied. Biopsy results cannot be totally relied on to identify the presence of sarcoma, and it is often the polypoid nature of the lesion that arouses suspicion that it may be something other than carcinoma.

Polypoid sarcomas of the esophagus, in contrast to infiltrating carcinomas, remain superficial to the muscularis propria and are less likely to metastasize to regional LNs. In one series of 14 patients, local extension or tumor metastasis would have prevented a potentially curative resection in only five. Thus, the presence of a large polypoid tumor should not deter the surgeon from resecting the lesion.

Sarcomatous lesions of the esophagus can be divided into epidermoid carcinomas with spindle cell features, such as carcinosarcoma, and true sarcomas that arise from mesenchymal tissue, such as leiomyosarcoma, fibrosarcoma, and rhabdomyosarcoma. Based on current histologic criteria for diagnosis, fibrosarcoma and rhabdomyosarcoma of the esophagus are extremely rare lesions and may not, in fact, exist.

Surgical resection of polypoid sarcoma of the esophagus is the treatment of choice, because radiation therapy has little success and the tumors remain superficial, with local invasion or distant metastases occurring late in the course of the disease. As with carcinoma, the absence of both wall penetration and LN metastases is necessary for curative treatment, and surgical resection is consequently responsible for the majority of the reported 5-year survivals. Resection also provides an excellent means of palliating the patient's symptoms. The surgical technique for resection and the subsequent restoration of the GI continuity is similar to that described for carcinoma.

In these authors' experience, four of the eight patients with carcinosarcoma survived for 5 years or longer. Even though this number is small, it suggests that resection produces better results in epithelial carcinoma with spindle cell features than in squamous cell carcinoma of the esophagus. Similarly, with leiomyosarcoma of the esophagus, the same scattered reports exist with little information on survival. Of seven patients with leiomyosarcoma, two died from their disease—one in 3 months and the other 4 years and 7 months after resection. The other five patients were reported to have survived more than 5 years.

It is difficult to evaluate the benefits of resection for leiomyoblastoma of the esophagus, due to the small number of reported patients with tumors in this location. Most leiomyoblastomas occur in the

stomach, and 38% of these patients succumb to the cancer in 3 years. Fifty-five percent of patients with extragastric leiomyoblastoma also die from the disease, within an average of 3 years. Consequently, leiomyoblastoma should be considered a malignant lesion and apt to behave like a leiomyosarcoma. The presence of nuclear hyperchromatism, increased mitotic figures (more than one per high-power field), tumor size larger than 10 cm, and clinical symptoms of longer than 6 months' duration are associated with a poor prognosis.

BENIGN TUMORS AND CYSTS

Benign tumors and cysts of the esophagus are relatively uncommon. From the perspectives of both the clinician and the pathologist, benign tumors may be divided into those that are within the muscular wall and those that are within the lumen of the esophagus.

Intramural lesions are either solid tumors or cysts, and the vast majority are leiomyomas. They are made up of varying portions of smooth muscle and fibrous tissue. Fibromas, myomas, fibromyomas, and lipomyomas are closely related and occur rarely. Other histologic types of solid intramural tumors have been described, such as lipomas, neurofibromas, hemangiomas, osteochondromas, granular cell myoblastomas, and glomus tumors, but they are medical curiosities.

Intraluminal lesions are polypoid or pedunculated growths that usually originate in the submucosa, develop mainly into the lumen, and are covered with normal stratified squamous epithelium. The majority of these tumors are composed of fibrous tissue of varying degrees of compactness with a rich vascular supply. Some are loose and myxoid (e.g., myxoma and myxofibroma), some are more collagenous (e.g., fibroma), and some contain adipose tissue (e.g., fibrolipoma). These different types of tumor are frequently collectively designated as fibrovascular polyps, or simply as polyps. Pedunculated intraluminal tumors should be removed. If the lesion is not too large, endoscopic removal with a snare is feasible.

Leiomyoma

Leiomyomas constitute more than 50% of benign esophageal tumors. The average age at presentation is 38, which is in sharp contrast to that seen with esophageal carcinoma. Leiomyomas are twice as common in males. Because they originate in smooth muscle, 90% are located in the lower two thirds of the esophagus. They are usually solitary, but multiple tumors have been found on occasion. They vary greatly in size and shape. Tumors as small as 1 cm in diameter and as large as 10 lb have been removed.

Typically, leiomyomas are oval. During their growth, they remain intramural, having the bulk of their mass protruding toward the outer wall of the esophagus. The overlying mucosa is freely movable and normal in appearance. Neither their size nor location correlates with the degree of symptoms. Dysphagia and pain are the most common complaints, the two symptoms occurring more frequently together than separately. Bleeding directly related to the tumor is rare, and when hematemesis or melena occurs in a patient with an esophageal leiomyoma, other causes should be investigated.

A barium swallow is the most useful method to demonstrate a leiomyoma of the esophagus (Fig. 25-74). In profile, the tumor appears as a smooth, semilunar, or crescent-shaped filling defect that moves with swallowing, is sharply demarcated, and is covered and surrounded by normal mucosa. Esophagoscopy should be performed to exclude the reported observation of a coexistence with carcinoma. The freely movable mass, which bulges into the lumen, should not be biopsied because of an increased chance of mucosal perforation at the time of surgical enucleation.

Barium esophagogram showing a classical, smooth, contoured, punched-out defect of a leiomyoma.

Despite their slow growth and limited potential for malignant degeneration, leiomyomas should be removed unless there are specific contraindications. The majority can be removed by simple enucleation. If, during removal, the mucosa is inadvertently entered, the defect can be repaired primarily. After tumor removal, the outer esophageal wall should be reconstructed by closure of the muscle layer. The location of the lesion and the extent of surgery required will dictate the approach. Lesions of the proximal and middle esophagus require a right thoracotomy, whereas distal esophageal lesions require a left thoracotomy. Videothoroscopic approaches have been reported. The mortality rate associated with enucleation is <2%, and success in relieving the dysphagia is near 100%. Large lesions or those involving the GEJ may require esophageal resection.

Esophageal Cyst

Cysts may be congenital or acquired. Congenital cysts are lined wholly or partly by columnar ciliated epithelium of the respiratory type, by glandular epithelium of the gastric type, by squamous epithelium, or by transitional epithelium. In some, epithelial lining cells may be absent. Confusion over the embryologic origin of congenital cysts has led to a variety of names, such as enteric, bronchogenic, and mediastinal cysts. Acquired retention cysts also occur, probably as a result of obstruction of the excretory ducts of the esophageal glands.

Enteric and bronchogenic cysts are the most common, and arise as a result of developmental abnormalities during the formation and differentiation of the lower respiratory tract, esophagus, and stomach from the foregut. During its embryologic development, the esophagus is lined successively with simple columnar, pseudostratified ciliated columnar, and, finally, stratified squamous epithelium. This sequence probably accounts for the fact that the lining epithelium may be any or a combination of these; the presence of cilia does not necessarily indicate a respiratory origin.

Cysts vary in size from small to very large, and are usually located intramurally in the middle to lower third of the esophagus. Their symptoms are similar to those of a leiomyoma. The diagnosis similarly depends on radiographic and endoscopic findings. Surgical excision by enucleation is the preferred treatment. During removal, a fistulous tract connecting the cysts to the airways should be sought, particularly in patients who have had repetitive bronchopulmonary infections.

ESOPHAGEAL PERFORATION

Perforation of the esophagus constitutes a true emergency. It most commonly occurs following diagnostic or therapeutic procedures. Spontaneous perforation, referred to as *Boerhaave's syndrome*, accounts for only 15% of cases of esophageal perforation, foreign bodies for 14%, and trauma for 10%. Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred,

particularly if located in the cervical area following instrumentation of the esophagus, or substernally in a patient with a history of resisting vomiting. If subcutaneous emphysema is present, the diagnosis is almost certain.

Spontaneous rupture of the esophagus is associated with a high mortality rate because of the delay in recognition and treatment. Although there usually is a history of resisting vomiting, in a small number of patients, the injury occurs silently, without any antecedent history. When the chest radiogram of a patient with an esophageal perforation shows air or an effusion in the pleural space, the condition is often misdiagnosed as a pneumothorax or pancreatitis. An elevated serum amylase caused by the extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest radiogram is normal, a mistaken diagnosis of myocardial infarction or dissecting aneurysm is often made.

Spontaneous rupture usually occurs into the left pleural cavity or just above the GEJ. Fifty percent of patients have concomitant GERD, suggesting that minimal resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. During vomiting, high peaks of intragastric pressure can be recorded, frequently exceeding 200 mmHg, but because extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably, depending on the position of the GEJ. When it is in the abdomen and exposed to intra-abdominal pressure, the pressure transmitted to the esophagus is much less than when it is exposed to the negative thoracic pressure. In the latter situation, the pressure in the lower esophagus will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mmHg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is due to the stretching of the supradiaphragmatic portion of the gastric wall. In this situation, the hernia sac represents an extension of the abdominal cavity, and the GEJ remains exposed to abdominal pressure.

Diagnosis

Abnormalities on the chest radiogram can be variable and should not be depended upon to make the diagnosis. This is because the abnormalities are dependent on three factors: (a) the time interval between the perforation and the radiographic examination, (b) the site of perforation, and (c) the integrity of the mediastinal pleura. Mediastinal emphysema, a strong indicator of perforation, takes at least 1 hour to be demonstrated, and is present in only 40% of patients. Mediastinal widening secondary to edema may not occur for several hours. The site of perforation also can influence the radiographic findings. In cervical perforation, cervical emphysema is common and mediastinal emphysema rare; the converse is true for thoracic perforations. Frequently, air will be visible in the erector spinae muscles on a neck radiogram before it can be palpated or seen on a chest radiogram (Fig. 25-75). The integrity of the mediastinal pleura influences the radiographic abnormality in that rupture of the pleura results in a pneumothorax, a finding that is seen in 77% of patients. In two thirds of patients, the perforation is on the left side; in one fifth, it is on the right side; and in one tenth, it is bilateral. If pleural integrity is maintained, mediastinal emphysema (rather than a pneumothorax) appears rapidly. A pleural effusion secondary to inflammation of the mediastinum occurs late. In 9% of patients, the chest radiogram is normal.

Chest radiogram showing air in the deep muscles of the neck following perforation of the esophagus (*arrow*). This is often the earliest sign of perforation and can be present without evidence of air in the mediastinum.

The diagnosis is confirmed with a contrast esophagogram, which will demonstrate extravasation in 90% of patients. The use of a water-soluble medium such as Gastrografin is preferred. Of concern is that there is a 10% false-negative rate. This may be due to obtaining the radiographic study with the patient in the upright position. When the patient is upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position (Fig. 25-76). In this, the contrast material fills the entire length of the esophagus, allowing the actual site of perforation and its interconnecting cavities to be visualized in almost all patients.

Fig. 25-76.

Radiographic study of a patient with a perforation of the esophagus using water-soluble contrast material. The patient is placed in the lateral decubitus position with the left side up to allow complete filling of the esophagus and demonstration of the defect.

Management

The key to optimum management is early diagnosis. The most favorable outcome is obtained following primary closure of the perforation within 24 hours, resulting in 80 to 90% survival. Figure 25-77 is an operative photograph taken through a left thoracotomy of an esophageal rupture following a pneumatic dilation for achalasia. The most common location for the injury is the left lateral wall of the esophagus, just above the GEJ. To get adequate exposure of the injury, a dissection similar to that described for esophageal myotomy is performed. A flap of stomach is pulled up and the soiled fat pad at the GEJ is removed. The edges of the injury are trimmed and closed using a modified Gambee stitch (Fig. 25-78). The closure is reinforced by the use of a pleural patch or construction of a Nissen fundoplication.

Fig. 25-77.

The technique of closure of an esophageal perforation through a left thoracotomy. **A.** A tongue of stomach is pulled up through the esophageal hiatus, and the gastroesophageal fat pad is removed; the edges of the mucosal injury are trimmed and closed using interrupted modified Gambee stitches. **B.** Reinforcement of the closure with a parietal pleural patch.

Mortality associated with immediate closure varies between 8 and 20%. After 24 hours, survival decreases to <50%, and is not influenced by the type of operative therapy (i.e., drainage alone or drainage plus closure of the perforation). If the time delay before closing a perforation approaches 24 hours and the tissues are inflamed, division of the cardia and resection of the diseased portion of the esophagus are recommended. The remainder of the esophagus is mobilized, and as much normal esophagus as possible is saved and brought out as an end cervical esophagostomy. In some situations, the retained esophagus may be so long that it loops down into the chest. The contaminated mediastinum is drained and a feeding jejunostomy tube is inserted. The recovery from sepsis is often immediate, dramatic, and reflected by a marked improvement in the patient's condition over a 24-hour period. On recovery from the sepsis, the patient is discharged and returns on a subsequent date for reconstruction with a substernal colon interposition. Failure to apply this aggressive therapy can result in a mortality rate in excess of 50% in patients in whom the diagnosis has been delayed.

Nonoperative management of esophageal perforation has been advocated in select situations. The choice of conservative therapy requires skillful judgment and necessitates careful radiographic examination of the esophagus. This course of management usually follows an injury occurring during dilation of esophageal strictures or pneumatic dilations of achalasia. Conservative management should not be used in patients who have free perforations into the pleural space. Cameron proposed three criteria for the nonoperative management of esophageal perforation: (a) The barium swallow must show the perforation to be contained within the mediastinum and drain well back into the esophagus (Fig. 25-79), (b) symptoms should be mild, and (c) there should be minimal evidence of clinical sepsis. If these conditions are met, it is reasonable to treat the patient with hyperalimentation, antibiotics, and cimetidine to decrease acid secretion and diminish pepsin activity. Oral intake is resumed in 7 to 14 days, dependent on subsequent radiographic examinations.

Barium esophagogram showing a stricture and a contained perforation following dilation. The injury meets Cameron criteria: It is contained within the mediastinum and drawn back into the esophagus, the patient had mild symptoms, and there was no evidence of clinical sepsis. Nonoperative management was successful.

MALLORY-WEISS SYNDROME

In 1929, Mallory and Weiss described four patients with acute upper GI bleeding who were found at autopsy to have mucosal tears at the GEJ. This syndrome, characterized by acute upper GI bleeding following repeated vomiting, is considered to be the cause of up to 15% of all severe upper GI bleeds. The mechanism is similar to spontaneous esophageal perforation: an acute increase in intra-abdominal pressure against a closed glottis in a patient with a hiatal hernia.

Mallory-Weiss tears are characterized by arterial bleeding, which may be massive. Vomiting is not an obligatory factor, as there may be other causes of an acute increase in intra-abdominal pressure, such as paroxysmal coughing, seizures, and retching. The diagnosis requires a high index of suspicion, particularly in the patient who develops upper GI bleeding following prolonged vomiting or retching. Upper endoscopy confirms the suspicion by identifying one or more longitudinal fissures in the mucosa of the herniated stomach as the source of bleeding.

In the majority of patients, the bleeding will stop spontaneously with nonoperative management. In addition to blood replacement, the stomach should be decompressed and antiemetics administered, as a distended stomach and continued vomiting aggravate further bleeding. A Sengstaken-Blakemore tube will not stop the bleeding, as the pressure in the balloon is not sufficient to overcome arterial pressure. Endoscopic injection of epinephrine may be therapeutic if bleeding does not stop spontaneously. Only occasionally will surgery be required to stop blood loss. The procedure consists of laparotomy and high gastrotomy with oversewing of the linear tear. Mortality is uncommon, and recurrence is rare.

CAUSTIC INJURY

Accidental caustic lesions occur mainly in children, and, in general, rather small quantities of caustics are taken. In adults or teenagers, the swallowing of caustic liquids is usually deliberate, during suicide attempts, and greater quantities are swallowed. Alkalies are more frequently swallowed accidentally than acids, because strong acids cause an immediate burning pain in the mouth.

Pathology

The swallowing of caustic substances causes an acute and a chronic injury. During the acute phase, care focuses on controlling the immediate tissue injury and the potential for perforation. During the chronic phase, the focus is on treatment of strictures and disturbances in pharyngeal swallowing. In the acute phase, the degree and extent of the lesion are dependent on several factors: the nature of the

caustic substance, its concentration, the quantity swallowed, and the time the substance is in contact with the tissues.

Acids and alkalies affect tissue in different ways. Alkalies dissolve tissue, and therefore penetrate more deeply, while acids cause a coagulative necrosis that limits their penetration. Animal experiments have shown that there is a correlation between the depth of the lesion and the concentration of sodium hydroxide solution. When a solution of 3.8% comes into contact with the esophagus for 10 seconds, it causes necrosis of the mucosa and the submucosa, but spares the muscular layer. A concentration of 22.5% penetrates the whole esophageal wall and into the periesophageal tissues. Cleansing products can contain up to 90% sodium hydroxide. The strength of esophageal contractions varies according to the level of the esophagus, being weakest at the striated muscle–smooth muscle interface. Consequently, clearance from this area may be somewhat slower, allowing caustic substances to remain in contact with the mucosa longer. This explains why the esophagus is preferentially and more severely affected at this level than in the lower portions.

The lesions caused by lye injury occur in three phases. First is the acute necrotic phase, lasting 1 to 4 days after injury. During this period, coagulation of intracellular proteins results in cell necrosis, and the living tissue surrounding the area of necrosis develops an intense inflammatory reaction. Second is the ulceration and granulation phase, starting 3 to 5 days after injury. During this period, the superficial necrotic tissue sloughs, leaving an ulcerated, acutely inflamed base, and granulation tissue fills the defect left by the sloughed mucosa. This phase lasts 10 to 12 days, and it is during this period that the esophagus is the weakest. Third is the phase of cicatrization and scarring, which begins the third week following injury. During this period, the previously formed connective tissue begins to contract, resulting in narrowing of the esophagus. Adhesions between granulating areas occur, resulting in pockets and bands. It is during this period that efforts must be made to reduce stricture formation.

Clinical Manifestations

The clinical picture of an esophageal burn is determined by the degree and extent of the lesion. In the initial phase, complaints consist of pain in the mouth and substernal region, hypersalivation, pain on swallowing, and dysphagia. The presence of fever is strongly correlated with the presence of an esophageal lesion. Bleeding can occur, and frequently, the patient vomits. These initial complaints disappear during the quiescent period of ulceration and granulation. During the cicatrization and scarring phase, the complaint of dysphagia reappears and is due to fibrosis and retraction, resulting in narrowing of the esophagus. Of the patients who develop strictures, 60% do so within 1 month, and 80% within 2 months. If dysphagia does not develop within 8 months, it is unlikely that a stricture will occur. Serious systemic reactions such as hypovolemia and acidosis resulting in renal damage can occur in cases in which the burns have been caused by strong acids. Respiratory complications such as laryngospasm, laryngoedema, and occasionally pulmonary edema can occur, especially when strong acids are aspirated.

Inspection of the oral cavity and pharynx can indicate that caustic substances were swallowed, but does not reveal that the esophagus has been burned. Conversely, esophageal burns can be present without apparent oral injuries. Because of this poor correlation, early esophagoscopy is advocated to establish the presence of an esophageal injury. To lessen the chance of perforation, the scope should not be introduced beyond the proximal esophageal lesion. The degree of injury can be graded according to the criteria listed in Table 25-17. Even if the esophagoscopy is normal, strictures may appear later. Radiographic examination is not a reliable means to identify the presence of early esophageal injury, but is important in later follow-up to identify strictures. The most common locations of caustic injuries are shown in Table 25-18.

Table 25-17 Endoscopic Grading of Corrosive Esophageal and Gastric Burns
First degree: Mucosal hyperemia and edema
Second degree: Limited hemorrhage, exudate ulceration, and pseudomembrane formation
Third degree: Sloughing of mucosa, deep ulcers, massive hemorrhage, complete obstruction of lumen by edema, charring, and perforation

Table 25-18 Location of Caustic Injury (n = 62)	
Pharynx	10%
Esophagus	70%
Upper	15%
Middle	65%
Lower	2%
Whole	18%
Stomach	20%
Antral	91%
Whole	9%
Both stomach and esophagus	14%

Treatment

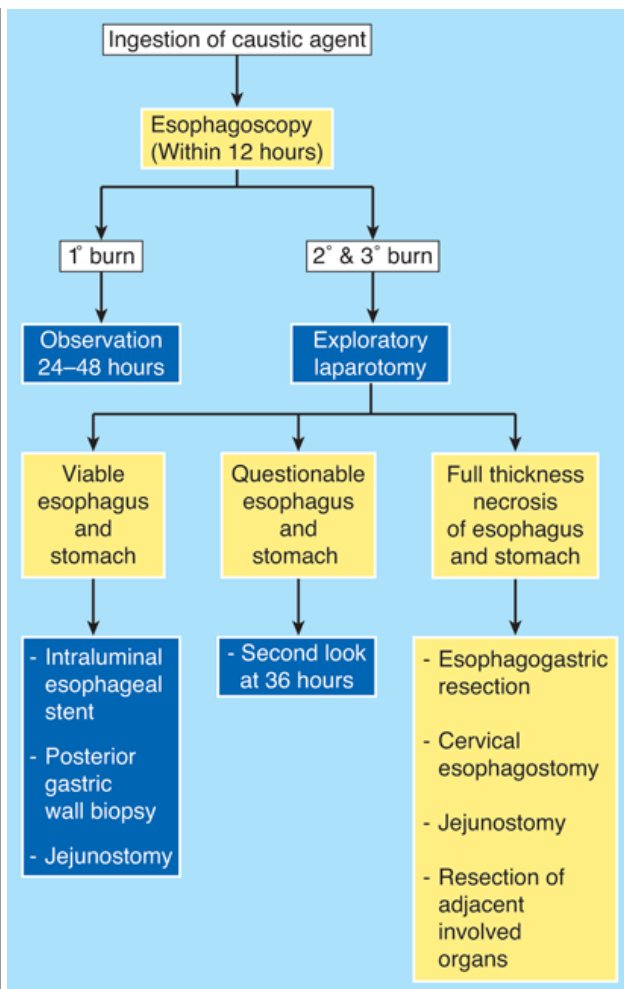

Treatment of a caustic lesion of the esophagus is directed toward management of both the immediate and late consequences of the injury. The immediate treatment consists of limiting the burn by administering neutralizing agents. To be effective, this must be done within the first hour. Lye or other alkali can be neutralized with half-strength vinegar, lemon juice, or orange juice. Acid can be neutralized with milk, egg white, or antacids. Sodium bicarbonate is not used because it generates carbon dioxide, which might increase the danger of perforation. Emetics are contraindicated, because vomiting renews the contact of the caustic substance with the esophagus and can contribute to perforation if too forceful. Hypovolemia is corrected and broad-spectrum antibiotics are administered to lessen the inflammatory reaction and prevent infectious complications. If necessary, a feeding jejunostomy tube is inserted to provide nutrition. Oral feeding can be started when the dysphagia of the initial phase has regressed.

In the past, surgeons waited until the appearance of a stricture before starting treatment. Currently, dilations are started the first day after the injury, with the aim of preserving the esophageal lumen by removing the adhesions that occurred in the injured segments. However, this approach is controversial in that dilations can traumatize the esophagus, causing bleeding and perforation, and there are data indicating that excessive dilations cause increased fibrosis secondary to the added trauma. The use of steroids to limit fibrosis has been shown to be effective in animals, but their effectiveness in human beings is debatable.

Extensive necrosis of the esophagus frequently leads to perforation, and is best managed by resection. When there is extensive gastric involvement, the esophagus is nearly always necrotic or severely burned, and total gastrectomy and near-total esophagectomy are necessary. The presence of air in the esophageal wall is a sign of muscle necrosis and impending perforation and is a strong indication for esophagectomy.

Management of acute injury is summarized in the algorithm in Fig. 25-80. Some authors have advocated the use of an intraluminal esophageal stent (Fig. 25-81) in patients who are operated on and found to have no evidence of extensive esophagogastric necrosis. In these patients, a biopsy of the posterior gastric wall should be performed to exclude occult injury. If, histologically, there is a question of viability, a second-look operation should be done within 36 hours. If a stent is inserted, it should be kept in position for 21 days, and removed after a satisfactory barium esophagogram. Esophagoscopy should be done, and, if strictures are present, dilations initiated.

The use of an esophageal stent to prevent stricture. The stent is constructed from a chest tube and placed in the esophagus at the time of an exploratory laparotomy. A Penrose drain is placed over the distal end as a flap valve to prevent reflux. The stent is supported at its upper end by attaching it to a suction catheter that is secured to the nares. Continuous suction removes saliva and mucus trapped in the pharynx and upper esophagus.

Once the acute phase has passed, attention is turned to the prevention and management of strictures. Both antegrade dilation with a Hurst or Maloney bougie and retrograde dilation with a Tucker bougie have been satisfactory. Occasionally, particularly with severe strictures, the patient is instructed to swallow a string, over which metal Sippy dilators are passed until an adequate lumen can be obtained for passage of a mercury bougie. In a series of 1079 patients, early dilations started during the acute phase gave excellent results in 78%, good results in 13%, and poor results in 2%. Fifty-five patients died during the treatment. In contrast, of 333 patients whose strictures were dilated when they became symptomatic, only 21% had excellent results, 46% good, and 6% poor, with three dying during the process. The length of time the surgeon should persist with dilation before consideration of esophageal resection is problematic. An adequate lumen should be re-established within 6 months to 1 year, with progressively longer intervals between dilations. If, during the course of treatment, an adequate lumen cannot be established or maintained (i.e., smaller bougies must be used), operative intervention should be considered. Surgical intervention is indicated when there is (a) complete stenosis in which all attempts from above and below have failed to establish a lumen, (b) marked irregularity and pocketing on barium swallow, (c) the development of a severe periesophageal reaction or mediastinitis with dilatation, (d) a fistula, (e) the inability to dilate or maintain the lumen above a 40F bougie, or (f) a patient who is unwilling or unable to undergo prolonged periods of dilation.

The variety of abnormalities seen requires that creativity be used when considering esophageal reconstruction. Skin tube esophagoplasties are now used much less frequently than they were in the past, and are mainly of historical interest. Currently, the stomach, jejunum, and colon are the organs used to replace the esophagus, through either the posterior mediastinum or the retrosternal route. A retrosternal route is chosen when there has been a previous esophagectomy or there is extensive fibrosis in the posterior mediastinum. When all factors are considered, the order of preference for an esophageal substitute is (a) colon, (b) stomach, and (c) jejunum. Free jejunal grafts based on the superior thyroid artery have provided excellent results. Whatever method is selected, it must be emphasized that these procedures cannot be taken lightly; minor errors of judgment or technique may lead to serious or even fatal complications.

Critical in the planning of the operation is the selection of cervical esophagus, pyriform sinus, or posterior pharynx as the site for proximal anastomosis. The site of the upper anastomosis depends on the extent of the pharyngeal and cervical esophageal damage encountered. When the cervical esophagus is destroyed and a pyriform sinus remains open the anastomosis can be made to the hypopharynx (Fig. 25-82). When the pyriform sinuses are completely stenosed, a transglottic approach is used to perform an anastomosis to the posterior oropharyngeal wall (Fig. 25-83). This allows excision of supraglottic strictures and elevation and anterior tilting of the larynx. In both of these situations, the patient must relearn to swallow. Recovery is long and difficult and may require several endoscopic dilations, and

often reoperations. Sleeve resections of short strictures are not successful because the extent of damage to the wall of the esophagus can be greater than realized, and almost invariably the anastomosis is carried out in a diseased area.

Fig. 25-82.

Anastomosis of the bowel to the posterior oropharynx. The anastomosis is done through an inverted trapezoid incision above the thyroid cartilage (*dotted line*). A triangle-shaped piece of the upper half of the cartilage is resected. Closure of the oropharynx is done so that the larynx is pulled up (sagittal section).

The management of a bypassed damaged esophagus after injury is problematic. If the esophagus is left in place, ulceration from gastroesophageal reflux or the development of carcinoma must be considered. The extensive dissection necessary to remove the esophagus, particularly in the presence of marked periesophagitis, is associated with significant morbidity. Leaving the esophagus in place preserves the function of the vagus nerves, and, in turn, the function of the stomach. On the other hand, leaving a damaged esophagus in place can result in multiple blind sacs and subsequent development of mediastinal abscesses years later. Most experienced surgeons recommend that the esophagus be removed unless the operative risk is unduly high.

ACQUIRED FISTULA

The esophagus lies in close contact with the membranous portion of the trachea and left bronchus, predisposing to the formation of fistula to these structures. Most acquired esophageal fistulas are to the tracheobronchial tree, and secondary to either esophageal or pulmonary malignancy. Traumatic fistulas and those associated with esophageal diverticula account for the remainder. Fistulas associated with traction diverticula are usually due to mediastinal inflammatory disease, and traumatic fistulas usually occur secondary to penetrating wounds, lye ingestion, or iatrogenic injury.

These fistulas are characterized by paroxysmal coughing following the ingestion of liquids, and by recurrent or chronic pulmonary infections. The onset of cough immediately after swallowing suggests aspiration, whereas a brief delay (30 to 60 seconds) suggests a fistula.

Spontaneous closure is rare, owing to the presence of malignancy or a recurrent infectious process. Surgical treatment of benign fistulas consists of division of the fistulous tract, resection of irreversibly damaged lung tissue, and closure of the esophageal defect. To prevent recurrence, a pleural flap should be interposed. Treatment of malignant fistulas is difficult, particularly in the presence of prior irradiation. Generally, only palliative treatment is indicated. This can best be done by using a specially designed esophageal endoprosthesis that bridges and occludes the fistula, allowing the patient to eat. Rarely, esophageal diversion, coupled with placement of a feeding jejunostomy, can be used as a last resort.

TECHNIQUES OF ESOPHAGEAL RECONSTRUCTION

Options for esophageal substitution include gastric advancement, colonic interposition, and either jejunal free transfer or advancement into the chest. Rarely, combinations of these grafts will be the only possible option. The indications for esophageal resection and substitution include malignant and end-stage benign disease. The latter includes reflux- or drug-induced stricture formation that cannot be dilated without damage to the esophagus, a dilated and tortuous esophagus secondary to severe motility disorders, lye-induced strictures, and multiple previous antireflux procedures. The choice of esophageal substitution has significant impact upon the technical difficulty of the procedure, and influences the long-term outcome.

Partial Esophageal Resection

Low-lying benign lesions, with preserved proximal esophageal function, are best treated with the interposition of a segment of proximal jejunum into the chest and primary anastomosis. A jejunal interposition can reach to the inferior border of the pulmonary hilum with ease, but the architecture of its blood supply rarely allows the use of the jejunum above this point. Because the anastomosis is within the chest, a thoracotomy is necessary.

The jejunum is a dynamic graft and contributes to bolus transport, whereas the stomach and colon function more as a conduit. The stomach is a poor choice in this circumstance because of the propensity for the reflux of gastric contents into the upper esophagus following an intrathoracic esophagogastrostomy. It is now well recognized that this occurs, and can lead to incapacitating symptoms and esophageal destruction in some patients. Short segments of colon, on the other hand, lack significant motility and have a propensity for the development of esophagitis above the anastomosis.

Replacement of the cervical portion of the esophagus, while preserving the distal portion, is occasionally indicated in cervical esophageal or head and neck malignancy, and following the ingestion of lye. Free transfer of a portion of jejunum to the neck has become a viable option and is successful in the majority of cases. Revascularization is achieved via use of the internal mammary artery and the internal mammary or innominate vein. Removal of the sternoclavicular joint aids in performing the vascular and distal esophageal anastomosis (Fig. 25-84).

Reconstruction after Total Esophagectomy

Neither the intrathoracic stomach nor the intrathoracic colon functions as well as the native esophagus after an esophagogastrectomy. The choice between these organs will be influenced by several factors, such as the adequacy of their blood supply and the length of resected esophagus that they are capable of bridging. If the stomach shows evidence of disease, or has been contracted or reduced by previous gastric surgery, the length available for esophageal replacement may not be adequate. The presence of diverticular disease, unrecognized carcinoma, or colitis prohibits the use of the colon. The blood supply of the colon is more affected by vascular disease than the blood supply of the stomach, which may prevent its use. Of the two, the colon provides the longest graft. The stomach can usually reach to the neck if the amount of lesser curvature resected does not interfere with the blood supply to the fundus. Gastric interposition has the advantage that only one anastomosis is required. On the other hand, there is greater potential for aspiration of gastric juice or stricturing of the cervical anastomosis from chronic reflux when stomach is used for replacement.

Following an esophagogastrectomy, patients may have discomfort during or shortly after eating. The most common symptom is a postprandial pressure sensation or a feeling of being stuffed, which probably results from the loss of the gastric reservoir. This symptom is less common when the colon is used as an esophageal substitute, probably because the distal third of the stomach is retained in the abdomen and the interposed colon provides an additional reservoir function.

King and Hölscher have reported a 40 and 50% incidence of dysphagia after re-establishing GI continuity with the stomach following esophagogastrectomy. This incidence is similar to Orringer's results after using the stomach to replace the esophagus in patients with benign disease. More than one-half of the patients experienced dysphagia postoperatively; two-thirds of this group required postoperative dilation and one-fourth had persistent dysphagia and required home dilation. By contrast, dysphagia is uncommon and the need for dilation is rare following a colonic interposition. Isolauri reported on 248 patients with colonic interpositions and noted a 24% incidence of dysphagia 12 months after the operation. When it occurred, the most common cause was recurrent mediastinal tumor. The high incidence of dysphagia with the use of the stomach is probably related to the esophagogastric anastomosis in the neck and the resulting difficulty of passing a swallowed bolus.

Another consequence of the transposition of the stomach into the chest is the development of postoperative duodenogastric reflux, probably due to pyloric denervation, and adding a pyloroplasty may worsen this problem. Following gastric advancement, the pylorus lies at the level of the esophageal hiatus, and a distinct pressure differential develops between the intrathoracic gastric and intra-abdominal duodenal lumina. Unless the pyloric valve is extremely efficient, the pressure differential will encourage reflux of duodenal contents into the stomach. Duodenogastric reflux is less likely to occur following colonic interposition, because there is sufficient intra-abdominal colon to be compressed by the abdominal pressure, and the pylorus and duodenum remain in their normal intra-abdominal position.

Although there is general acceptance of the concept that an esophagogastric anastomosis in the neck results in less postoperative esophagitis and stricture than one at a lower level, reflux esophagitis following a cervical anastomosis does occur, albeit at a slower rate than when the anastomosis is at a lower level. Most patients undergo cervical esophagogastronomy for malignancy; thus the long-term sequelae of an esophagogastric anastomosis in the neck are not of concern. However, patients who have had a cervical esophagogastronomy for benign disease may develop problems associated with the

anastomosis in the fourth or fifth postoperative year that are severe enough to require anastomotic revision. This is less likely in patients who have had a colonic interposition for esophageal replacement. Consequently, in patients who have a benign process or a potentially curable carcinoma of the esophagus or cardia, a colonic interposition is used to obviate the late problems associated with a cervical esophagogastrostomy. Colonic interposition for esophageal substitution is a more complex procedure than gastric advancement, with the potential for greater perioperative morbidity, particularly in inexperienced hands.

Composite Reconstruction

Occasionally, a combination of colon, jejunum, and stomach is the only reconstructive option available. This situation may arise when there has been previous gastric or colonic resection, when dysphagia has recurred after a previous esophageal resection, or following postoperative complications such as ischemia of an esophageal substitute. Although not ideal, combinations of colon, jejunum, and stomach used to restore GI continuity function surprisingly well, and allow alimentary reconstruction in an otherwise impossible situation.

Vagal Sparing Esophagectomy with Colon Interposition

Traditional esophagectomy typically results in bilateral vagotomy and its attendant consequences. It is likely that symptoms such as dumping, diarrhea, early satiety, and weight loss seen in 15 to 20% of patients postesophagectomy are at least in part, if not completely, due to vagal interruption. The technique of vagal sparing esophagectomy with colon interposition has been described in an effort to avoid the morbidities associated with standard esophagectomy.

Through an upper midline abdominal incision, the right and left vagal nerves are identified, circled with a tape, and retracted to the right. A limited, highly selective proximal gastric vagotomy is performed along the cephalad 4 cm of the lesser curvature. The stomach is divided with an Endo-GIA stapler just below the GEJ. The colon is prepared to provide an interposed segment as previously described. A neck incision is made along the anterior border of the left sternocleidomastoid muscle, and the strap muscles are exposed. The omohyoid muscle is divided at its pulley, and the sternohyoid and sternothyroid muscles are divided at their manubrial insertion. The left carotid sheath is retracted laterally and the thyroid and trachea medially. The left inferior thyroid artery is ligated laterally as it passes under the left common carotid artery. The left recurrent laryngeal nerve is identified and protected. The esophagus is dissected out circumferentially in an inferior direction, from the left neck to the apex of the right chest, to avoid injury to the right recurrent laryngeal nerve. The esophagus is divided at the level of the thoracic inlet, leaving about 3 to 4 cm of cervical esophagus. The proximal esophagus is retracted anteriorly and to the right with the use of two sutures to keep saliva and oral contents from contaminating the neck wound.

Returning to the abdomen, the proximal staple line of the gastric division is opened and the esophagus is flushed with povidone-iodine solution. A vein stripper is passed up the esophagus into the neck wound. The distal portion of the esophagus in the neck is secured tightly around the stripping cable with "endoloops" and an umbilical tape for a trailer. The tip of the stripper is exchanged for a mushroom head, and the stripper is pulled back into the abdomen, inverting the esophagus as it transverses the posterior mediastinum. This maneuver strips the branches of the esophageal plexus off the longitudinal muscle of the esophagus, preserving the esophageal plexus along with the proximal vagal nerves and the distal vagal nerve trunks. In patients with end-stage achalasia, only the mucosa is secured around the stripping cable, so that it alone is stripped and the dilated muscular wall of the esophagus, with its enriched blood supply, remains. The resulting mediastinal tunnel, or in the case of achalasia the muscular tube, is dilated with a Foley catheter containing 90 mL of fluid in the balloon. The previously prepared interposed portion of the transverse colon is passed behind the stomach and up through the mediastinal tunnel into the neck. An end-to-end anastomosis is performed to the cervical esophagus using a single layer technique. The colon is pulled taut and secured to the left crus with four or five interrupted sutures. Five centimeters below the crura, an opening is made in the mesentery adjacent to the colon along its mesenteric border, through which an Endo-GIA stapler is passed and the colon is divided. The proximal end, which is the distal end of the interposed colon, is anastomosed high on the posterior fundic wall of the stomach, using a triangular stapling anastomotic technique. This is done by stapling longitudinally the stomach and colon together with a 75-mm Endo-GIA stapler, spreading the base of the incision apart, and closing it with a T-55 stapler. Colonic continuity is re-established by bringing the proximal right colon to the distal staple line in the left colon and performing an end-to-end anastomosis using a double layer technique.

Although conceptually appealing, preservation of vagal nerve integrity or the gastric reservoir function after vagal sparing esophagectomy only recently has been validated. Banki and associates compared patients undergoing vagal sparing esophagectomy to those with conventional esophagectomy and colon or gastric interposition. This study showed that vagal sparing esophagectomy preserved gastric secretion, gastric emptying, meal capacity, and body mass index, when compared to esophagogastrrectomy with colon interposition or standard esophagectomy with gastric pull-up. Vagal sparing esophagectomy patients functioned, for the most part, similarly to normal subjects, allowing them to eat a normal meal, free of dumping or diarrhea. These results indicate that the vagal sparing esophagectomy procedure does indeed preserve the vagal nerves, and may be considered in the treatment of benign and early malignant lesions requiring esophagectomy.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 26. Stomach >

KEY POINTS

1. Any patient admitted to a hospital because of peptic ulcer disease should be placed on lifelong acid suppression.
2. Patients who regularly take NSAIDs or aspirin should take concomitant acid suppressive medication if they are more than age 60 years old, or on anticoagulants, or if they have multiple medical comorbidities.
3. Lifelong acid suppressive medication may be equivalent to surgical vagotomy in preventing recurrent peptic ulcer or ulcer complications.
4. Gastric resection for peptic ulcer should be avoided in the asthenic or high-risk patient.
5. Many patients with locally advanced gastric cancer (T2b, T3, T4) are cured by an oncologically sound operation that includes wide margins and adequate lymphadenectomy.
6. Most patients with primary gastric lymphoma can be treated without gastric resection.
7. Gastric carcinoids should usually be removed either endoscopically or surgically. The surgeon should treat gastric carcinoid without hypergastrinemia (type 3) as if it were malignant.
8. Roux-en-Y gastrojejunostomy should be avoided unless more than half of the stomach has been removed. Otherwise marginal ulceration and/or gastric stasis (Roux syndrome) may become problematic.

HISTORY

The stomach is a remarkable organ with important digestive, nutritional, and endocrine functions. The stomach stores and facilitates the digestion and absorption of ingested food, and it helps regulate appetite. Treatable diseases of the stomach are common, and it is accessible and relatively forgiving. Thus, the stomach is a favorite therapeutic target. To provide intelligent diagnosis and treatment, the physician and surgeon must understand gastric anatomy, physiology, and pathophysiology. This includes a sound understanding of the mechanical, secretory, and endocrine processes through which the stomach accomplishes its important functions. It also includes a familiarity with the common benign and malignant gastric disorders of clinical significance. The purpose of this chapter is to enhance the reader's current understanding and familiarity with these concepts and topics. Some important milestones in the history of gastric surgery^{1–6} are listed in Table 26-1.

Table 26-1 Historic Milestones in Gastric Surgery

Date	Event
350 B.C. – 201 A.D.	Existence of gastric ulceration was acknowledged by Diocles of Carystos (350 B.C.), Celsus, and Galen (131–201 A.D.).
1363	Guy de Chauliac describes closure of gastric wound.
1586	Marcellus Donatus of Mantua describes gastric ulcer at autopsy.
1600– 1700	Reports of surgeons cutting stomach to remove foreign bodies.
1688	Muralto describes duodenal ulcer at autopsy.
1737	Morgagni describes both gastric and duodenal ulcer at autopsy.
1833	William Beaumont reports data recorded during his care of Alexis St. Martin who developed a gastric fistula from a left upper quadrant musket wound.
1869	Maury reportedly performs feeding gastrostomy to palliate esophageal stricture following consultation with Samuel D. Gross.
1875	Sidney Jones in London publishes the first successful gastrostomy for feeding.
1879	Paen performed distal gastrectomy and gastroduodenostomy. The patient died 5 d later.
1880	Rydygier resected a distal gastric cancer, and the patient died 12 h later.
1880	Billroth resects distal gastric cancer and performs gastroduodenostomy (Billroth I). Patient Therese Heller recovers and survives 4 mo.

1881	Anton Wolfler performs loop gastrojejunostomy to palliate an obstructing distal gastric cancer.
1884	Rydygier reports an unsuccessful gastrojejunostomy for benign gastric outlet obstruction.
1885	Billroth performs a successful distal gastrectomy and gastrojejunostomy (Billroth II) for gastric cancer.
1886	Heineke performs pyloroplasty.
1888	Mikulicz performs similar operation.
1892	Jaboulay describes bypassing the intact pylorus with gastroduodenostomy.
1902	Finney from Baltimore describes pyloroplasty technique.
1891–1913	Different techniques of gastrostomy are described by Witzel (1891), Stamm (1894), and Janeway (1913).
1920–1950	Subtotal gastrectomy grows popular as an operation for peptic ulcer. Von Haberer and Finsterer proponents.
1943	Dragstedt and Owen describe transthoracic truncal vagotomy to treat peptic ulcer disease. By the early 1950s, it is well recognized that some patients developed gastric stasis after this procedure, and transabdominal truncal vagotomy and drainage (pyloroplasty or gastrojejunostomy) become a standard ulcer operation.
1952	Farmer and Smithwick describe good results with truncal vagotomy and hemigastrectomy for peptic ulcer.
1953	Edwards and Herrington (Nashville) describe truncal vagotomy and antrectomy for peptic ulcer.
1955	Zollinger and Ellison describe the eponymous syndrome.
1957	Griffith and Harkins (Seattle) describe parietal cell vagotomy (highly selective vagotomy) for the elective treatment of peptic ulcer disease.
1980–2000	Japanese surgeons and other surgical groups from East Asia demonstrate that more aggressive lymphadenectomy may improve survival in patients with gastric cancer.
1990–current	Evolving role of laparoscopic techniques in the treatment of surgical gastric disease.
1995–current	Dramatic increase in bariatric operations.
2000–current	Development of natural orifice transluminal endoscopic surgery.

ANATOMY

Anatomic Relationships and Gross Morphology

The stomach is readily recognizable as the asymmetrical, pear-shaped, most proximal abdominal organ of the digestive tract (Fig. 26-1).⁷ The part of the stomach attached to the esophagus is called the cardia. Just proximal to the cardia at the gastroesophageal (GE) junction is the anatomically indistinct but physiologically demonstrable lower esophageal sphincter. At the distal end, the pyloric sphincter connects the stomach to the proximal duodenum. The stomach is relatively fixed at these points, but the large midportion is quite mobile.

Fig. 26-1.

The superior-most part of the stomach is the distensible floppy fundus, bounded superiorly by the diaphragm and laterally by the spleen. The angle of His is where the fundus meets the left side of the GE junction. Generally, the inferior extent of the fundus is considered to be the horizontal plane of the GE junction, where the body (corpus) of the stomach begins. The body of the stomach contains most of the parietal (oxyntic) cells, some of which are also present in the cardia and fundus. The body is bounded on the right by the relatively straight lesser curvature and on the left by the more curved greater curvature. At the angularis incisura, the lesser curvature turns rather abruptly to the right, marking the anatomic beginning of the antrum, which comprises the distal 25 to 30% of the stomach.

The organs that commonly abut the stomach are the liver, colon, spleen, pancreas, and occasionally the kidney (Fig. 26-2). The left lateral segment of the liver usually covers a large part of the anterior stomach. Inferiorly, the stomach is attached to the transverse colon by the gastrocolic omentum. The lesser curvature is tethered to the liver by the hepatogastric ligament, also referred to as the lesser omentum or pars flaccida. Posterior to the stomach is the lesser omental bursa and the pancreas.

Arterial and Venous Blood Supply

The stomach is the most richly vascularized portion of the alimentary tube. Both the quantity of blood delivered to the stomach and the richness of the intramural gastric vascular anastomotic network are impressive. The large majority of the gastric blood supply is from the celiac axis via four named arteries (Fig. 26-3). The left and right gastric arteries form an anastomotic arcade along the lesser curvature, and the right and left gastroepiploic arteries form an arcade along the greater gastric curvature. The consistently largest artery to the stomach is the left gastric artery, which usually arises directly from the celiac trunk and divides into an ascending and descending branch along the lesser gastric curvature. Approximately 15% of the time, the left gastric artery supplies an aberrant vessel that travels in the gastrohepatic ligament (lesser omentum) to the left side of the liver. Rarely, this is the only arterial blood supply to this part of the liver, and inadvertent ligation may lead to clinically significant hepatic ischemia in this unusual circumstance. The more common smaller aberrant left hepatic artery may usually be ligated without significant consequences.

Arterial blood supply to the stomach. a. = artery; v. = vein.

[Reproduced with permission from Mercer DW, Liu TH, Castaneda A: Anatomy and physiology of the stomach, in Zuidema GD, Yeo CJ (eds): *Shackelford's Surgery of the Alimentary Tract*, 5th ed., Vol. II. Philadelphia: Saunders, 2002, p 3. Copyright Elsevier.]

The second largest artery to the stomach is the right gastroepiploic artery, which arises consistently from the gastroduodenal artery behind the first portion of the duodenum. The left gastroepiploic artery arises from the splenic artery, and, together with the right gastroepiploic artery, forms the rich gastroepiploic arcade along the greater curvature. The right gastric artery usually arises from the hepatic artery near the pylorus and hepatoduodenal ligament, and runs proximally along the distal stomach. In the fundus along the proximal greater curvature, the short gastric arteries and veins arise from the splenic circulation. There also may be additional vascular branches to the proximal stomach from the phrenic and splenic circulation.

The veins draining the stomach generally parallel the arteries. The left gastric (coronary vein) and right gastric veins usually drain into the portal vein, though occasionally the coronary vein drains into the splenic vein. The right gastroepiploic vein drains into the superior mesenteric vein near the inferior border of the pancreatic neck, and the left gastroepiploic vein drains into the splenic vein.

The richness of the gastric blood supply and the extensiveness of the anastomotic connections have some important clinical implications. Erosion of a peptic ulcer or gastric cancer into a large perigastric vessel may cause life-threatening hemorrhage. Because of the rich venous interconnections in the stomach, a distal splenorenal shunt, which connects the distal end of the divided splenic vein to the side of the left renal vein, can effectively decompress esophagogastric varices in patients with portal hypertension.⁸ Finally, at least two of the four named gastric arteries may be occluded or ligated with impunity. This is done routinely when the stomach is mobilized and pedicled on the right gastric and right gastroepiploic vessels to reach into the neck as an esophageal replacement (see Chap. 25).⁹

Lymphatic Drainage

Generally speaking, the gastric lymphatics parallel the blood vessels (Fig. 26-4).¹⁰ The cardia and medial half of the corpus commonly drain to nodes along the left gastric and celiac axis. The lesser curvature side of the antrum usually drains to the right gastric and pyloric nodes, while the greater curvature half of the distal stomach drains to the nodes along the right gastroepiploic chain. The proximal greater curvature side of the stomach usually drains into nodes along the left gastroepiploic or splenic hilum. The nodes along both the greater and lesser curvature commonly drain into the celiac nodal basin. There is a

rich anastomotic network of lymphatics that drain the stomach, often in a somewhat unpredictable fashion. Thus, a tumor arising in the distal stomach may give rise to positive lymph nodes in the splenic hilum. The rich intramural plexus of lymphatics and veins accounts for the fact that there can be microscopic evidence of malignant cells in the gastric wall at a resection margin that is several centimeters away from palpable malignant tumor. It also helps explain the not infrequent finding of positive lymph nodes which may be many centimeters away from the primary tumor, with closer nodes that remain negative.

Extensive and meticulous lymphadenectomy is considered by many surgeons to be an important part of the operation for gastric cancer. Surgeons and pathologists have numbered the primary and secondary lymph node groups to which the stomach drains (see Fig. 26-4).^{11,12}

Innervation

Both the extrinsic and intrinsic innervation of the stomach play an important role in gastric secretory and motor function.¹³ The vagus nerves provide the extrinsic parasympathetic innervation to the stomach, and acetylcholine is the most important neurotransmitter. From the vagal nucleus in the floor of the fourth cerebral ventricle, the vagus traverses the neck in the carotid sheath and enters the mediastinum, where it gives off the recurrent laryngeal nerve and divides into several branches around the esophagus. These branches come together again above the esophageal hiatus and form the *left (anterior)* and *right (posterior)* vagal trunks (mnemonic LARP). Near the GE junction the anterior vagus sends a branch (or branches) to the liver in the gastrohepatic ligament, and continues along the lesser curvature as the anterior nerve of Latarjet (Fig. 26-5). Similarly, the posterior vagus sends branches to the celiac plexus and continues along the posterior lesser curvature. The nerves of Latarjet send segmental branches to the body of the stomach before they terminate near the angularis incisura as the "crow's foot," sending branches to the antropyloric region. There may be additional branches to the distal stomach and pylorus that travel near the right gastric and/or gastroepiploic arteries. In 50% of patients, there are more than two vagal nerves at the esophageal hiatus. The branch that the posterior vagus sends to the posterior fundus is termed the *criminal nerve of Grassi*. This branch typically arises above the esophageal hiatus and is easily missed during truncal or highly selective vagotomy (HSV). Vagal fibers originating in the brain synapse with neurons in Auerbach's myenteric plexus and Meissner's submucosal plexus. Although clinicians are accustomed to thinking about the vagus nerves as important efferent nerves (i.e., carrying stimuli to the viscera), it is important to consider the fact that fully 75% of the axons contained in the vagal trunks are afferent (i.e., carrying stimuli from the viscera to the brain).

The extrinsic sympathetic nerve supply to the stomach originates at spinal levels T5 through T10 and travels in the splanchnic nerves to the celiac ganglion. Postganglionic sympathetic nerves then travel from the celiac ganglion to the stomach along the blood vessels.

Neurons in the myenteric and submucosal plexuses constitute the intrinsic nervous system of the stomach. There may be more intrinsic gastric neurons than extrinsic neurons, but their function is poorly understood.

It is obviously an oversimplification (and incorrect) to think exclusively of the vagus as the cholinergic system and the sympathetic system as the adrenergic system of innervation. Although acetylcholine is an important neurotransmitter mediating vagal function, and epinephrine is important in the sympathetic nerves, both systems (as well as the intrinsic neurons) have various and diverse neurotransmitters including cholinergic, adrenergic, and peptidergic (e.g., substance P and somatostatin).

Histology

There are four distinct layers of the gastric wall: mucosa, submucosa, muscularis propria, and serosa (Fig. 26-6).⁷ The inner layer of the stomach is the mucosa, which is lined with columnar epithelial cells of various types. Beneath the basement membrane of the epithelial cells is the lamina propria, which contains connective tissue, blood vessels, nerve fibers, and inflammatory cells. Beneath the lamina propria is a thin muscle layer called the *muscularis mucosa*, the deep boundary of the mucosal layer of the gut. The epithelium, lamina propria, and muscularis mucosa constitute the mucosa (Fig. 26-7).¹⁴ The epithelium of the gastric mucosa is columnar glandular. A scanning electron micrograph shows a smooth mucosal carpet punctuated by the openings of the gastric glands. The gastric glands are lined with different types of epithelial cells, depending upon their location in the stomach (Fig. 26-8, Table 26-2).^{15,16} There are also endocrine cells present in the gastric glands. Progenitor cells at the base of the glands differentiate and replenish sloughed cells on a regular basis. Throughout the stomach, the carpet consists primarily of mucus-secreting surface epithelial cells (SECs) that extend down into the gland pits for variable distances. These cells also secrete bicarbonate and play an important role in protecting the stomach from injury due to acid, pepsin, and/or ingested irritants. In fact, all epithelial cells of the stomach (except the endocrine cells) contain carbonic anhydrase and are capable of producing bicarbonate.

Table 26-2 Epithelial Cells of the Stomach

Cell Type	Distinctive Ultrastructural Features	Major Functions
Surface-foveolar mucous cells	Apical stippled granules up to 1 μm in diameter	Production of neutral glycoprotein and bicarbonate to form a gel on the gastric luminal surface; neutralization of hydrochloric acid ^a
Mucous neck cell	Heterogeneous granules 1–2 μm in diameter dispersed throughout the cytoplasm	Progenitor cell for all other gastric epithelial cells; glycoprotein production; production of pepsinogens I and II
Oxyntic (parietal) cell	Surface membrane invaginations (canaliculi); tubulovesicle structures; numerous mitochondria	Production of hydrochloric acid; production of intrinsic factor; production of bicarbonate
Chief cell	Moderately dense apical granules up to 2 μm in diameter; prominent supranuclear Golgi apparatus; extensive basolateral granular endoplasmic reticulum	Production of pepsinogens I and II, and of lipase

Cardiopyloric mucous cell	Mixture of granules like those in mucous neck and chief cells; extensive basolateral granular endoplasmic reticulum	Production of glycoprotein; production of pepsinogen II
Endocrine cells	See Figure 26-11	

^aBicarbonate is probably produced by other gastric epithelial cells in addition to surface-foveolar mucous cells.

Source: From Antonioli et al,¹⁶ with permission.

In the cardia, the gastric glands are branched and secrete primarily mucus and bicarbonate, but not much acid. In the fundus and body, the glands are more tubular and the pits are deep. Parietal and chief cells are common in these glands (Fig. 26-9). Histamine-secreting enterochromaffin-like (ECL) cells and somatostatin-secreting D cells are also found. Parietal cells secrete acid and intrinsic factor into the gastric lumen, and bicarbonate into the intercellular space. They have a characteristic ultrastructural appearance with secretory canaliculi (deep invaginations of the surface membrane), and cytoplasmic tubulovesicles containing the acid-producing apparatus $H^+/K^+-ATPase$ (proton pump) (see Fig. 26-9). There are numerous mitochondria; in fact the parietal cell is the most mitochondria rich cell in the body. When the parietal cell is stimulated, the cytoplasmic tubulovesicles fuse with the membrane of the secretory canaliculus; when acid production ceases, the process is reversed. Arguably, parietal cells produce the only truly essential substance produced by the stomach (i.e., intrinsic factor). Parietal cells tend to occupy the midportion of the gastric glands found in the corpus of the stomach.

Chief cells (also called *zymogenic cells*) secrete pepsinogen I, which is maximally activated at a pH of 2.5. They tend to be clustered toward the base of the gastric glands and have a low columnar shape. Ultrastructurally, chief cells have the characteristics of protein-synthesizing cells: basal granular endoplasmic reticulum, supranuclear Golgi apparatus, and apical zymogen granules (Fig. 26-10). When stimulated, the chief cells produce two immunologically distinct proenzyme forms of pepsinogen: predominantly pepsinogen I and some pepsinogen II, most of which is produced by SECs. These proenzymes are activated in an acidic luminal environment.

In the antrum, the gastric glands are again more branched and shallow, parietal cells are rare, and gastrin-secreting G cells and somatostatin-secreting D cells are present. A variety of hormone-secreting cells are present in various proportions throughout the gastric mucosa (Fig. 26-11).¹⁷ Histologic analysis suggests that in the normal stomach, 13% of the epithelial cells are oxyntic (parietal) cells, 44% are chief (zymogenic) cells, 40% are mucous cells, and 3% are endocrine cells. In general, the antrum produces gastrin but not acid, and the proximal stomach produces acid but not gastrin. The border between the corpus and antrum migrates proximally with age (especially on the lesser curvature side of the stomach).

Deep to the muscularis mucosa is the submucosa, which is rich in branching blood vessels, lymphatics, collagen, various inflammatory cells, autonomic

nerve fibers, and ganglion cells of Meissner's autonomic submucosal plexus. The collagen-rich submucosa gives strength to GI anastomoses. The mucosa and submucosa are folded into the grossly visible gastric rugae, which tend to flatten out as the stomach becomes distended.

Below the submucosa is the thick muscularis propria (also referred to as the *muscularis externa*), which consists of an incomplete inner oblique layer, a complete middle circular layer (continuous with the esophageal circular muscle and the circular muscle of the pylorus), and a complete outer longitudinal layer (continuous with the longitudinal layer of the esophagus and duodenum). Within the muscularis propria is the rich network of autonomic ganglia and nerves that make up Auerbach's myenteric plexus. Specialized pacemaker cells, the interstitial cells of Cajal (ICC), also are present.

The outer layer of the stomach is the serosa, also known as the *visceral peritoneum*. This layer provides significant tensile strength to gastric anastomoses. When tumors originating in the mucosa penetrate and breach the serosa, microscopic or gross peritoneal metastases are common, presumably from shedding of tumor cells that would not have occurred if the serosa had not been penetrated. In this way, the serosa may be thought of as an outer envelope of the stomach.

PHYSIOLOGY

The stomach stores food and facilitates digestion through a variety of secretory and motor functions. Important secretory functions include the production of acid, pepsin, intrinsic factor, mucus, and a variety of GI hormones. Important motor functions include food storage (receptive relaxation and accommodation), grinding and mixing, controlled emptying of ingested food, and periodic interprandial "housekeeping."

Acid Secretion

Hydrochloric acid in the stomach hastens both the physical and (with pepsin) the biochemical breakdown of ingested food. In an acidic environment, pepsin and acid facilitate proteolysis. Gastric acid also inhibits the proliferation of ingested pathogens, which protects against both infectious gastroenteritides and intestinal bacterial overgrowth. Long-term acid suppression with proton pump inhibitors (PPIs) has been associated with an increased risk of community acquired *Clostridium difficile* colitis and other gastroenteritides, presumably because of the absence of this protective germicidal barrier.^{18,19}

PARIETAL CELL

The parietal cell is stimulated to secrete acid (Fig. 26-12) when one or more of three membrane receptor types is stimulated by acetylcholine (from vagal nerve fibers), gastrin (from D cells), or histamine (from ECL cells).^{7,20,21} The enzyme H^{+}/K^{+} -ATPase is the proton pump. It is stored within the intracellular tubulovesicles and is the final common pathway for gastric acid secretion. When the parietal cell is stimulated, there is a cytoskeletal rearrangement and fusion of the tubulovesicles with the apical membrane of the secretory canaliculus. The heterodimer assembly of the enzyme subunits into the microvilli of the secretory canaliculus results in acid secretion, with extracellular potassium being exchanged for cytosolic hydrogen. Although electro-neutral, this is an energy requiring process because the hydrogen is secreted against a gradient of at least 1 million-fold, which explains why the parietal cell is packed with energy producing mitochondria. During acid production, potassium and chloride are also secreted into the secretory canaliculus through separate channels, providing potassium for the H^{+}/K^{+} -ATPase, and chloride for the secreted hydrogen.

Control of acid secretion in the parietal cell. ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; CCK = cholecystokinin; H_2 = histamine 2; IP_3 = inositol trisphosphate; PIP_2 = phosphatidylinositol 4,5-bisphosphate; PLC = phospholipase C.

[Reproduced with permission from Mercer DW, Liu TH, Castaneda A: Anatomy and physiology of the stomach, in Zuidema GD, Yeo CJ (eds): *Shackelford's Surgery of the Alimentary Tract*, 5th ed., Vol. II. Philadelphia: Saunders, 2002, p 3. Copyright Elsevier.]

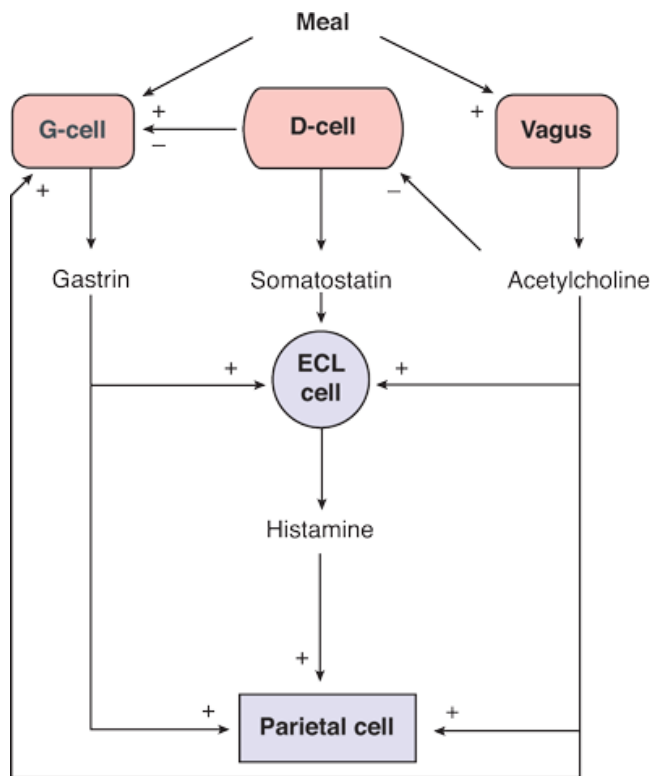

The normal human stomach contains approximately 1 billion parietal cells, and total gastric acid production is proportional to parietal cell mass. The potent acid-suppressing PPI drugs irreversibly interfere with the function of the $H^+/K^+-ATPase$ molecule. These agents must be incorporated into the activated enzyme to be effective, and thus work best when taken before or during a meal (when the parietal cell is stimulated). When PPI therapy is stopped, acid secretory capability gradually returns (within days) as new $H^+/K^+-ATPase$ is synthesized.

Gastrin, acetylcholine, and histamine stimulate the parietal cell to secrete hydrochloric acid (see Fig. 26-12). Gastrin binds to type B cholecystokinin (CCK) receptors, and acetylcholine binds to M_3 muscarinic receptors. Both stimulate phospholipase C via a G-protein-linked mechanism leading to increased production of inositol trisphosphate from membrane bound phospholipids. Inositol trisphosphate stimulates the release of calcium from intracellular stores, which leads to activation of protein kinases and activation of $H^+/K^+-ATPase$. Histamine binds to the histamine 2 (H_2) receptor, which stimulates adenylate cyclase, also via a G-protein-linked mechanism. Activation of adenylate cyclase results in an increase in intracellular cyclic adenosine monophosphate which activates protein kinases, leading to increased levels of phosphoproteins and activation of the proton pump. Somatostatin from mucosal D cells binds to membrane receptors and inhibits the activation of adenylate cyclase through an inhibitory G protein.

PHYSIOLOGIC ACID SECRETION

Food ingestion is the physiologic stimulus for acid secretion (Fig. 26-13). The acid secretory response that occurs after a meal is traditionally described in three phases: cephalic, gastric, and intestinal.^{22,23} The cephalic or vagal phase begins with the thought, sight, smell, and/or taste of food. These stimuli activate several cortical and hypothalamic sites (e.g., tractus solitarius, dorsal motor nucleus, and dorsal vagal complex), and signals are transmitted to the stomach by the vagal nerves. Acetylcholine is released, leading to stimulation of ECL cells and parietal cells. Although the acid secreted per unit of time in the cephalic phase is greater than in the other two phases, the cephalic phase is shorter. Thus, the cephalic phase accounts for no more than 30% of total acid secretion in response to a meal. Sham feeding (chewing and spitting) stimulates gastric acid secretion only via the cephalic phase, and results in acid secretion that is about half of that seen in response to IV pentagastrin or histamine.

Fig. 26-13.

Physiologic control of acid secretion. ECL = enterochromaffin-like.

[Reproduced with permission from Mercer DW, Liu TH, Castaneda A: Anatomy and physiology of the stomach, in Zuidema GD, Yeo CJ (eds): *Shackelford's Surgery of the Alimentary Tract*, 5th ed., Vol. II. Philadelphia: Saunders, 2002, p 3. Copyright Elsevier.]

When food reaches the stomach, the gastric phase of acid secretion begins. This phase lasts until the stomach is empty, and accounts for about 60% of the total acid secretion in response to a meal. The gastric phase of acid secretion has several components. Amino acids and small peptides directly stimulate antral G cells to secrete gastrin, which is carried in the bloodstream to the parietal cells and stimulates acid secretion in an endocrine fashion. In addition, proximal gastric distention stimulates acid secretion via a vagovagal reflex arc, which is abolished by truncal or HSV. Antral distention also stimulates antral gastrin secretion. Acetylcholine stimulates gastrin release and gastrin stimulates histamine release from ECL cells.

The intestinal phase of gastric secretion is poorly understood. It is thought to be mediated by a hormone yet to be discovered that is released from the proximal small bowel mucosa in response to luminal chyme. This phase starts when gastric emptying of ingested food begins, and continues as long as nutrients remain in the proximal small intestine. It accounts for about 10% of meal-induced acid secretion.

Interprandial basal acid secretion is 2 to 5 mEq hydrochloric acid per hour, about 10% of maximal acid output (MAO), and it is greater at night. Basal acid secretion probably contributes to the relatively low bacterial counts found in the stomach. Basal acid secretion is reduced 75 to 90% by vagotomy or H₂ receptor blockade.

The pivotal role that ECL cells play in the regulation of gastric acid secretion is emphasized in Fig. 26-13. A large part of the acid stimulatory effects of both acetylcholine and gastrin are mediated by histamine released from mucosal ECL cells. This explains why the histamine 2 receptor antagonists (H₂RAs) are such effective inhibitors of acid secretion, even though histamine is only one of three parietal cell stimulants. The mucosal D cell, which releases somatostatin, is also an important regulator of acid secretion. Somatostatin inhibits histamine release from ECL cells and gastrin release from antral G cells. The function of D cells is inhibited by *Helicobacter pylori* infection, and this leads to an exaggerated acid secretory response (see below under *Helicobacter pylori* Infection).

Pepsinogen Secretion

The most potent physiologic stimulus for pepsinogen secretion from chief cells is food ingestion; acetylcholine is the most important mediator. Somatostatin inhibits pepsinogen secretion. Pepsinogen I is produced by chief cells in acid producing glands, whereas pepsinogen II is produced by SECs in both acid producing and gastrin producing (i.e., antral) glands. Pepsinogen is cleaved to the active pepsin enzyme in an acidic environment and is maximally active at pH 2.5, and inactive at pH >5, although pepsinogen II may be activated over a wider pH range than pepsinogen I. Pepsin catalyzes the hydrolysis of proteins and is denatured at alkaline pH.

Intrinsic Factor

Activated parietal cells secrete intrinsic factor in addition to hydrochloric acid. Presumably the stimulants are similar, but acid secretion and intrinsic factor secretion may not be linked. Intrinsic factor binds to luminal vitamin B12, and the complex is absorbed in the terminal ileum via mucosal receptors. Vitamin B₁₂ deficiency can be life threatening, and patients with total gastrectomy or pernicious anemia (i.e., patients with no parietal cells) require B₁₂ supplementation by a nonenteric route. Some patients develop vitamin B₁₂ deficiency following gastric bypass, presumably because there is insufficient intrinsic factor present in the small proximal gastric pouch. Under normal conditions, a significant excess of intrinsic factor is secreted, and acid-suppressive medication does not appear to inhibit intrinsic factor production and release.

Gastric Mucosal Barrier

The stomach's durable resistance to autodigestion by caustic hydrochloric acid and active pepsin is intriguing. Some of the important elements of gastric barrier function and cytoprotection are listed in Table 26-3.^{24,25} When these defenses break down, ulceration occurs. A variety of factors are important in maintaining an intact gastric mucosal layer. The mucus and bicarbonate secreted by SECs form an unstirred mucous gel with a favorable pH gradient. Cell membranes and tight junctions prevent hydrogen ions from gaining access to the interstitial space. Hydrogen ions that do break through are buffered by the alkaline tide created by basolateral bicarbonate secretion from stimulated parietal cells. Any sloughed or denuded SECs are rapidly replaced by migration of adjacent cells, a process known as *restitution*. Mucosal blood flow plays a crucial role in maintaining a healthy mucosa, providing nutrients and oxygen for the cellular functions involved in cytoprotection. "Back-diffused" hydrogen is buffered and rapidly removed by the rich blood supply. When "barrier breakers" such as bile or aspirin lead to increased back-diffusion of hydrogen ions from the lumen into the lamina propria and submucosa, there is a protective increase in mucosal blood flow. If this protective response is blocked, gross ulceration can occur. Important mediators of these protective mechanisms include prostaglandins, nitric oxide, intrinsic nerves, and peptides (e.g., calcitonin gene-related peptide, gastrin-releasing peptide [GRP], and gastrin). Misoprostol is a commercially available prostaglandin E analogue that has been shown to prevent gastric mucosal damage in chronic users of NSAIDs. More commonly used is sucralfate, which acts locally to enhance mucosal defenses. Some protective reflexes involve afferent sensory neurons, and can be blocked by the application of topical anesthetics to the gastric mucosa, or the experimental destruction of the afferent sensory nerves. In addition to these local defenses, there are important protective factors in saliva, duodenal secretions, and pancreatic or biliary secretions.

Table 26-3 Important Components and Mediators of Mucosal Defenses in the Stomach

Epidermal growth factor
Calcitonin gene-related peptide
Hepatocyte growth factor
Histamine
Gastrin-releasing peptide

Gastric Hormones

GASTRIN

Gastrin is produced by antral G cells and is the major hormonal stimulant of acid secretion during the gastric phase. Gastrin is also trophic to GI epithelial and enterochromaffin cells. A variety of molecular forms exist: big gastrin (34 amino acids; G₃₄), little gastrin (17 amino acids; G₁₇), and minigastrin (14 amino acids; G₁₄). The large majority of gastrin released by the human antrum is G₁₇. The biologically active pentapeptide sequence at the C-terminal end

of gastrin is identical to that of CCK. Luminal peptides and amino acids are the most potent stimulants of gastrin release, and luminal acid is the most potent inhibitor of gastrin secretion. The latter effect is predominantly mediated in a paracrine fashion by somatostatin released from antral D cells. Gastrin-stimulated acid secretion is significantly blocked by H₂ antagonists, suggesting that the principal mediator of gastrin-stimulated acid production is histamine from mucosal ECL cells (see Fig. 26-13). In fact, chronic hypergastrinemia such as that seen with pernicious anemia or long-term use of potent acid suppressants or gastrinoma is associated with hyperplasia of gastric ECL cells and, rarely, gastric carcinoid. Gastrin also is trophic to gastric parietal cells and to other GI mucosal cells. Important causes of hypergastrinemia include pernicious anemia, acid-suppressive medication, gastrinoma, retained antrum following distal gastrectomy and Billroth II surgery, and vagotomy.

SOMATOSTATIN

Somatostatin is produced by D cells located throughout the gastric mucosa. The predominant form in humans is somatostatin 14, though somatostatin 28 is present as well. The major stimulus for somatostatin release is antral acidification; acetylcholine from vagal nerve fibers inhibits its release. Somatostatin inhibits acid secretion from parietal cells and gastrin release from G cells. It also decreases histamine release from ECL cells. The proximity of the D cells to these target cells suggests that the primary effect of somatostatin is mediated in a paracrine fashion, but an endocrine (i.e., bloodstream) effect also is possible.

GASTRIN-RELEASING PEPTIDE

GRP is the mammalian equivalent of bombesin, a hormone discovered more than two decades ago in an extract of skin from a frog. In the antrum, GRP stimulates both gastrin and somatostatin release by binding to receptors on the G and D cells. There are nerve terminals ending near the mucosa in the gastric body and antrum, which are rich in GRP immunoreactivity. When GRP is given peripherally, it stimulates acid secretion, but when it is given centrally into the cerebral ventricles of animals, it inhibits acid secretion, apparently via a pathway involving the sympathetic nervous system. GRP is a mediator of gastroprotective increased mucosal blood flow in response to luminal irritants.

LEPTIN

Leptin is a protein primarily synthesized in adipocytes. It is also made by chief cells in the stomach, the main source of leptin in the GI tract.²⁶ Leptin works at least in part via vagally mediated pathways to decrease food intake in animals. Not surprisingly, leptin, a satiety signal hormone, and ghrelin, a hunger signal hormone, are both primarily synthesized in the stomach, an organ increasingly recognized as central to the mechanisms of appetite control.^{26,27}

GHRELIN

Ghrelin is a small peptide described in 1999 that is produced primarily in the stomach.²⁸ Ghrelin is a potent secretagogue of pituitary growth hormone (but not adrenocorticotrophic hormone, follicle-stimulating hormone, luteinizing hormone, prolactin, or thyroid-stimulating hormone). Ghrelin appears to be an orexigenic regulator of appetite (i.e., when ghrelin is elevated, appetite is stimulated, and when it is suppressed, appetite is suppressed). Resection of the primary source of this hormone (i.e., the stomach) may partly account for the anorexia and weight loss seen in some patients following gastrectomy (Fig. 26-14).²⁹ The gastric bypass operation, a very effective treatment for morbid obesity, has been shown by some investigators to be associated with suppression of plasma ghrelin levels (and appetite) in humans (Fig. 26-15A).³⁰

A and B. Ghrelin secretion after bariatric surgery. Some investigators have suggested that ghrelin secretion is dramatically decreased after gastric bypass. Other groups have shown statistically insignificant changes in ghrelin levels after gastric bypass, but significant decreases after sleeve gastrectomy. **A:** green = gastric bypass; blue = obese controls; red = normal weight controls; **B:** blue = fasting; pink = postprandial.

(Fig. 26-15A reproduced with permission from Cummings DE, et al: Plasma ghrelin levels after diet-induced weight loss or gastric bypass surgery. *N Engl J Med* 346:1623, 2002. Copyright ©2002 Massachusetts Medical Society. All rights reserved. Fig. 26-15B reproduced with permission from Karamanakos SN, et al: Weight loss, appetite suppression, and changes in fasting and postprandial ghrelin and peptide-YY levels after Roux-en-Y gastric bypass and sleeve gastrectomy: A prospective, double blind study. *Ann Surg* 247:401, 2008.)

Other groups have failed to show a significant decrease in ghrelin levels following gastric bypass but have found such decreases following sleeve gastrectomy, another effective weight loss operation (Fig. 26-15B).³¹ Obviously appetite control is complex with redundant and overlapping orexigenic and anorexigenic pathways and signals.^{26,27}

Gastric Motility and Emptying

Gastric motor function has several purposes.³²⁻³⁴ Interprandial motor activity clears the stomach of undigested debris, sloughed cells, and mucus. When feeding begins, the stomach relaxes to accommodate the meal. Regulated motor activity then breaks down the food into small particles and controls the output into the duodenum. The stomach accomplishes these functions by coordinated smooth muscle relaxation and contraction of the various gastric segments (proximal, distal, and pyloric). Smooth muscle myoelectric potentials are translated into muscular activity, which is modulated by extrinsic and intrinsic innervation and hormones. The mechanisms by which gastric distention is translated into a neurohormonal satiety signal have only been partially elucidated.^{26,27}

INTRINSIC GASTRIC INNERVATION

The extrinsic parasympathetic and sympathetic gastric innervation was discussed above under Innervation. The intrinsic innervation consists of ganglia and nerves that constitute the enteric nervous system (Fig. 26-16).³⁵ There are a variety of neurotransmitters, which are generally grouped as excitatory (augment muscular activity) and inhibitory (decrease muscular activity). Important excitatory neurotransmitters include acetylcholine, the tachykinins, substance P, and neurokinin A. Important inhibitory neurotransmitters include nitric oxide (NO) and vasoactive intestinal peptide (VIP). Serotonin has been shown to modulate both contraction and relaxation. A variety of other molecules affect motility, including GRP, histamine, neuropeptide Y, norepinephrine, and endogenous opioids.

Specialized cells in the muscularis propria also are important modulators of GI motility. These cells, called *interstitial cells of Cajal*, are distinguishable histologically from neurons and myocytes, and appear to amplify both cholinergic excitatory and nitrergic inhibitory input to the smooth muscle of the stomach and intestine.³⁶ They are thought either to share a common stem cell of origin with, or to be the cell of origin for, gastrointestinal stromal tumors (GISTs) which are the most common mesenchymal neoplasm in the GI tract.

SEGMENTAL GASTRIC MOTILITY

In general, the proximal stomach serves as short-term food storage function and helps regulate basal intragastric tone, and the distal stomach mixes and grinds the food. The pylorus helps the latter process when closed, facilitating retropulsion of the solid food bolus back into the body of the stomach for additional breakdown. The pylorus opens intermittently to allow metered emptying of liquids and small solid particles into the duodenum.

Most of the motor activity of the proximal stomach consists of slow tonic contractions and relaxations, lasting up to 5 minutes. This activity is the main determinant of basal intragastric pressure, an important determinant of liquid emptying. Rapid phasic contractions may be superimposed on the slower tonic motor activity. When food is ingested, intragastric pressure falls as the proximal stomach relaxes. This proximal relaxation is mediated by two important vagovagal reflexes: receptive relaxation and gastric accommodation. Receptive relaxation refers to the reduction in proximal gastric tone associated with the act of swallowing. This occurs before the food reaches the stomach, and can be reproduced by mechanical stimulation of the pharynx or esophagus. Gastric accommodation refers to the proximal gastric relaxation associated with distention of the stomach. Accommodation is mediated through stretch receptors in the gastric wall and does not require esophageal or pharyngeal stimulation. Because both of these reflexes are mediated by afferent and efferent vagal fibers, they are significantly altered by truncal and HSV. Both these operations result in decreased gastric compliance, shifting the

volume/pressure curve to the left. That is, interference with normal receptive relaxation and/or accommodation results in decreased gastric compliance, such that for any given amount of food or liquid ingested, the intragastric pressure is greater. This may increase the rate of liquid emptying, perhaps contributing to dumping symptoms in some patients after vagotomy.

NO and VIP are the principal mediators of proximal gastric relaxation. But a variety of other agents increase proximal gastric relaxation and compliance, including dopamine, gastrin, CCK, secretin, GRP, and glucagon. Proximal gastric tone also is decreased by duodenal distention, colonic distention, and ileal perfusion with glucose (ileal brake).

The distal stomach breaks up solid food and is the main determinant of gastric emptying of solids. Slow waves of myoelectric depolarization sweep down the distal stomach at a rate of about three per minute. These waves originate from the proximal gastric pacemaker, high on the greater curvature. The pacing cells may be ICC, which have been shown to have a similar function in the small intestine and colon. Most of these myoelectric waves are below the threshold for smooth muscle contraction in the quiescent state, and thus are associated with negligible changes in pressure. Neural and/or hormonal input, which increases the plateau phase of the action potential, can trigger muscle contraction, resulting in a peristaltic wave associated with the electrical slow wave, and of the same frequency (three per minute) (Fig. 26-17). It is possible that implantable gastric pacemakers benefit some patients with gastroparesis by favorably impacting this myoelectric coupling.

Fig. 26-17.

The relationship between intracellular electrical activity and muscle cell contraction. Note that contractile activity is always associated with electrical activity, but the converse is not so. During mechanical quiescence, there are regular depolarizations that do not reach threshold. In the stimulated state, the threshold for contraction is reached, and motor activity is demonstrable.

[Reproduced with permission from Kim CH: Electrical activity of the stomach: clinical implications. *Mayo Clin Proc* 61:205, 1986.]

During fasting, distal gastric motor activity is controlled by the migrating motor complex (MMC), the "gastrointestinal housekeeper" (Fig. 26-18). The purported function of the MMC is to sweep along any undigested food, debris, sloughed cells, and mucus after the fed phase of digestion is complete. The MMC lasts approximately 100 minutes (longer at night, shorter during daytime) and is divided into four phases. Phase I (about half the length of the entire cycle) is a period of relative motor inactivity. High-amplitude muscular contractions do not occur in phase I of the MMC. Phase II (about 25% of the entire MMC cycle) consists of some irregular, high-amplitude, generally nonpropulsive contractions. Phase III, a period of intense, regular, (about three per minute) propulsive contractions, only lasts about 5 to 10 minutes. Most phase III complexes of the GI MMC begin in the stomach, and the frequency approximates that of the myoelectric gastric slow wave. Phase IV is a transition period.

Fig. 26-18.

Migrating motor complex, the fasting pattern of GI activity. During phase III of the migrating motor complex, effective peristaltic waves progress from the stomach to the distal small intestine.

[Reproduced with permission from Rees WDW, et al: Human interdigestive and postprandial gastrointestinal motor and gastrointestinal hormone patterns. *Dig Dis Sci* 27(4):321, 1982. Copyright 1982, with kind permission of Springer Science + Business Media.]

Neurohormonal control of the MMC is poorly understood, but it appears that different phases are regulated by different mechanisms. For example, vagotomy abolishes phase II of the gastric MMC but has little influence on phase III. In fact, phase III persists in the autotransplanted stomach, totally devoid of extrinsic neural input. This suggests that phase III is regulated by intrinsic nerves and/or hormones. Indeed, the initiation of phase III of the MMC in the distal stomach corresponds temporally to elevation in serum levels of motilin, a hormone produced in the duodenal mucosa. Resection of the duodenum abolishes distal gastric phase III in dogs. Resection of the duodenum in humans (e.g., with pancreaticoduodenectomy, the Whipple procedure) commonly results in early postoperative delayed gastric emptying sometimes responsive to erythromycin, a motilin agonist.³⁷ There are clearly motilin receptors on antral smooth muscle and nerves. Other modulators of gastric MMC activity include NO, endogenous opioids, intrinsic cholinergic and adrenergic nerves, and duodenal pH (MMC phase III does not occur if the duodenal pH is below 7).

Feeding abolishes the MMC and leads to the fed motor pattern. The fed motor pattern of gastric activity starts within 10 minutes of food ingestion and persists until all the food has left the stomach. The neurohormonal initiator of this change is unknown, but CCK and the vagus appear to play some role: Sham feeding transiently induces antral motor activity resembling the fed motor pattern, and this is blocked by the CCK receptor antagonist loxiglumide. Gastric motility during the fed pattern resembles phase II of the MMC, with irregular but continuous phasic contractions of the distal stomach. During the fed state, about half of the myoelectric slow waves are associated with strong distal gastric contractions. Some are prograde and some are retrograde, serving to mix and grind the solid components of the meal. The magnitude of gastric contractions and the duration of the pattern is influenced by the consistency and composition of the meal.

The pylorus functions as an effective regulator of gastric emptying and an effective barrier to duodenogastric reflux. Bypass, transection, or resection of the pylorus may lead to uncontrolled gastric emptying of food and the dumping syndrome (see below under Postgastrectomy Problems). Pyloric dysfunction or disruption may also result in uncontrolled entry of duodenal contents into the stomach. Perfusion of the duodenum with lipids, glucose, amino acids, hypertonic saline, or hydrochloric acid results in closure of the pylorus and decreased transpyloric flow. Ileal perfusion with fat has the same effect. A variety of neurohumoral pathways are involved with these physiologic responses, and there is evidence that different pathways may be involved for different stimuli.

The pylorus is readily apparent grossly as a thick ring of muscle and connective tissue. The density of nerve tissue in the pyloric smooth muscle is severalfold higher than in the antrum, with increased numbers of neurons staining positive for substance P, neuropeptide Y, VIP, and galanin. ICC are more closely associated with pyloric myocytes, and the myoelectric slow wave of the pylorus has the same frequency as that seen in the distal stomach. The

motor activity of the pylorus is both tonic and phasic. During phase III of the MMC, the pylorus is open as gastric contents are swept into the duodenum. During the fed phase, the pylorus is closed most of the time. It relaxes intermittently, usually in synchronization with lower-amplitude, minor antral contractions. The higher-amplitude, more major antral contractions are usually met with a closed pylorus, facilitating retropulsion and further grinding of food.

Modulation of pyloric motor activity is complex. There is evidence of both inhibitory and excitatory vagal pathways. Some contractile vagal effects are mediated by opioid pathways, because they are blocked by naloxone. Electrical stimulation of the duodenum causes the pylorus to contract, whereas electrical stimulation of the antrum causes pyloric relaxation. Generally, NO mediates pyloric relaxation; NO donors lead to pyloric relaxation and decreased resistance to flow in a variety of models, whereas NO synthetase inhibitors have the opposite effect. Other molecules that may play a physiologic role in controlling pyloric smooth muscle include serotonin, VIP, prostaglandin E₁, and galanin (pyloric relaxation); and histamine, CCK, and secretin (pyloric contraction).

GASTRIC EMPTYING

The control of gastric emptying is complex. In general, gastric emptying is slowed by increasing caloric content or osmolarity, increased fat content, and increased particle size; liquid emptying is faster than solid emptying. Osmolarity, acidity, caloric content, and nutrient composition are important modulators. Stimulation of duodenal osmoreceptors, glucoreceptors, and pH receptors clearly inhibits gastric emptying by a variety of neurohumoral mechanisms. CCK has been consistently shown to inhibit gastric emptying at physiologic doses (Fig. 26-19). Recently, it has been noted that the anorexigenic hormone leptin, secreted mostly by fat but also by gastric mucosa, inhibits gastric emptying, perhaps through the same pathway as CCK (which also has properties of a satiety hormone). The orexigenic hormone ghrelin has the opposite effect.

Fig. 26-19.

Cholecystokinin (CCK) inhibits gastric emptying.

[Reproduced with permission from Covasa M, Ritter RC: Adaptation to high-fat diet reduces inhibition of gastric emptying by CCK and intestinal oleate. *Am J Physiol Regulatory Integrative Comp Physiol* 278:R166, 2000.]

LIQUID EMPTYING

The gastric emptying of water or isotonic saline follows first-order kinetics, with a half emptying time around 12 minutes. Thus, if one drinks 200 mL of water, about 100 mL enters the duodenum by 12 minutes, whereas if one drinks 400 mL of water, about 200 mL enters the duodenum by 12 minutes. This emptying pattern of liquids is modified considerably as the caloric density, osmolarity, and nutrient composition of the liquid changes (Fig. 26-20). Up to an osmolarity of about 1 M, liquid emptying occurs at a rate of about 200 kcal per hour. Duodenal osmoreceptors and hormones (e.g., secretin and VIP) are important modulators of liquid gastric emptying. Generally, liquid emptying is delayed in the supine position.

Fig. 26-20.

Nutrient composition and caloric density affect liquid gastric emptying. Glucose solution (solid circles), the least calorically dense, emptied the fastest. Other more calorically dense solutions, such as milk protein (solid triangles) and peptide hydrolysates (open circles and solid triangles), emptied slower.

[Reproduced with permission from Calbet JA, MacLean DA: Role of caloric content on gastric emptying in humans. *J Physiol* 498:533, 1997.]

Traditionally, liquid emptying has been attributed to the activity of the proximal stomach, but it is probably more complicated than previously thought. Clearly, receptive relaxation and gastric accommodation play a role in gastric emptying of liquids. Patients with a denervated (e.g., vagotomized), resected, or plicated (e.g., fundoplication) proximal stomach have decreased gastric compliance and may show accelerated gastric emptying of liquids. A swallowed liquid meal induces receptive relaxation, but the same meal delivered via nasogastric tube bypasses this reflex and is associated with a higher intragastric pressure and accelerated emptying.

Some observations suggest an active role for the distal stomach in liquid emptying. For instance even if the proximal intragastric pressure is lower than duodenal pressure, normal gastric emptying of liquids can occur. Also, diabetic patients may have normal proximal gastric motor function and profoundly delayed gastric emptying of liquids. Indeed, antral contractile activity does correlate with liquid gastric emptying, and this distal gastric activity appears to vary with the nutrient composition and caloric content of the liquid meal. Depending on the circumstances, distal gastric motor activity can promote or inhibit gastric emptying of liquids. Distal gastrectomy and pyloric stenting both obviously interfere with distal gastric motor activity, and both accelerate the initial rapid phase of liquid gastric emptying.

SOLID EMPTYING

Normally, the half-time of solid gastric emptying is <2 hours. Unlike liquids, which display an initial rapid phase followed by a slower linear phase of emptying, solids have an initial lag phase during which little emptying of solids occurs. It is during this phase that much of the grinding and mixing occurs. A linear emptying phase follows, during which the smaller particles are metered out to the duodenum. Solid gastric emptying is a function of meal particle size, caloric content, and composition (especially fat). When liquids and solids are ingested together, the liquids empty first. Solids are stored in the fundus and delivered to the distal stomach at constant rates for grinding. Liquids also are sequestered in the fundus, but they appear to be readily delivered to the distal stomach for early emptying. The larger the solid component of the meal, the slower the liquid emptying. Patients bothered by dumping syndrome are advised to limit the amount of liquid consumed with the solid meal, taking advantage of this effect. Three prokinetic agents are commonly used to treat delayed gastric emptying. Typical doses and mechanism of action are shown in Table 26-4.

Table 26-4 Drugs that Accelerate Gastric Emptying		
Agent	Typical Adult Dose	Mechanism of Action
Metoclopramide	10 mg PO qid	Dopamine antagonist
Erythromycin	250 mg PO qid	Motilin agonist
Domperidone	10 mg PO qid	Dopamine antagonist

DIAGNOSIS OF GASTRIC DISEASE

Signs and Symptoms

The most common symptoms of gastric disease are pain, weight loss, early satiety, and anorexia. Nausea, vomiting, bloating, and anemia also are frequent complaints. Several of these symptoms (pain, bloating, nausea, and early satiety) are often described by physicians as dyspepsia, synonymous with the common nonmedical term *indigestion*. Common causes of dyspepsia include gastroesophageal reflux disease (GERD) and disorders of the stomach, gallbladder, and pancreas. Although none of the above symptoms alone is specific for gastric disease, when elicited in the context of a careful history and physical examination, they can clearly point to a probable differential diagnosis, which can then be refined with certain tests.

Diagnostic Tests

ESOPHAGOGASTRODUODENOSCOPY

Patients with one or more of the alarm symptoms listed in Table 26-5 should undergo expeditious upper endoscopy. Esophagogastroduodenoscopy (EGD) is a safe and accurate outpatient procedure performed under conscious sedation.³⁸ Smaller flexible scopes with excellent optics and a working channel are easily passed transnasally in the unsedated patient. Following an 8-hour fast, the flexible scope is advanced under direct vision into the esophagus, stomach, and duodenum. The fundus and GE junction are inspected by retroflexing the scope. To rule out cancer with a high degree of accuracy, all patients with gastric ulcer diagnosed on upper GI series or found at EGD should have multiple biopsies of the base and rim of the lesion. Brush cytology also should be considered. Gastritis should be biopsied both for histologic examination and for a tissue urease test to rule out the presence of *H. pylori*. If *Helicobacter* infection is detected, it should probably be treated because of the etiologic association with peptic ulcers, mucosa-associated lymphoid tissue (MALT), and gastric cancer. The most serious complications of EGD are perforation (which is rare, but can occur anywhere from the cervical esophagus to the duodenum), aspiration, and respiratory depression from excessive sedation. Although EGD is a more sensitive test than double-contrast upper GI series, these modalities should be considered complementary rather than mutually exclusive.

Table 26-5 Alarm Symptoms that Indicate the Need for Upper Endoscopy
Weight loss
Recurrent vomiting
Dysphagia
Bleeding
Anemia

RADIOLOGIC TESTS

Plain abdominal x-rays may be helpful in the diagnosis of gastric perforation (pneumoperitoneum) or delayed gastric emptying (large air-fluid level). *Double-contrast upper GI series* may be better than EGD at elucidating the following: diverticula, fistula, tortuosity or stricture location, and size of hiatal hernia. Although there are radiologic characteristics of ulcers that suggest the presence or absence of malignancy, it must be reiterated that gastric ulcers require adequate biopsy.

COMPUTED TOMOGRAPHIC SCANNING AND MAGNETIC RESONANCE IMAGING

Most cases of significant gastric disease can be diagnosed without these sophisticated imaging studies. However, one or the other should be part of the routine staging work-up for most patients with a malignant gastric tumor. Magnetic resonance imaging (MRI) may prove clinically useful as a quantitative test for gastric emptying, and may even hold some promise for the analysis of myoelectric derangements in patients with gastroparesis. Advanced processing of high-resolution helical computed tomography (CT) and MRI data has made virtual endoscopy a reality.^{39–41} Currently a research tool, it may have potential as a screening tool for gastric disease because it is noninvasive and does not require a physician on site to perform. Digital transmission allows the images to be analyzed remotely. In specialized centers, impressive virtual endoscopic images are obtained with CT scan or MRI (Fig. 26-21). Of course suspicious lesions discovered by such techniques require endoscopic evaluation. And, before screening at-risk populations with these noninvasive modalities for gastric disease, the false-negative rates would have to be shown to be acceptably low.

Conventional double-contrast barium study (**A**) shows a focal protruding mass (*arrow*) on the gastric fundus. Axial computed tomographic scan (**B**) also shows a protruding polyp (*arrow*). The three dimensional computed tomographic gastrographic images in the transparent (**C**) and virtual endoscopic (**D**) modes show an elevated lesion on the gastric fundus (*arrows*). Photograph of the total gastrectomy specimen (**E**) shows a well-demarcated polypoid mass (*arrow*); this lesion was confirmed as early gastric carcinoma type I on microscopic examination (not shown).

(Reproduced with permission from Shin KS, et al: Three-dimensional MDCT gastrography compared with axial CT for the detection of early gastric cancer. *J Comput Assist Tomogr* 31:741, 2007.)

Arteriography rarely is necessary or useful in the diagnosis of gastric disease. It may be helpful in the occasional poor-risk patient with exsanguinating gastric hemorrhage, or in the patient with occult gastric bleeding that is difficult to diagnose. Extravasation of contrast indicates the location of the bleeding vessel, and embolization or selective infusion of vasopressin may be therapeutic. Occasionally, empiric embolization of the suspected but unproven bleeding vessel helps. Arteriovenous malformations have a characteristic angiographic appearance.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) is useful in the evaluation and management of some gastric lesions.^{42–44} Local staging of gastric adenocarcinoma with EUS is quite accurate, and this modality can be used to plan therapy. At some centers, patients with transmural and/or node positive adenocarcinoma of the stomach are considered for preoperative (neoadjuvant) chemoradiation therapy. EUS is the best way to clinically stage these patients locoregionally. Suspicious nodes can be sampled with EUS-guided endoscopic needle biopsy. Malignant tumors that are confined to the mucosa on EUS may be amenable to endoscopic mucosal resection (EMR). EUS also can be used to assess tumor response to chemotherapy. Submucosal masses are commonly discovered during routine EGD. Large submucosal masses should be resected because of the risk of malignancy, but observation may be appropriate for some small submucosal masses (e.g., lipoma or small GIST). There are endoscopic characteristics of benign and malignant mesenchymal tumors, and thus, EUS can provide reassurance, but no guarantee, that small lesions under observation are probably benign. Submucosal varices also can be assessed by EUS.

GASTRIC SECRETORY ANALYSIS

Analysis of gastric acid output requires gastric intubation, and it is performed infrequently nowadays. This test may be useful in the evaluation of patients with hypergastrinemia, including the Zollinger-Ellison syndrome (ZES), patients with refractory ulcer or GERD, and patients with recurrent ulcer after operation. Historically, gastric analysis was performed most commonly to test for the adequacy of vagotomy in postoperative patients with recurrent or persistent ulcer. Now this can be done by assessing peripheral pancreatic polypeptide levels in response to sham feeding.⁴⁵ A 50% increase in pancreatic polypeptide within 30 minutes of sham feeding suggests vagal integrity.

Gastric analysis is performed in the fasted state with the semirecumbent patient in the left lateral position. After the position of the nasogastric tube is verified, the tube is hand aspirated every 5 minutes. Four successive 15-minute samples are created by pooling 5-minute aliquots. An IV stimulant of acid secretion may then be administered (typically pentagastrin) or, more commonly, the patient is sham fed ("chew and spit"), and the process repeated. Samples are analyzed by titration. Normal basal acid output (BAO) is <5 mEq/h. MAO is the average of the two final stimulated 15-minute periods and is usually 10 to 15 mEq/h. Peak acid output is defined as the highest of the four stimulated periods. Patients with a gastrinoma commonly have a high BAO, often above 30 mEq/h, but consistently above 15 mEq/h unless there has been previous vagotomy or gastric resection. In patients with gastrinoma, the

ratio of BAO to MAO exceeds 0.6. Normal acid output in the patient prescribed acid-suppressive medication usually means that the patient is noncompliant. To assess acid-secretory capacity in the absence of medication effect, H₂ blockers and PPIs should be withheld for a week before gastric analysis.

SCINTIGRAPHY

Nuclear medicine tests can be helpful in the evaluation of gastric emptying and duodenogastric reflux. The standard scintigraphic evaluation of gastric emptying involves the ingestion of a test meal with one or two isotopes, and scanning the patient under a gamma camera. A curve for liquid and solid emptying is plotted, and the half-time calculated. Normal standards exist for each facility. Duodenogastric reflux can be quantitated by the IV administration of hepatobiliary iminodiacetic acid, which is concentrated and excreted by the liver into the duodenum. Software allows a semiquantitative assessment of how much of the isotope refluxes into the stomach. Positron emission tomography (PET) scan or CT/PET scan may be useful in certain patients with gastric malignancy.

TESTS FOR *HELICOBACTER PYLORI*

Over the past two decades, *H. pylori* infection has emerged as a significant human pathogen. It is present in most patients with peptic ulcer disease (PUD), and has been associated with gastric lymphoma and adenocarcinoma. A variety of tests can help the clinician to determine whether the patient has active *H. pylori* infection.⁴⁶ The predictive value (positive and negative) of any of these tests when used as a screening tool depends on the prevalence of *H. pylori* infection in the screened population. *A positive test is quite accurate in predicting H. pylori infection, but a negative test is characteristically unreliable.* Thus, in the appropriate clinical setting, treatment for *H. pylori* should be initiated on the basis of a positive test, but not necessarily withheld if the test is negative. Because of the association between *H. pylori* infection and gastric lymphoma and carcinoma, many clinicians recommend treating *Helicobacter* infection when the diagnosis is made.

A positive serologic test is presumptive evidence of active infection if the patient has never been treated for *H. pylori*. Histologic examination of an antral mucosal biopsy using special stains is the gold standard test. Other sensitive tests include commercially available rapid urease tests, which assay for the presence of urease in mucosal biopsies (strong presumptive evidence of infection). Urease is an omnipresent enzyme in *H. pylori* strains that colonize the gastric mucosa. The labeled carbon-13 urea breath test has become the standard test to confirm eradication of *H. pylori* following appropriate treatment.⁴⁷ In this test, the patient ingests urea labeled with nonradioactive ¹³C. The labeled urea is acted upon by the urease present in the *H. pylori* and converted into ammonia and carbon dioxide. The radiolabeled carbon dioxide is excreted from the lungs and can be detected in the expired air (Fig. 26-22). It also can be detected in a blood sample. The fecal antigen test also is quite sensitive and specific for active *H. pylori* infection and may prove more practical in confirming a cure.

ANTRODUODENAL MOTILITY TESTING AND ELECTROGASTROGRAPHY

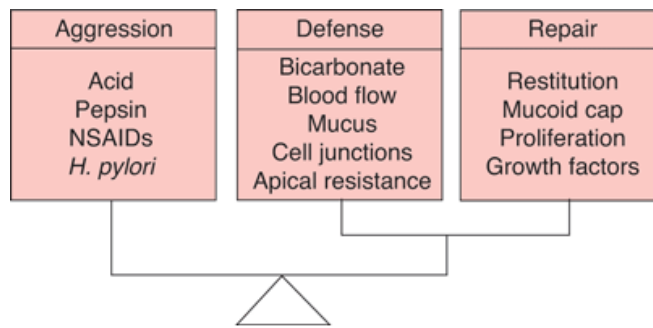

Antroduodenal motility testing and electrogastrography (EGG) are performed in specialized centers and may be useful in the evaluation of the patient with anomalous epigastric symptoms. EGG consists of the transcutaneous recording of gastric myoelectric activity. Antroduodenal motility testing is done with a tube placed transnasally or transorally into the distal duodenum. There are pressure-recording sensors extending from the stomach to the distal duodenum. The combination of these two tests together with scintigraphy provides a thorough assessment of gastric motility.

PEPTIC ULCER DISEASE

Peptic ulcers are focal defects in the gastric or duodenal mucosa that extend into the submucosa or deeper. They may be acute or chronic and, ultimately, are caused by an imbalance between mucosal defenses and acid/peptic injury (Fig. 26-23).^{48,49} Peptic ulcer remains a common outpatient diagnosis, but the number of physician visits, hospital admissions, and elective operations for PUD has decreased steadily and dramatically over the past three decades. Interestingly, the start of these trends all predated the use of H₂ receptor blockers, fiber-optic endoscopy, and HSV. However, the incidence of emergency surgery and the death rate associated with peptic ulcers has not decreased nearly so dramatically. These epidemiologic changes probably represent the net effect of several factors, including (beneficially) decreased prevalence of *H. pylori* infection, better medical therapy, and increased outpatient management; and (detrimentally) the use of NSAIDs and aspirin (with and without ulcer prophylaxis) in an aging population with multiple risk factors.

Balance of aggressive and defensive factors in the gastric mucosa.

(Reproduced with permission from Mertz HR, Walsh JH: Peptic ulcer pathophysiology. *Med Clin North Am* 75:799, 1991. Copyright Elsevier.)

PUD is one of the most common GI disorders in the United States with a prevalence of about 2%, and a lifetime cumulative prevalence of about 10%, peaking around age 70 years.⁵⁰ The costs of PUD, including lost work time and productivity, are estimated to be above \$8 billion per year in the United States. In 1998, approximately 1.5% of all Medicare hospital costs were spent treating PUD, and the crude mortality rate for peptic ulcer was 1.7 per 100,000 individuals. Gastric ulcer has a higher mortality than duodenal ulcer because of its increased prevalence in the elderly. Recent studies have shown an increase in the rates of hospitalization and mortality in elderly patients for the peptic ulcer complications of bleeding and perforation. Presumably, this is due to the increasingly common use of NSAIDs and aspirin in this elderly cohort, many of whom also have *H. pylori* infection.

Pathophysiology and Etiology

A variety of factors may contribute to the development of PUD. Although it is now recognized that the large majority of duodenal and gastric ulcers are caused by *H. pylori* infection and/or NSAID use^{17,51} (Fig. 26-24), the final common pathway to ulcer formation is acid-peptic injury of the gastroduodenal mucosal barrier. Thus, the adage "no acid, no ulcer" remains true even today. Acid suppression remains a mainstay in healing both duodenal and gastric ulcers and in preventing recurrence. It generally is thought that *H. pylori* predisposes to ulceration, both by acid hypersecretion, and by compromise of mucosal defense mechanisms including damage to SECs. NSAID use is thought to lead to PUD predominantly by compromise of mucosal defenses. Duodenal ulcer has typically been viewed as a disease of increased acid-peptic action on the duodenal mucosa, whereas gastric ulcer has been thought of as a disease of weakened mucosal defenses in the face of relatively normal or even decreased acid-peptic activity. However, an increased understanding of peptic ulcer pathophysiology has blurred this overly simplistic distinction. Clearly, weakened mucosal defenses play a role in many duodenal and most gastric ulcers (e.g., duodenal ulcer in an *H. pylori*-negative patient on NSAIDs or a patient with a typical type I gastric ulcer with acid hyposecretion), whereas increased aggressive activity of peptic acid may result in a duodenal or gastric ulcer in the setting of normal mucosal defenses (e.g., a duodenal ulcer in a patient with ZES, or a gastric ulcer in a patient with gastric outlet obstruction, antral stasis, and acid hypersecretion).

Elimination of *H. pylori* infection or NSAID use is important for optimal ulcer healing, and perhaps is even more important in preventing ulcer recurrence and/or complications. A variety of other diseases are known to cause peptic ulcer, including ZES (gastrinoma), antral G-cell hyperfunction and/or hyperplasia, systemic mastocytosis, trauma, burns, and major physiologic stress. Other causative agents include drugs (all NSAIDs, aspirin, and cocaine), smoking, alcohol, and psychologic stress. In the United States, probably more than 90% of serious peptic ulcer complications can be attributed to *H. pylori* infection, NSAID use, and/or cigarette smoking.

HELICOBACTER PYLORI INFECTION

With specialized flagella and a rich supply of urease, *H. pylori* is uniquely equipped for survival in the hostile environment of the stomach.^{52–55} Fifty percent of the world's population is infected with *H. pylori*, a major cause of chronic gastritis. The same sequence of inflammation to metaplasia to dysplasia to carcinoma, that is well known to occur in the esophagus from reflux-induced inflammation (and in the colon from inflammatory bowel disease), is now increasingly well recognized to occur in the stomach with *Helicobacter*-induced gastritis. The influence of prolonged acid suppression with PPIs or H₂RAs on these esophagogastric processes is largely unknown. *Helicobacter* also clearly has an etiologic role in the development of gastric lymphoma.

The organism possesses the enzyme urease, which converts urea into ammonia and bicarbonate, thus creating an environment around the bacteria that buffers the acid secreted by the stomach. The ammonia is damaging to the SECs. Mutant strains of *H. pylori* that do not produce urease are unable to colonize the stomach. The organism lives in the mucus layer atop the gastric SECs, and some attach to these cells (Fig. 26-25).^{53,54} Apparently *Helicobacter* strains that lack flagella are unable to navigate through the unstirred mucus layer to get to the apical membrane of the SEC for attachment, and are nonpathogenic. One of the mechanisms by which *Helicobacter* causes gastric injury may be through a disturbance in gastric acid secretion. This is due, in part, to the inhibitory effect that *H. pylori* exerts on antral D cells that secrete somatostatin, a potent inhibitor of antral G-cell gastrin production. *H. pylori* infection is associated with decreased levels of somatostatin, decreased somatostatin messenger RNA production, and fewer somatostatin-producing D cells. These effects are probably mediated by *H. pylori*-induced local alkalization of the antrum (antral acidification is the most potent antagonist to antral gastrin secretion), and *H. pylori*-mediated increases in other local mediators and cytokines. The end result is hypergastrinemia and acid hypersecretion (Fig. 26-26).⁴⁹ This hypergastrinemia presumably leads to the parietal cell hyperplasia seen in many patients with duodenal ulcer. The acid hypersecretion and the antral gastritis are thought to lead to antral epithelial metaplasia in the postpyloric duodenum. This duodenal metaplasia allows *H. pylori* to colonize the duodenal mucosa and, in these patients, the risk of developing a duodenal ulcer increases 50-fold. When *H. pylori* colonizes the duodenum, there is a significant decrease in acid-stimulated duodenal bicarbonate release. When *H. pylori* infection is successfully treated, acid secretory physiology tends to normalize. Other mechanisms whereby *H. pylori* can induce gastroduodenal mucosal injury include the production of toxins (vacA and cagA), local elaboration of cytokines (particularly interleukin-8) by infected mucosa, recruitment of inflammatory cells and release of inflammatory mediators, recruitment and activation of local immune factors, and increased apoptosis (Fig. 26-27).^{54,55} The net effect is a weakening of mucosal defenses.

The evidence supporting the central role of *H. pylori* in the pathophysiology of PUD is strong. Patients with *H. pylori* infection and antral gastritis are three and one-half times more likely to develop PUD than patients without *H. pylori* infection. Up to 90% of patients with duodenal ulcers, and 70 to 90% of patients with gastric ulcers, have *H. pylori* infection. It is clear from multiple randomized prospective studies that curing *H. pylori* infection dramatically alters the natural history of PUD, decreasing the recurrent ulcer rate from more than 75% in patients treated with a course of acid-suppressive therapy alone (in whom *H. pylori* is not eradicated) to less than 20% in patients treated with a course of antibacterial therapy (Fig. 26-28).⁵⁶

Fig. 26-28.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Helicobacter treatment dramatically decreases the recurrence rate of duodenal and gastric ulcer.

(Data from Graham DY, Lew GM, Klein PD, et al: Effect of treatment of *Helicobacter pylori* infection on the long-term recurrence of gastric or duodenal ulcer. A randomized controlled study. *Ann Intern Med* 116:705, 1992.)

Obviously, other factors are involved in the etiology of PUD because everyone who has *H. pylori* (up to 50% of the adult population in some areas of the United States) does not get PUD. Only about 10 to 15% of patients colonized with *H. pylori* will develop PUD over their lifetime. Many patients on aspirin and NSAIDs develop PUD without *H. pylori* infection. These observations notwithstanding, it is clear from a variety of well-designed laboratory, clinical, and epidemiologic studies that *H. pylori* is indubitably an important factor in the development and recurrence of PUD. *H. pylori* also plays an etiologic role in gastric cancer and lymphoma.⁵⁴

ACID SECRETION AND PEPTIC ULCER

A variety of abnormalities related to mucosal acid exposure have been described in patients with duodenal ulcer (Fig. 26-29).⁵⁷ As a rule, duodenal ulcer patients secrete more acid than patients with gastric ulcer. It has long been recognized that duodenal ulcer patients as a group have a higher mean BAO and also a higher mean MAO compared to normal controls. Nocturnal acid secretion is more commonly elevated than daytime secretion. However, many duodenal ulcer patients have basal and peak acid outputs in the normal range, and there is no correlation between acid secretion and the severity of the

ulcer disease. Duodenal ulcer patients produce more acid than normal controls in response to any known secretory stimulus for gastric acid output. Although duodenal ulcer patients usually have normal fasting gastrin concentrations, they often produce more gastric acid at any given dose of gastrin than controls. Considering that many duodenal ulcer patients do produce excessive gastric acid, it has been argued that a "normal" fasting gastrin level in these patients is inappropriately high, and that there is an impaired feedback mechanism, especially in light of the apparently increased sensitivity of the parietal cell mass to gastrin. Many of these long-standing observations now seem reasonable in light of recently gained understanding of the perturbations in acid and gastrin secretion associated with *H. pylori* infection. Some patients with duodenal ulcer also have increased rates of gastric emptying that deliver an increased acid load per unit of time to the duodenum. Finally, the buffering capacity of the duodenum in many patients with duodenal ulcer is compromised due to decreased duodenal bicarbonate secretion.

Fig. 26-29.

Frequency of physiologic abnormalities in patients with duodenal ulcer (DU). HCO₃ = bicarbonate; MAO = maximal acid output.

[Reproduced with permission from Del Valle J, Chey WD, Scheiman JM: Acid peptic disorders, in Yamada T, et al (eds): *Textbook of Gastroenterology*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2003, p 1321.]

In patients with gastric ulcer, acid secretion is variable. Currently, five types of gastric ulcer are described, although the original Johnson classification contained three types (Fig. 26-30).⁵⁸ The most common, Johnson type I gastric ulcer, is typically located near the angularis incisura on the lesser curvature, close to the border between the antrum and the body of the stomach. Patients with type I gastric ulcer usually have normal or decreased acid secretion. Type II gastric ulcer is associated with active or quiescent duodenal ulcer disease, and type III gastric ulcer is prepyloric ulcer disease. Both type II and type III gastric ulcers are associated with normal or increased gastric acid secretion. Type IV gastric ulcers occur near the GE junction, and acid secretion is normal or below normal. Type V gastric ulcers are medication induced and may occur anywhere in the stomach. Patients with gastric ulcers may have weak mucosal defenses that permit an abnormal amount of injurious acid back-diffusion into the mucosa. Duodenogastric reflux may play a role in weakening the gastric mucosal defenses, and a variety of components in duodenal juice, including bile, lysolecithin, and pancreatic juice, have been shown to cause injury and inflammation in the gastric mucosa. NSAIDs and aspirin have similar effects. Although chronic gastric ulcer usually is associated with surrounding gastritis, it is unproven that the latter leads to the former.

NONSTEROIDAL ANTI -INFLAMMATORY DRUGS IN PEPTIC ULCER DISEASE

NSAIDs (including aspirin) are inextricably linked to PUD.⁵⁹ Patients with rheumatoid arthritis and osteoarthritis who take NSAIDs have a 15 to 20% annual incidence of peptic ulcer, and the prevalence of peptic ulcer in chronic NSAID users is about 25% (15% gastric and 10% duodenal). Complications of PUD (specifically hemorrhage and perforation) are much more common in patients taking NSAIDs. More than half of patients who present with peptic ulcer hemorrhage or perforation report the recent use of NSAIDs, including aspirin. Many of these patients remain asymptomatic until they develop these life-threatening complications.

The overall risk of significant serious adverse GI events in patients taking NSAIDs is more than three times that of controls (Table 26-6). This risk increases to five times in patients more than age 60 years old. In elderly patients taking NSAIDs, the likelihood that they will require an operation related to a GI complication is 10 times that of the control group, and the risk that they will die from a GI cause is about four and one-half times higher. This problem is put into perspective when one realizes that approximately 20 million patients in the United States take NSAIDs on a regular basis; perhaps as many regularly take aspirin. Persons who take NSAIDs also have a higher hospitalization rate for serious GI events than those who do not.

Table 26-6 Hospitalization Rates for GI Events with and without NSAID Use in Selected Large Populations

Therapies Used		Annualized Incidence ^b	
		Clinical Upper GI Events ^c	Complicated Upper GI Events ^d

Study ^a	NSAID Control	Study Drugs	Control	Study Drug	Control	Study Drug
MUCOSA	10 NSAIDs (n = 4439)	Misoprostol 200 µg qid + NSAID (n = 4404)	3.1%	1.6%	1.5%	0.7%
CLASS	Ibuprofen 800 mg tid, diclofenac 75 mg bid (n = 3987)	Celecoxib 400 mg bid (n = 3995)	3.5%	2.1%	1.5%	0.8%
			(No aspirin ^e : 2.9%)	1.4%	1.3%	0.4%
VIGOR	Naproxen 500 mg bid (n = 4047)	Rofecoxib 50 mg qd (n = 4029)	4.5%	2.1%	1.4%	0.6%

^aMUCOSA and VIGOR trials included only rheumatoid arthritis patients; CLASS trial included osteoarthritis (73%) and rheumatoid arthritis (27%).

^bIncidence for MUCOSA trial represents doubling of results provided at 6 months (although median follow-up was <6 months). Incidences for VIGOR and CLASS trials represent rates per 100 patient-years, although VIGOR median follow-up was 9 months and CLASS data include only the first 6 months of the study.

^cIncludes perforations, obstructions, bleeding, and uncomplicated ulcers discovered on clinically indicated work-up.

^dIncludes perforation, obstruction, bleeding (documented due to ulcer or erosions in MUCOSA and CLASS; major bleeding in VIGOR).

^e21% of patients in CLASS study were taking low-dose aspirin.

Note: All differences between controls and study drugs were significant except clinical upper GI events in overall CLASS study (*P* = .09).

Factors that clearly put patients at increased risk for NSAID-induced GI complications include age >60, prior GI event, high NSAID dose, concurrent steroid intake, and concurrent anticoagulant intake. *Any patient taking NSAIDs or aspirin who has one or more of these risk factors should receive concomitant acid suppressive medication* (Table 26-7).⁶⁰

Table 26-7 Patients Taking NSAIDs or Aspirin Need Concomitant Acid Suppressing Medication if Any of the Following Risk Factors Is Present
<ul style="list-style-type: none"> ● Age over 60
<ul style="list-style-type: none"> ● History of acid/peptic disease
<ul style="list-style-type: none"> ● Concurrent steroid intake
<ul style="list-style-type: none"> ● Concurrent anticoagulant intake ● High-dose NSAID or acetylsalicylic acid

SMOKING, STRESS, AND OTHER FACTORS

Epidemiologic studies suggest that smokers are about twice as likely to develop PUD as nonsmokers. Smoking increases gastric acid secretion and duodenogastric reflux. Smoking decreases both gastroduodenal prostaglandin production and pancreaticoduodenal bicarbonate production. These observations may be related, and any or all could explain the observed association between smoking and PUD.

Although difficult to measure, both physiologic and psychologic stress undoubtedly play a role in the development of peptic ulcer in some patients. In 1842, Curling described duodenal ulcer and/or duodenitis in burn patients. Decades later, Cushing described the appearance of acute peptic ulceration in patients with head trauma (Cushing's ulcer). Even the ancients recognized the undeniable links between PUD and stress. Patients still present with ulcer complications (bleeding, perforation, and obstruction) that are seemingly exacerbated by stressful life events. The use of crack cocaine has been linked to juxtapyloric peptic ulcers with a propensity to perforate. Alcohol is commonly mentioned as a risk factor for PUD, but confirmatory data are lacking.

Clinical Manifestations

More than 90% of patients with PUD complain of abdominal pain. The pain is typically nonradiating, burning in quality, and located in the epigastrium. The mechanism of the pain is unclear. Patients with duodenal ulcer often experience pain 2 to 3 hours after a meal and at night. Two thirds of patients with duodenal ulcers will complain of pain that awakens them from sleep. The pain of gastric ulcer more commonly occurs with eating and is less likely to awaken the patient at night. A history of PUD, use of NSAIDs, over-the-counter antacids, or antisecretory drugs is suggestive of the diagnosis. Other signs and symptoms include nausea, bloating, weight loss, stool positive for occult blood, and anemia. Duodenal ulcer is about twice as common in men compared to women, but the incidence of gastric ulcer is similar in men and women. On average, gastric ulcer patients are 10 years older than duodenal ulcer patients, and the incidence is increasing in the elderly, probably because of increasing NSAID use in this cohort with a high incidence of *H. pylori*

infection.

Diagnosis

In the young patient with dyspepsia and/or epigastric pain, it may be appropriate to initiate empiric PPI therapy for PUD without confirmatory testing. In such cases, it is prudent to discuss with the patient the small possibility of an alternative diagnosis, including malignancy, even if symptoms improve with the initiation of therapy. All patients more than 45 years old with the above symptoms should have an upper endoscopy, and all patients, regardless of age, should have this study if any alarm symptoms (see Table 26-5) are present. A double-contrast upper GI x-ray study may be useful. Once an ulcer has been confirmed endoscopically or radiologically, obvious possible causes (*Helicobacter*, NSAIDs, gastrinoma, cancer) should always be considered. All gastric ulcers should be adequately biopsied, and any sites of gastritis should be biopsied to rule out *H. pylori*, and for histologic evaluation. Additional testing for *H. pylori* may be indicated. It is not unreasonable to test all peptic ulcer patients for *H. pylori* (Table 26-8).⁶¹ A baseline serum gastrin level is appropriate to rule out gastrinoma.

Table 26-8 Indications for Diagnosis and Treatment of <i>Helicobacter pylori</i>
Established
● Active peptic ulcer disease (gastric or duodenal ulcer)
● Confirmed history of peptic ulcer disease (not previously treated for <i>H. pylori</i>)
Gastric mucosa-associated lymphoid tissue lymphoma (low grade)
● After endoscopic resection of early gastric cancer
● Uninvestigated dyspepsia (depending on <i>H. pylori</i> prevalence)
Controversial
● Nonulcer dyspepsia
● Gastroesophageal reflux disease
● Persons using NSAIDs
● Unexplained iron deficiency anemia
● Populations at higher risk for gastric cancer

Complications

The three most common complications of PUD, in decreasing order of frequency, are bleeding, perforation, and obstruction.^{62–64} Most peptic ulcer–related deaths in the United States are due to bleeding. Bleeding peptic ulcers are by far the most common cause of upper GI bleeding in patient admitted to hospital (Fig. 26-31).⁶⁵ Patients with a bleeding peptic ulcer typically present with melena and/or hematemesis. Nasogastric aspiration is usually confirmatory of the upper GI bleeding. Abdominal pain is quite uncommon. Shock may be present, necessitating aggressive resuscitation and blood transfusion. Early endoscopy is important to diagnose the cause of the bleeding and to assess the need for hemostatic therapy.

Causes of upper GI bleeding.

(Reproduced with permission from Dallal HJ, Palmer KR: Clinical Review: Upper gastrointestinal hemorrhage. *BMJ* 323:1115, 2001. With permission from the BMJ Publishing Group.)

Three fourths of the patients who come to the hospital with bleeding peptic ulcer will stop bleeding if given acid suppression and nothing by mouth. However, one fourth will continue to bleed or will rebleed after an initial quiescent period, and virtually all the mortalities (and all the operations for bleeding) occur in this group. This group can be fairly well delineated based on clinical factors related to the magnitude of the hemorrhage, comorbidities, age, and endoscopic findings. Shock, hematemesis, transfusion requirement exceeding four units in 24 hours, and certain endoscopic stigmata (active bleeding or visible vessel) define this high-risk group. Two widely used risk stratification tools have proven useful in predicting rebleeding and death: the Blatchford and Rockall scores (Table 26-9).⁶⁶ High-risk patients benefit from endoscopic therapy to stop the bleeding. The most common endoscopic hemostatic modalities used are injection with epinephrine, and electrocautery. Persistent bleeding or rebleeding after endoscopic therapy is an indication for operation, although repeat endoscopic treatment has been successful in treating rebleeding. Elderly patients and patients with multiple comorbidities do not tolerate repeated episodes of hemodynamically significant hemorrhage, and may benefit from early elective operation after initially successful endoscopic treatment, especially if they have one or more of the risk factors mentioned above or a high-risk ulcer. Planned surgery under controlled circumstances often yields better outcomes than emergent surgery performed in the middle of the night. Deep bleeding ulcers on the posterior duodenal bulb or lesser gastric curvature are high-risk lesions, because they often erode large arteries not amenable to nonoperative treatment, and early operation should be considered.

Table 26-9 Risk-Stratification Tools for Upper Gastrointestinal Hemorrhage ^a			
A. Blatchford Score			
At Presentation	Points		
Systolic blood pressure			
100–109 mmHg	1		
90–99 mmHg	2		
<90 mmHg	3		
Blood urea nitrogen			
6.5–7.9 mmol/L	2		
8.0–9.9 mmol/L	3		
10.0–24.9 mmol/L	4		
≥25 mmol/L	6		
Hemoglobin for men			
12.0–12.9 g/dL	1		
10.0–11.9 g/dL	3		
<10.0 g/dL	6		
Hemoglobin for women			
10.0–11.9 g/dL	1		
<10.0 g/dL	6		
Other variables at presentation			
Pulse ≥100 beats/min	1		
Melena	1		
Syncope	2		
Hepatic disease	2		
Cardiac failure	2		
B. Rockall Score			
		Variable	Points
Complete Rockall Score	Clinical Rockall Score	Age	
		<60 y	0
		60–79 y	1
		≥80 y	2
		Shock	
		Heart rate >100 beats/min	1
		Systolic blood pressure <100 mmHg	2

		Coexisting illness	
		Ischemic heart disease, congestive heart failure, other major illness	2
		Renal failure, hepatic failure, metastatic cancer	3
		Endoscopic diagnosis	
		No lesions observed, Mallory-Weiss syndrome	0
		Peptic ulcer, erosive disease, esophagitis	1
		Cancer of the upper GI tract	2
		Endoscopic stigmata of recent hemorrhage	
		Clean base ulcer, flat pigmented spot	0
		Blood in upper GI tract, active bleeding, visible vessel, clot	2

^aPanel A shows the values used in the Blatchford risk-stratification score, which ranges from 0 to 23, with higher scores indicating higher risk. Panel B shows the Rockall score, with point values assigned for each of three clinical variables (age and the presence of shock and coexisting illnesses) and two endoscopic variables (diagnosis and stigmata of recent hemorrhage). The complete Rockall score ranges from 0 to 11, with higher scores indicating higher risk. Patients with a clinical Rockall score of 0 or a complete Rockall score of 2 or less are considered to be at low risk for rebleeding or death.

Perforated peptic ulcer usually presents as an acute abdomen. The patient can often give the exact time of onset of the excruciating abdominal pain. Initially, a chemical peritonitis develops from the gastric and/or duodenal secretions, but within hours a bacterial peritonitis supervenes. Fluid sequestration into the third space of the inflamed peritoneum can be impressive, and fluid resuscitation is mandatory. The patient is in obvious distress, and the abdominal examination shows peritoneal signs. Usually, marked involuntary guarding and rebound tenderness is evoked by a gentle examination. Upright chest x-ray shows free air in about 80% of patients (Fig. 26-32). Once the diagnosis has been made, the patient is given analgesia and antibiotics, resuscitated with isotonic fluid, and taken to the operating room. Sometimes, the perforation has sealed spontaneously by the time of presentation, and surgery can be avoided if the patient is doing well. Nonoperative management is appropriate only if there is objective evidence that the leak has sealed (i.e., radiologic contrast study), and in the absence of clinical peritonitis.

 Pneumoperitoneum on upright chest x-ray in patient with perforated ulcer.

Gastric outlet obstruction occurs in no more than 5% of patients with PUD. It is usually due to duodenal or prepyloric ulcer disease, and may be acute

(from inflammatory swelling and peristaltic dysfunction) or chronic (from cicatrix). Patients typically present with nonbilious vomiting and may have a profound hypokalemic hypochloremic metabolic alkalosis. Pain or discomfort is common. Weight loss may be prominent, depending on the duration of symptoms. A succussion splash may be audible with stethoscope placed in the epigastrium. Initial treatment is nasogastric suction, IV hydration and electrolyte repletion, and antisecretory medication. The diagnosis is confirmed by endoscopy. Most patients admitted to the hospital nowadays with obstructing ulcer disease require intervention, either balloon dilation or operation. Cancer must be ruled out because most patients who present with the symptoms of gastric outlet obstruction will have a pancreatic, gastric, or duodenal malignancy.

Medical Treatment of Peptic Ulcer Disease

PPIs are the mainstay of medical therapy for PUD, but high dose H₂RAs are also quite effective. Patients hospitalized for ulcer complications should receive PPI by continuous IV infusion and, when discharged, should be considered for lifelong PPIs unless the definitive cause is eliminated or a definitive operation performed. Peptic ulcer patients should stop smoking and avoid alcohol and NSAIDs (including aspirin). Patients who require NSAIDs or aspirin to treat other medical conditions should always take concomitant PPIs or high dose H₂ receptor blockers. If *H. pylori* infection is documented, it should be treated with one of several acceptable regimens (Table 26-10).⁶¹ Infectious disease consultation may be helpful in the compliant, symptomatic patient with persistent *H. pylori* infection following treatment, or another regimen could be tried (e.g., quadruple therapy). If initial *H. pylori* testing is negative and ulcer symptoms persist, an empiric trial of anti-*H. pylori* therapy is reasonable (false-negative *H. pylori* tests are common). Generally, antisecretory therapy can be stopped after 3 months if the ulcerogenic stimulus (usually *H. pylori*, NSAIDs, or aspirin) has been removed. However, long-term maintenance PPI therapy should be considered in all patients admitted to hospital with ulcer complications, all high-risk patients on NSAIDs or aspirin (the elderly or debilitated), and all patients with a history of recurrent ulcer or bleeding. Consideration should be given to maintenance therapy in refractory smokers with a history of peptic ulcer. Misoprostol, sucralfate, and acid suppression may be quite comparable in many patient groups; occasionally treatment with more than one agent is useful. Misoprostol may cause diarrhea and cramps, and cannot be used in women of childbearing age because of its abortifacient properties. For these reasons, it is not widely used to treat PUD. Sucralfate acts locally and is well tolerated.

Table 26-10 Treatment Regimens for <i>Helicobacter pylori</i>	
Medications/Dose/Frequency	Duration
PPI + clarithromycin 500 mg bid + amoxicillin 1000 mg bid	10–14 d
PPI + clarithromycin 500 bid + metronidazole 500 bid	10–14 d
PPI + amoxicillin 1000 mg bid, then	5 d
PPI + clarithromycin 500 mg bid + tinidazole 500 mg bid	5 d
Salvage regimens for patients who fail one of the above initial regimens:	
Bismuth subsalicylate 525 mg qid + metronidazole 250 mg qid + tetracycline 500 mg qid + PPI	10–14 d
PPI + amoxicillin 1000 mg bid + levofloxacin 500 mg daily	10 d

PPI = proton pump inhibitor.

Surgical Treatment of Peptic Ulcer Disease

The indications for surgery in PUD are bleeding, perforation, obstruction, and intractability or nonhealing.^{67,68} Gastric cancer must always be considered in patients with gastric ulcer or gastric outlet obstruction.

Today, most patients undergoing operation for PUD have simple oversewing of a bleeding ulcer, or simple patch of a perforated ulcer, or distal gastrectomy. Simultaneous performance of vagotomy either truncal or highly selective is increasingly uncommon, probably due to surgeon unfamiliarity with the procedure and reliance on postoperative PPIs to decrease acid secretion.

Unfortunately, the data from many excellent randomized clinical trials evaluating elective operation for peptic ulcer over the last several decades may be irrelevant to most patients presenting for ulcer surgery today.⁶⁷ The large majority of these excellent studies were done in the pre-PPI, pre-*Helicobacter*, pre-NSAID era, and focused on elective operation for intractable disease, an unusual indication in the modern era. Thus, today's surgeon should take great care in applying this literature to inform surgical decision making.

Classically, in the previous era, the vast majority of peptic ulcers were adequately treated by a variant of one of the three basic operations: HSV, vagotomy and drainage (V+D), and vagotomy and distal gastrectomy. Recurrence rates were lowest but morbidity highest with the latter procedure, while the opposite was true for HSV (Table 26-11).^{67–69}

Table 26-11 Clinical Results of Surgery for Duodenal Ulcer

	Parietal Cell Vagotomy	Truncal Vagotomy and Pyloroplasty	Truncal Vagotomy and Antrectomy
Operative mortality rate (%)	0	<1	1
Ulcer recurrence rate (%)	5–15	5–15	<2
Dumping (%)			
Mild	<5	10	10–15
Severe	0	1	1–2
Diarrhea (%)			
Mild	<5	25	20
Severe	0	2	1–2

Source: Modified from Mulholland et al,⁶⁸ with permission. Copyright Elsevier.

HSV, also called *parietal cell vagotomy* or *proximal gastric vagotomy*, is safe (mortality risk <0.5%) and causes minimal side effects. The operation severs the vagal nerve supply to the proximal two thirds of the stomach, where essentially all the parietal cells are located, and preserves the vagal innervation to the antrum and pylorus, and the remaining abdominal viscera (Fig. 26-33). Thus, the operation decreases total gastric acid secretion by about 75%, and GI side effects are rare. Elective HSV has largely been supplanted by long-term PPI treatment, but the operation, which has a learning curve, may still be useful in the patient (elective or emergent) who is noncompliant with, intolerant of, or cannot afford medical treatment. Historically, HSV has not performed particularly well for type II (gastric and duodenal) and III (prepyloric) gastric ulcer, perhaps because of hypergastrinemia caused by gastric outlet obstruction and persistent antral stasis. The Taylor procedure consists of a posterior truncal vagotomy and anterior seromyotomy (but anterior HSV is probably equivalent), and is an attractive and simple alternative to HSV with similar results.

Highly selective vagotomy.

[Reproduced with permission from Zinner MJ et al (eds): *Maingot's Abdominal Operations*, 10th ed., Vol. I. Stamford, Connecticut: Appleton & Lange, 1997, p 987.]

Truncal vagotomy and pyloroplasty, and truncal vagotomy and gastrojejunostomy are the paradigmatic *vagotomy and drainage procedures*. HSV may be substituted for truncal vagotomy. The advantage of V+D is that it can be performed safely and quickly by the experienced surgeon. The main disadvantages are the side effect profile (10% of patients have significant dumping and/or diarrhea). During truncal vagotomy (Fig. 26-34), care must be taken not to perforate the esophagus, a potentially lethal complication. Intraoperative frozen section confirmation of at least two vagal trunks is prudent; additional vagal trunks are common. Unlike HSV, V+D is widely accepted as a successful operation for complicated PUD. It has been described as a useful part of the operative treatment for bleeding duodenal and gastric ulcer, perforated duodenal and gastric ulcer, and obstructing duodenal and gastric (type II and III) ulcer. When applied to gastric ulcer, the ulcer should be excised or biopsied.

Truncal vagotomy.

[Reproduced with permission from Zollinger RM Jr., Zollinger RM Sr. (eds): *Zollinger's Atlas of Surgical Operations*, 8th ed. New York: McGraw-Hill, 2003, p 45.]

Truncal vagotomy denervates the antropyloric mechanism, and therefore, some sort of procedure is necessary to ablate or bypass the pylorus. Gastrojejunostomy is a good choice in patients with gastric outlet obstruction or a severely diseased proximal duodenum. The anastomosis is done between the proximal jejunum and the most dependent portion of the greater gastric curvature, in either an antecolic or retrocolic fashion (Fig. 26-35). Marginal ulceration is a potential complication. Pyloroplasty is useful in patients who require a pyloroduodenotomy to deal with the ulcer complication (e.g., posterior bleeding duodenal ulcer), in those with limited or focal scarring in the pyloric region, or when gastrojejunostomy is technically difficult. The most commonly performed pyloroplasty is the Heineke-Mikulicz type (Fig 26-36). Other occasionally useful techniques include the Finney (Fig. 26-37) and the Jaboulay pyloroplasties (Fig. 26-38). These more extensive pyloroplasty techniques may make subsequent distal gastric resection more difficult and/or hazardous.

The advantages of *vagotomy and antrectomy* (V+A) are the extremely low ulcer recurrence rate and the applicability of the operation to many patients with complicated PUD (e.g., bleeding duodenal and gastric ulcer, obstructing peptic ulcer, nonhealing gastric ulcer, and recurrent ulcer). When applied to gastric ulcer disease, the resection is usually extended far enough proximally to include the ulcer. The disadvantage of V+A is the higher operative mortality risk (when compared with HSV or V+D), and its irreversibility. Following antrectomy, GI continuity may be re-established with a Billroth I gastroduodenostomy (Fig. 26-39) or a Billroth II loop gastrojejunostomy (Fig. 26-40). Since antrectomy routinely leaves a 60 to 70% gastric remnant, reconstruction as a Roux-en-Y gastrojejunostomy should be avoided (Fig. 26-41). Although the Roux-en-Y operation is an excellent procedure for keeping

duodenal contents out of the stomach and esophagus, in the presence of a large gastric remnant, this reconstruction will predispose to marginal ulceration and/or gastric stasis.

Roux-en-Y gastrojejunostomy.

[Reproduced with permission from Ritchie WP Jr.: Benign diseases of the stomach and duodenum, in Ritchie WP, Steele G, Dean RH (eds): *General Surgery*. Philadelphia: Lippincott, 1995, p 117.]

V+A should be avoided in hemodynamically unstable patients, and in patients with extensive inflammation and/or scarring of the proximal duodenum, because secure anastomosis (Billroth I) or duodenal closure (Billroth II) may be difficult.

Distal gastrectomy without vagotomy (usually about a 50% gastrectomy to include the ulcer) has traditionally been the procedure of choice for type I gastric ulcer. The addition of vagotomy should be considered for type II and III gastric ulcers (because the pathophysiology is more analogous to duodenal ulcer), or if the patient is believed to be at increased risk for recurrent ulcer, or perhaps even if Billroth II reconstruction is contemplated (to decrease the chance of marginal ulcer). Subtotal gastrectomy (75% distal gastrectomy) without vagotomy is rarely used to treat PUD today, although it was the most popular ulcer operation at the middle of the last century.

CHOICE OF OPERATION FOR PEPTIC ULCER

The choice of operation for the individual patient with PUD depends on a variety of factors, including the type of ulcer (duodenal, gastric, recurrent, or marginal), the indication for operation, and the condition of the patient, among others. Other important considerations are intra-abdominal factors (duodenal scarring/inflammation, adhesions, or difficult exposure), the ulcer diathesis status of the patient, the surgeon's experience and personal preference, whether *H. pylori* infection is present, the need for NSAID therapy, previous treatment, and the likelihood of future compliance with treatment. Table 26-12 shows the surgical options for managing various aspects of PUD. In general, resective procedures have a lower ulcer recurrence rate, but a higher operative morbidity and mortality rate (see Table 26-11) when compared to nonresective ulcer operations. Because ulcer recurrence often is related to *H. pylori* and/or NSAIDs, it is usually managed adequately without reoperation. Thus, gastric resection to minimize recurrence in duodenal ulcer disease is often not justified today; resection for gastric ulcer remains the standard because of the risk of cancer. Clearly, the modern trend in peptic ulcer operation could be described as "less is more."^{70,71} Vagotomy as a component of emergency ulcer surgery is increasingly uncommon.

Table 26-12 Surgical Options in the Treatment of Duodenal and Gastric Ulcer

Indication	Duodenal	Gastric
Bleeding	<ol style="list-style-type: none"> 1. Oversew^a 2. Oversew, V+D 	<ol style="list-style-type: none"> 1. Oversew and biopsy^a 2. Oversew, biopsy, V+D 3. Distal gastrectomy^b

^aUnless the patient is in shock or moribund, a definitive procedure should be considered.

^bOperation of choice in low-risk patient.

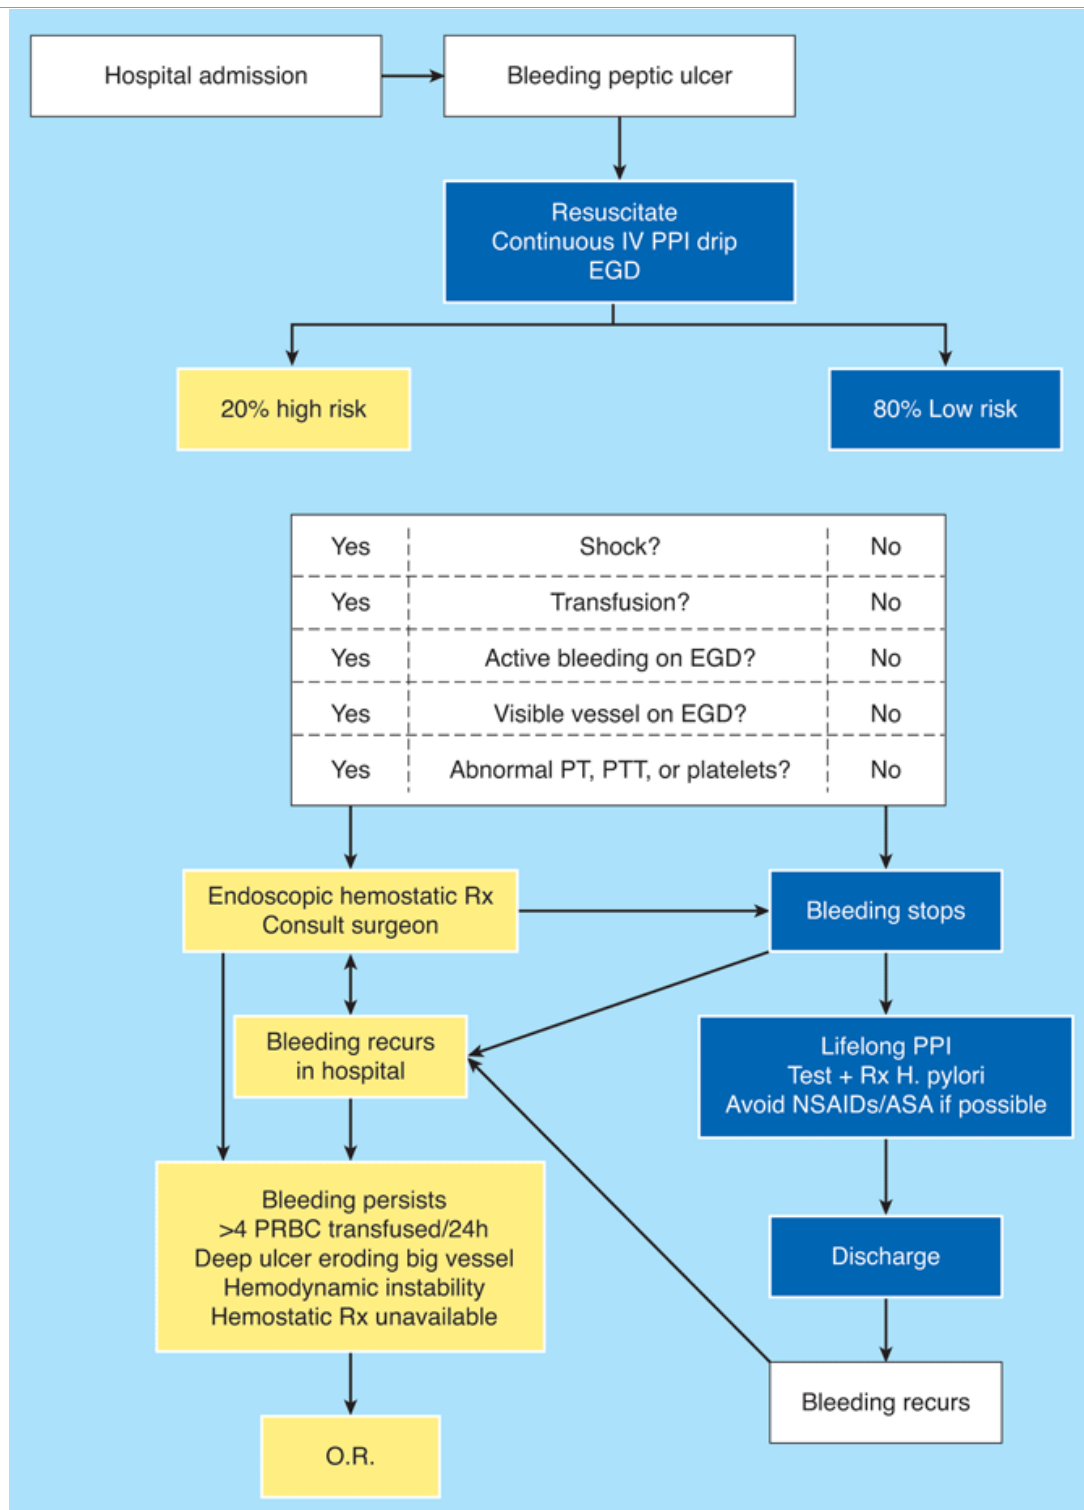

GJ = gastrojejunostomy; HSV = highly selective vagotomy; V+A = vagotomy and antrectomy; V+D = vagotomy and drainage.

Bleeding Peptic Ulcer

Bleeding is the most common cause of ulcer-related death, but most patients admitted to hospital with bleeding gastric or duodenal ulcer today will not require an operation. The success of endoscopic treatment and medical therapy in treating and preventing bleeding PUD has resulted in the selection of a subgroup of high-risk patients for today's surgeon. It is likely that patients currently coming to operation for bleeding PUD are at higher risk for a poor outcome than ever before. The surgical options for treating bleeding PUD include suture ligation of the bleeder; suture ligation and definitive nonresective ulcer operation (HSV or V+D); and gastric resection (usually including vagotomy and ulcer excision). Gastric ulcer requires biopsy if not resected.

The management of bleeding peptic ulcer is summarized in the algorithm provided in Fig. 26-42. All patients admitted to hospital with bleeding peptic ulcer should be adequately resuscitated and started on continuous IV PPI.⁷² Seventy-five percent of patients will stop bleeding with these measures alone, but 25% will continue to bleed or will rebleed in hospital. It is important to identify this high-risk group early with clinical and endoscopic parameters because, essentially, all the deaths from bleeding ulcer occur in this group. Surgical consultation is mandatory, and endoscopic hemostatic therapy (cautery, epinephrine injection, clipping) is indicated and usually successful in these high-risk patients.^{73,74} Indications for operation include massive hemorrhage unresponsive to endoscopic control, and transfusion requirement of more than four to six units of blood, despite attempts at endoscopic control. Lack of availability of a therapeutic endoscopist, recurrent hemorrhage after one or more attempts at endoscopic control, lack of availability of blood for transfusion, repeat hospitalization for bleeding ulcer, and concurrent indications for surgery such as perforation or obstruction, are also indications for surgery. Patients with massive bleeding from high-risk lesions (e.g., posterior duodenal ulcer with erosion of gastroduodenal artery, or lesser curvature gastric ulcer with erosion of left gastric artery or branch) should be considered for early operation. Early operation should also be considered in patients more than 60 years of age, those presenting in shock, those requiring more than four units of blood in 24 hours or eight units of blood in 48 hours, those with rebleeding, and those with ulcers >2 cm in diameter. The mortality rate for surgery for bleeding peptic ulcer is 10 to 20%.

Algorithm for operation for bleeding peptic ulcer. BMI = body mass index; Bx = biopsy; PPI = proton pump inhibitor; proc = procedure; TV = truncal vagotomy; TV/A = truncal vagotomy and antrectomy; TV/D = truncal vagotomy and drainage.

The two operations most commonly used for bleeding duodenal ulcer are oversewing of the ulcer usually without vagotomy,⁷⁰ or V+A. Oversewing alone results in a higher rebleeding rate but a lower operative mortality rate. When the mortality for reoperation for rebleeding is considered, the overall mortality is probably comparable for the two approaches. Patients who are in shock or medically unstable should not have gastric resection.

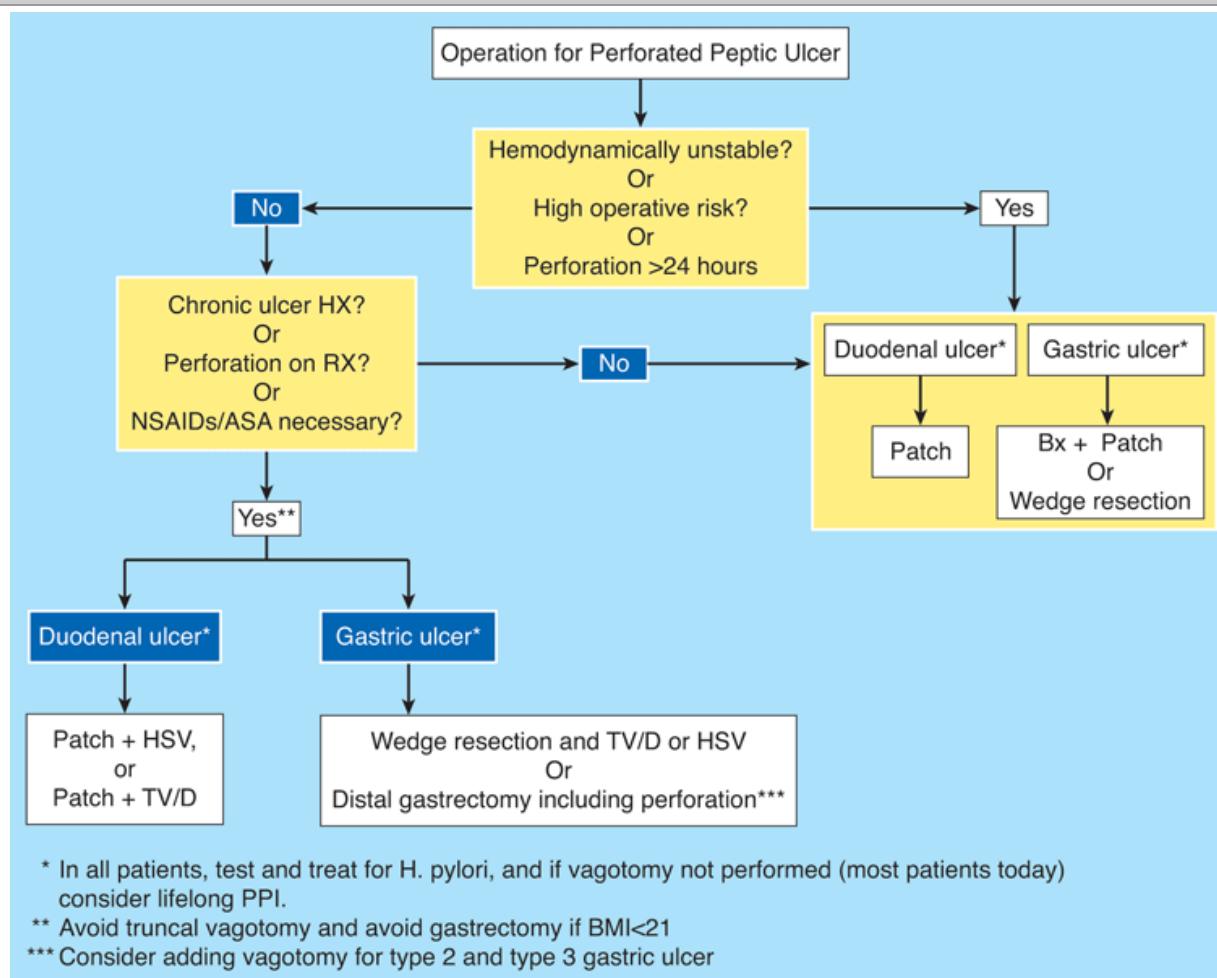

An initial pyloromyotomy incision allows access to the bleeding posterior duodenal ulcer, and an expeditious Kocher maneuver allows the surgeon to control the hemorrhage with the left hand if necessary. Heavy suture material on a stout needle is used to place figure-of-eight sutures or a U-stitch to secure the bleeding vessel at the base of the posterior duodenal ulcer. Multiple sutures are usually necessary. Once the surgeon is unequivocally convinced that hemostasis is secure, a pyloroplasty can be performed. If the patient is stable, vagotomy may be added. If the patient is not a high operative risk and V+A is selected, smaller duodenal ulcers are resected with the specimen; larger bleeding duodenal ulcers must often be left behind in the duodenal stump. In this situation, suture hemostasis must be attained and a secure duodenal closure accomplished. The anterior wall of the open duodenum can be sutured to either the proximal or distal lip of the posterior ulcer once the bleeding vessel has been sutured. The duodenal closure can be buttressed with omentum and the duodenum should be decompressed, either with a lateral duodenostomy or retrograde duodenostomy tube via the proximal jejunum or nasogastric route. Right upper quadrant closed suction peritoneal drainage is important. Use of a feeding jejunostomy is also considered. A Billroth II anastomosis is preferred.

The initial management of bleeding gastric ulcers and the indications for operation are similar to those for bleeding duodenal ulcer. These lesions tend to occur in older and/or medically complicated patients, and this fact may increase the operative risk. Although this has been used by some as an excuse not to operate early on these patients, experience shows that planned surgery in a resuscitated patient results in a better operative survival rate than emergent operation in a patient who has rebled and is in shock. Distal gastric resection to include the bleeding ulcer is the procedure of choice for bleeding gastric ulcer. Second best is V+D with oversewing and biopsy of the ulcer to rule out cancer. Oversewing of the bleeder followed by long-term acid suppression is a reasonable alternative in high-risk or unstable patients.

Perforated Peptic Ulcer (Fig. 26-44)

Perforation is the second most common complication of peptic ulcer. As with bleeding ulcer, NSAID and/or aspirin use have been inextricably linked with perforated PUD, especially in the elderly population.⁷⁵ Well over 20% of patients over the age of 60 years old presenting with a perforated ulcer are taking NSAIDs at the time of perforation. Surgery is almost always indicated, although occasionally nonsurgical treatment can be used in the stable patient without peritonitis in whom radiologic studies document a sealed perforation. Patients with acute perforation and GI blood loss (either chronic or acute) should be suspected of having a second ulcer.

Fig. 26-44.

Algorithm for operation for perforated peptic ulcer. ASA = acetylsalicylic acid; BMI = body mass index; Bx = biopsy; HSV = highly selective vagotomy; Hx = history; PPI = proton pump inhibitor; Rx = treatment; TV/D = truncal vagotomy and drainage.

The options for surgical treatment of perforated duodenal ulcer are simple patch closure, patch closure and HSV, or patch closure and V+D. Simple patch closure alone should be done in patients with hemodynamic instability and/or exudative peritonitis signifying a perforation >24 hours old. In all other patients, the addition of HSV may be considered because numerous studies have reported a negligible mortality with this approach.^{63,67} However, in the United States and Western Europe, there is clearly a trend away from definitive operation for perforated duodenal ulcer, probably because of the ready availability of PPI, and surgeon unfamiliarity with definitive operation in this setting.⁷⁰

Perforated gastric ulcer results in a higher mortality rate than perforated duodenal ulcer (10 to 40%) due to the following: patients' more advanced age, increased medical comorbidities, delay in seeking medical attention, and the larger size of gastric ulcers. In the stable patient without multiple operative risk factors, perforated gastric ulcers are best treated by distal gastric resection. Vagotomy is usually added for type II and III gastric ulcers. Patch closure with biopsy; or local excision and closure; or biopsy, closure, truncal vagotomy, and drainage are alternative operations in the unstable or high-risk patient, or in the patient with a perforation in an inopportune location (e.g., juxtapyloric). All perforated gastric ulcers, even those in the prepyloric position, should be biopsied if they are not removed at surgery.

Obstructing Peptic Ulcer

Currently, gastric outlet obstruction is the least common indication for operation in PUD. Acute ulcers associated with obstruction due to edema and/or motor dysfunction may respond to intensive antisecretory therapy and nasogastric suction. But most patients with significant obstruction from chronic ulceration will require some sort of more substantial intervention. Endoscopic balloon dilation can often transiently improve obstructive symptoms, but many of these patients ultimately fail and come to operation.⁷⁶

The most common operations for obstructing PUD are V+A and V+D. HSV and gastrojejunostomy is comparable to V+A in this setting⁷⁷ and is an appealing operation for obstruction, both because it can readily be done using laparoscopic techniques, and because it does not complicate future resection, should this be needed. However, potentially curable gastric or duodenal cancers can be missed with this approach.

Intractable or Nonhealing Peptic Ulcer

This should indeed be a rare indication for surgery performed today. Arguably, the patient referred for surgical evaluation because of intractable PUD should raise red flags for the surgeon: Maybe the patient has a missed cancer; maybe the patient is noncompliant (not taking prescribed PPI, still taking NSAIDs, still smoking); maybe the patient has *Helicobacter* despite the presence of a negative test or previous treatment. Because acid secretion can be totally blocked and *H. pylori* eradicated with modern medication, the question remains: "Why does the patient have a persistent ulcer diathesis?" The surgeon should review the differential diagnosis of nonhealing ulcer before any consideration of operative treatment (Table 26-13).

Table 26-13 Differential Diagnosis of Intractability or Nonhealing Peptic Ulcer Disease
Cancer
Gastric
Pancreatic
Duodenal
Persistent <i>Helicobacter pylori</i> infection
Tests may be false-negative
Consider empiric treatment
Noncompliant patient
Failure to take prescribed medication
Surreptitious use of NSAIDs
Motility disorder
Zollinger-Ellison syndrome

Surgical treatment should be considered in patients with nonhealing or intractable PUD who have multiple recurrences, large ulcers (>2 cm), complications (obstruction, perforation, or hemorrhage), or suspected malignancy. Definitive operation, particularly gastric resection, should be considered most cautiously in the thin or marginally nourished individual.

It is important that the surgeon not fall into the trap of performing a large, irreversible operation on these patients, based on the unproven theory that if all other methods have failed to heal the ulcer, a large operation is required. Although there is a large quantity of very good data in the surgical literature suggesting that the large majority of patients do well after the larger elective ulcer operations, these data may not be particularly relevant to the modern patient.⁶⁷ Candidates for ulcer operation today are different than those of three or four decades ago. One might argue that current medical care has healed the minor ulcers, and that patients presenting with true intractability or nonhealing will be more difficult to treat and are likely to have chronic problems after a major ulcer operation.

If surgery is necessary, a lesser operation may be preferable. It is the practice of this author never to perform a gastrectomy as the initial elective operation for intractable duodenal ulcer in the thin or asthenic patient. Instead, the preferred operation for this group of patients is HSV. In patients with nonhealing gastric ulcer, wedge resection with HSV should be considered in thin or frail patients. Otherwise, distal gastrectomy (to include the ulcer) is recommended. It is unnecessary to add a vagotomy in patients with type I or type IV (juxtaesophageal) gastric ulcers because they are usually associated with acid hyposecretion. Type IV gastric ulcers may be difficult to resect as part of a distal gastrectomy, and a variety of surgical techniques have been described to treat these more proximal lesions (Fig. 26-45).

Operations for gastric ulcer.

[Reproduced with permission from Seymour NE: Operations for peptic ulcer and their complications, in Feldman M, Sharschmidt BF, Sleisenger MH (eds): *Gastrointestinal and Liver Disease*, 6th ed. Philadelphia: Saunders, 1998, p 702. Copyright Elsevier.]

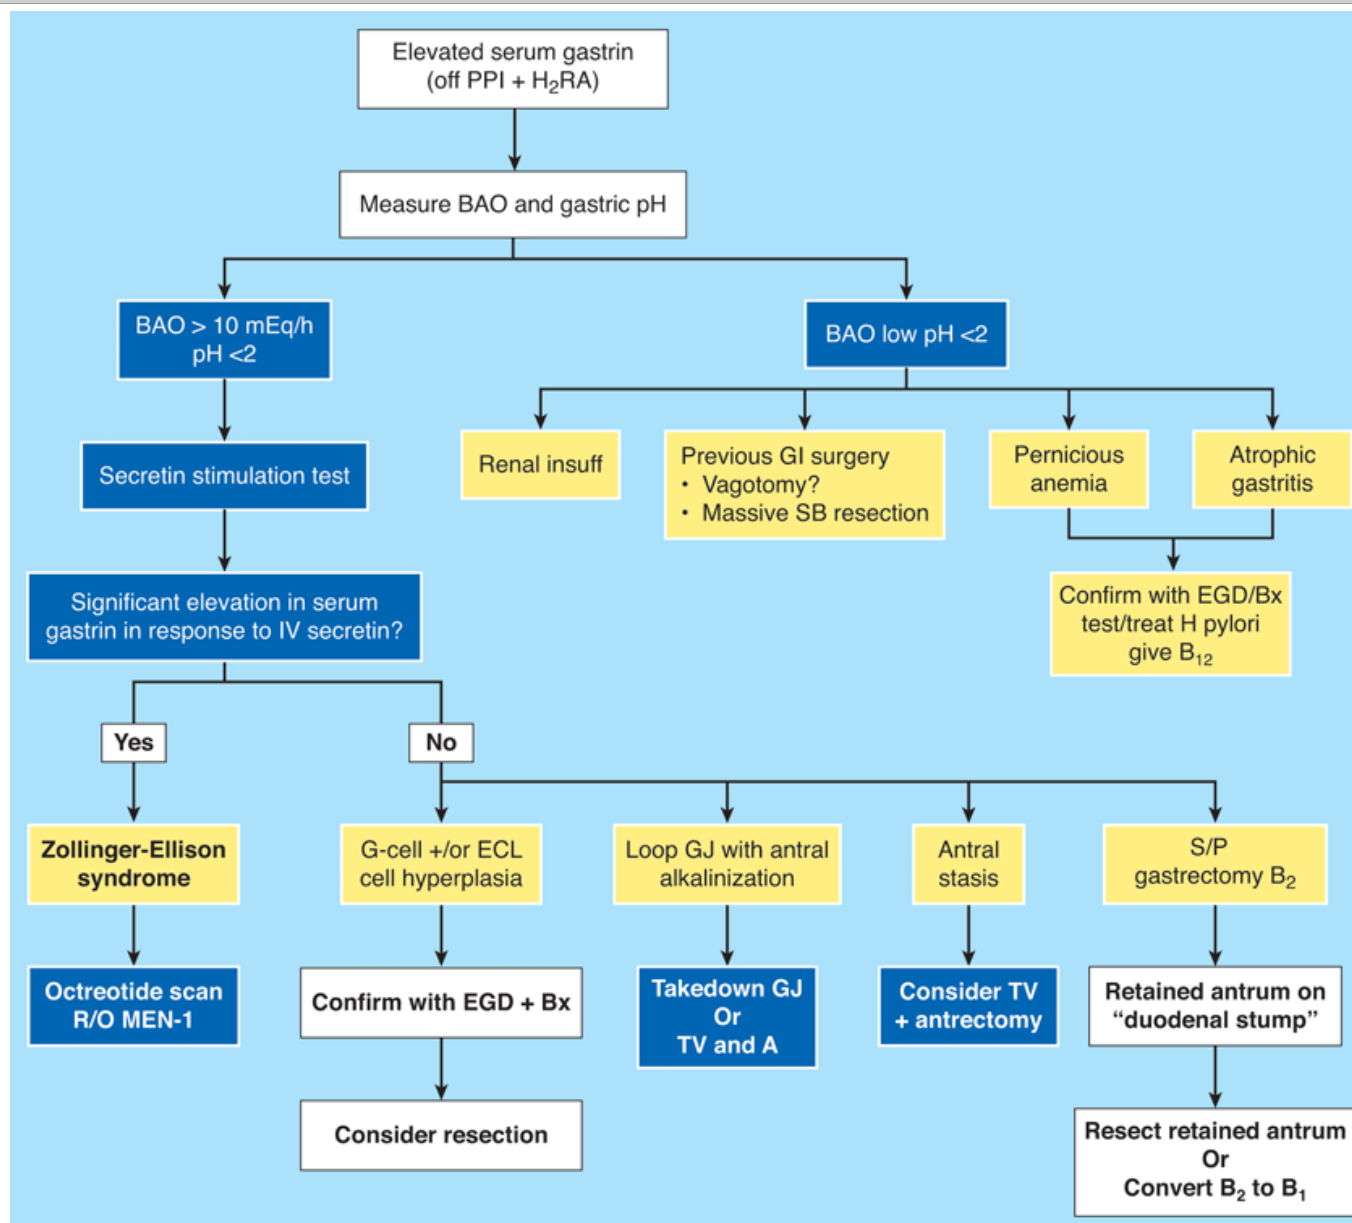

Zollinger-Ellison Syndrome⁷⁸⁻⁸¹

ZES is caused by the uncontrolled secretion of abnormal amounts of gastrin by a duodenal or pancreatic neuroendocrine tumor (i.e., gastrinoma). Most cases (80%) are sporadic, but 20% are inherited. The inherited or familial form of gastrinoma is associated with multiple endocrine neoplasia type 1 (MEN1), which consists of parathyroid, pituitary, and pancreatic (or duodenal) tumors. Gastrinoma is the most common pancreatic tumor in patients with MEN I. Patients with MEN I usually have multiple gastrinoma tumors, and surgical cure is unusual. Sporadic gastrinomas are more often solitary and amenable to surgical cure. Currently, about 50 to 60% of gastrinomas are malignant, with lymph node, liver, or other distant metastases at operation. Five-year survival in patients presenting with metastatic disease is approximately 40%. The larger the primary gastrinoma, the higher the likelihood of metastatic disease. More than 90% of patients with sporadically, completely resected gastrinoma will be cured.

The most common symptoms of ZES are epigastric pain, GERD, and diarrhea. More than 90% of patients with gastrinoma have peptic ulcer. Most ulcers are in the typical location (proximal duodenum), but atypical ulcer location (distal duodenum, jejunum, or multiple ulcers) should prompt an evaluation for gastrinoma. Gastrinoma also should be considered in the differential diagnosis of recurrent or refractory peptic ulcer, secretory diarrhea, gastric rugal hypertrophy, esophagitis with stricture, bleeding or perforated ulcer, familial ulcer, peptic ulcer with hypercalcemia, and gastric carcinoid. The majority of patients with ZES have been symptomatic for several years before definitive diagnosis and, in general, patients with ZES and MEN1 are diagnosed in their 20s and 30s, while those with sporadic ZES more typically are diagnosed in their 40s and 50s.

ZES is an important part of the differential diagnosis of hypergastrinemia (Fig. 26-46). All patients with gastrinoma have an elevated gastrin level, and hypergastrinemia in the presence of elevated BAO strongly suggests gastrinoma. Patients with gastrinoma usually have a BAO >15 mEq/h or >5 mEq/h if they have had a previous procedure for peptic ulcer. Acid secretory medications should be held for several days before gastrin measurement, because acid suppression may falsely elevate gastrin levels. Causes of hypergastrinemia can be divided into those associated with hyperacidity and those associated with hypoacidity (see Fig. 26-46). The diagnosis of ZES is confirmed by the secretin stimulation test. An IV bolus of secretin (2 U/kg) is given and gastrin levels are checked before and after injection. An increase in serum gastrin of 200 pg/mL or greater suggests the presence of gastrinoma. Patients with gastrinoma should have serum calcium and parathyroid hormone levels determined to rule out MEN1 and, if present, parathyroidectomy should be considered before resection of gastrinoma.

Algorithm for diagnosis and management of hypergastrinemia. BAO = basal acid output; B₁ = Billroth 1; B₂ = Billroth 2; Bx = biopsy; ECL = enterochromaffin-like; EGD = esophagogastroduodenoscopy; GJ = gastrojejunostomy; H₂RA = histamine 2 receptor antagonist; insuff = insufficiency; MEN1 = multiple endocrine neoplasia type 1; PPI = proton pump inhibitor; R/O = rule out; SB = small bowel; S/P = status post; TV = truncal vagotomy; TV and A = truncal vagotomy and antrectomy.

Eighty percent of primary tumors are found in the gastrinoma triangle (Fig. 26-47), and many tumors are small (<1 cm), making preoperative localization difficult. Transabdominal ultrasound is quite specific, but not very sensitive. CT will detect most lesions >2 cm in size and MRI is comparable. EUS is more sensitive than these other noninvasive imaging tests, but it still misses many of the smaller lesions, and may confuse normal lymph nodes for gastrinomas. Currently, the preoperative imaging study of choice for gastrinoma is somatostatin receptor scintigraphy (the octreotide scan). When the pretest probability of gastrinoma is high, the sensitivity and specificity of this modality approach 100%. Gastrinoma cells contain type 2 somatostatin receptors that bind the indium-labeled somatostatin analogue (octreotide) with high affinity, making imaging with a gamma camera possible (Fig. 26-48). Currently, angiographic localization studies are infrequently performed for gastrinoma. Both diagnostic angiography and transhepatic selective venous sampling of the portal system have been supplanted by selective secretin infusion, which helps to localize the tumor as inside or outside the gastrinoma triangle.

Positive octreotide scan in patient with gastrinoma.

(Courtesy of Dr. Alan Maurer.)

In this test, an arterial catheter is selectively placed in a named vessel supplying the pancreas (e.g., gastroduodenal or splenic), and a venous catheter is placed in a hepatic vein. Secretin is injected into the visceral artery and gastrin is sampled in the hepatic vein. A significant elevation in hepatic venous gastrin indicates that the tumor is supplied by the injected artery. This test should be performed if pancreaticoduodenectomy is contemplated. Probably the most important means of locating gastrinomas is intraoperative exploration.

All patients with sporadic (nonfamilial) gastrinoma should be considered for surgical resection and possible cure. The lesions should be located in 90% of patients, and the large majority is cured by extirpation of the gastrinoma(s). A thorough intraoperative exploration of the gastrinoma triangle and pancreas is essential, but other sites (i.e., liver, stomach, small bowel, mesentery, and pelvis) should be evaluated as part of a thorough intra-abdominal evaluation to find the primary tumor, which is usually solitary. The duodenum and pancreas should be extensively mobilized and intraoperative ultrasound should be used. Intraoperative EGD with transillumination should be considered. If the tumor cannot be located, generous longitudinal duodenotomy with inspection and palpation of the duodenal wall should be considered. Lymph nodes from the portal, peripancreatic, and celiac drainage basins should be sampled. Ablation or resection of hepatic metastases should be considered.

The management of gastrinoma in patients with MEN1 is controversial because the patients are rarely cured by operation, and the tumors tend to be small and multiple. If the tumor can be imaged preoperatively, operation by an experienced gastrinoma surgeon is reasonable.

Acid hypersecretion in patients with gastrinoma can always be managed with high-dose PPIs. Highly selective vagotomy may make management easier in some patients and should be considered in those with surgically untreatable or unresectable gastrinoma. Gastrectomy for ZES is no longer indicated.

GASTRITIS AND STRESS ULCER

Pathogenesis and Prevention

Gastritis is mucosal inflammation. The gross endoscopic diagnosis of gastritis correlates poorly with histologic findings, and is thus relatively useless as a diagnosis without confirmatory biopsy. Additionally, there is poor correlation between symptoms and histologic gastritis. The most common cause of gastritis is *H. pylori*. Other causes of gastritis include alcohol, NSAIDs, Crohn's disease, tuberculosis, and bile reflux (primary or secondary). These agents cause injury by a variety of different mechanisms. In general, the infectious and inflammatory causes result in immune cell infiltration and cytokine production which damage mucosal cells. The chemical agents (alcohol, aspirin, and bile) generally work to disrupt the mucosal barrier, allowing mucosal damage by back diffusion of luminal hydrogen ions.

Stress gastritis is a peculiar entity that has all but disappeared from the clinical (if not endoscopic) lexicon, largely due to better critical care and acid suppression or cytoprotective agents (e.g., sucralfate) in the intensive care unit (ICU). Stress gastritis and stress ulcer are probably due to inadequate gastric mucosal blood flow during periods of intense physiologic stress. Adequate mucosal blood flow is important to maintain the mucosal barrier, and to buffer any back-diffused hydrogen ions. When blood flow is inadequate, these processes fail and mucosal breakdown occurs. Modern intensive care, with emphasis on adequate tissue perfusion and oxygenation, has undoubtedly decreased the severity of gastric mucosal injury seen in the ICU today. Although it is still common to see small mucosal erosions when performing upper endoscopy in the ICU, it is rare for these lesions to coalesce into the larger bleeding erosions that plagued the ICU patient 30 to 40 years ago. The rationale for routine acid suppression in the ICU, supported by excellent data from clinical trials⁸² and the laboratory,⁸³ is that less mucosal injury will be caused in the potentially weakened gastric mucosa if there is less luminal acid. There are some studies suggesting that routine acid suppression leads to overgrowth of gastric bacteria, which increases the incidence and/or severity of aspiration pneumonia in the ICU. Nevertheless, acid suppression, particularly in the severely ill patient, remains an important part of clinical pathways in most ICUs.⁸⁴ In the extraordinarily rare patient requiring operation today for hemorrhagic stress gastritis, the surgical options include V+D with oversewing of the major bleeding lesions, or near total gastrectomy. Angiographic embolization and endoscopic hemostatic treatment should be considered as well.

MALIGNANT NEOPLASMS OF THE STOMACH

The three most common primary malignant gastric neoplasms are adenocarcinoma (95%), lymphoma (4%), and malignant GIST (1%) (Table 26-14). Other rare primary malignancies include carcinoid, angiosarcoma, carcinosarcoma, and squamous cell carcinoma. Occasionally the stomach is the site of hematogenous metastasis from other sites (e.g., melanoma or breast). More commonly, malignant tumors from adjacent organs invade the stomach by direct extension (e.g., colon or pancreas) or by peritoneal seeding (e.g., ovary).

Table 26-14 Frequency of Gastric Tumors		
Tumor Type	No. of Cases	Percent
Malignant tumors	4199	93.0
Carcinoma	3970	87.9

Lymphoma	136	3.0
Leiomyosarcoma	77	1.7
Carcinoid	11	0.3
Others	5	0.1
Benign tumors	315	7.0
Polyp	140	3.1
Leiomyoma	92	2.0
Inflammatory lesions	30	0.7
Heterotopic pancreas	20	0.4
Others	33	0.8

Adenocarcinoma

EPIDEMIOL OGY

In 1930 in the United States, gastric cancer was the leading cause of cancer death among men and the third leading cause of cancer death among women. Today, it is not even included among the top 10 causes. Over the past several decades, there has been a dramatic decrease in the gastric cancer incidence and death rate in the United States as well as in most Western industrialized countries (Fig. 26-49). This decrease has been mostly in the so-called *intestinal form* rather than in the *diffuse form* of gastric cancer. Worldwide, especially in Asia and Eastern Europe, gastric cancer remains a leading cause of cancer death. In 2007 in the United States, there were approximately 21,500 new cases of stomach cancer (13,190 in men and 8310 in women), and 10,848 deaths from this disease (6418 men and 4430 women).⁸⁵ The estimated 5-year survival rate is 22%, up from about 15% in 1975.

Fig. 26-49.

Death rates for gastric cancer in different countries.

[Reproduced with permission from Ming S-C, Hirota T: Malignant epithelial tumors of the stomach, in Ming S-C, Goldman H (eds): *Pathology of the Gastrointestinal Tract*, 2nd ed. Baltimore: Williams & Wilkins, 1998, p 607.]

In general, gastric cancer is a disease of the elderly, and it is twice as common in blacks as in whites. In younger patients, tumors are more often of the diffuse variety and tend to be large, aggressive, and more poorly differentiated, sometimes infiltrating the entire stomach (linitis plastica). Gastric cancer has a higher incidence in groups of lower socioeconomic status.

ETIOLOGY

Gastric cancer is more common in patients with pernicious anemia, blood group A, or a family history of gastric cancer. When patients migrate from a high-incidence region to a low-incidence region, the risk of gastric cancer decreases in the subsequent generations born in the new region. This strongly suggests an environmental influence on the development of gastric cancer. Environmental factors appear to be more related etiologically to the intestinal form of gastric cancer than the more aggressive diffuse form. The commonly accepted risk factors for gastric cancer are listed in Table 26-15.

Table 26-15 Factors Increasing or Decreasing the Risk of Gastric Cancer
Increase risk
Family history
Diet (high in nitrates, salt, fat)
Familial polyposis
Gastric adenomas
Hereditary nonpolyposis colorectal cancer
<i>Helicobacter pylori</i> infection
Atrophic gastritis, intestinal metaplasia, dysplasia
Previous gastrectomy or gastrojejunostomy (>10 y ago)
Tobacco use
Ménétrier's disease
Decrease risk
Aspirin
Diet (high fresh fruit and vegetable intake)
Vitamin C

Diet and Drugs

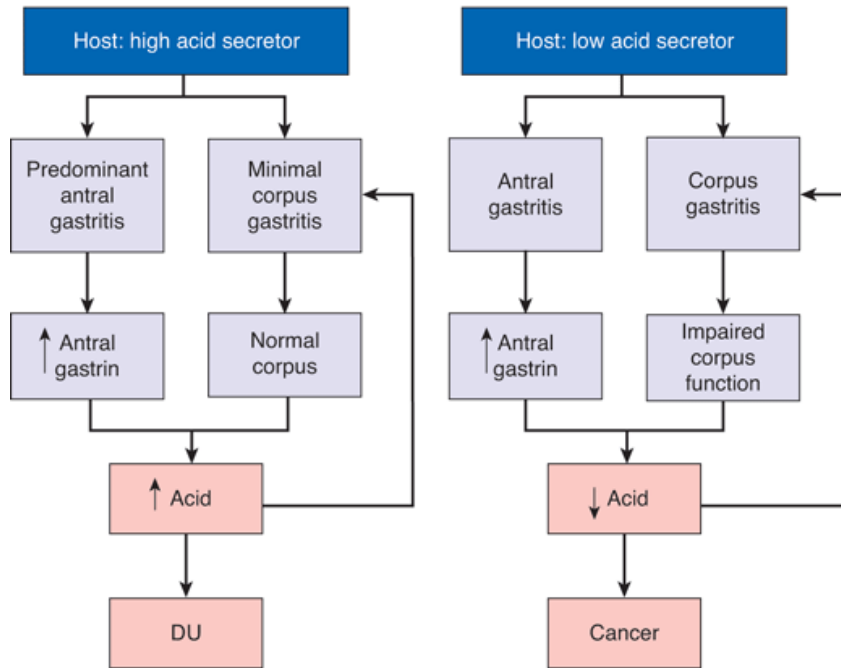

Typically, a starchy diet high in pickled, salted, or smoked food is found in many regions of high gastric cancer risk. Dietary nitrates have been impugned as a possible cause of gastric cancer. Gastric bacteria (more common in the achlorhydric stomach of patients with atrophic gastritis, a risk factor for gastric cancer) convert nitrate into nitrite, a proven carcinogen. A diet high in fresh fruits and vegetables and rich in vitamin C and E has been shown to decrease the population's risk of gastric cancer. The reduced consumption of nitrate-rich preserved foods seen with the growth of refrigeration has been suggested as a cause of the dramatic decrease in gastric cancer seen in North America and Western Europe. Tobacco use probably increases the risk of stomach cancer, and alcohol use probably has no effect. Regular aspirin use may be protective.

Helicobacter pylori^{54,86}

The risk of gastric cancer in patients with chronic *H. pylori* infection is increased about threefold. When compared to uninfected patients, patients with a history of gastric ulcer are more likely to develop gastric cancer (incidence ratio 1.8, 95% confidence interval 1.6 to 2.0), and patients with a history of duodenal ulcer are at decreased risk for gastric cancer (incidence ratio 0.6, 95% confidence interval 0.4 to 0.7). As diagrammed in Fig. 26-50, this may be due to the fact that some patients develop antral-predominant disease (predisposing to duodenal ulcer and somehow protecting against gastric cancer), while other patients develop corpus-predominant gastritis, resulting in hypochlorhydria and somehow predisposing to gastric ulcer and gastric cancer.⁸⁷ The theoretical sequence for development of gastric adenocarcinoma is diagrammed in Fig. 26-51.^{54,87} Recently, it has been demonstrated that bone marrow-derived stem cells play a key role in the pathogenesis of gastric adenocarcinoma in patients with chronic *H. pylori* infection.⁵⁴ However, it must be recognized that gastric adenocarcinoma is a multifactorial disease. Not all patients with gastric cancer have *H. pylori*, and there are some geographic areas with a high prevalence of chronic *H. pylori* infection and a low prevalence of gastric cancer (the "African enigma"). Finally, *H. pylori*-infected patients seem to be at decreased risk for the development of adenocarcinoma of the distal esophagus and cardia region.⁸⁸ Perhaps the corporeal gastritis decreases acid secretion, creating a less damaging refluxate and thus reducing the risk for Barrett's esophagus, the precursor lesion for these tumors.

Epstein-Barr Virus

About 10% of gastric adenocarcinomas carry the EBV virus. This amounts to about 50 to 75,000 cases worldwide. Recently it has been suggested that EBV infection is a rather late step in gastric carcinogenesis, since EBV transcripts are present in cancer cells but not in the metaplastic cells of precursor epithelium.⁸⁹

Genetic Factors

A variety of genetic abnormalities have been described in gastric cancer (Table 26-16). Most gastric cancers are aneuploid. The most common genetic abnormalities in sporadic gastric cancer affect the *p53* and *COX-2* genes. Over two thirds of gastric cancers have deletion or suppression of the important tumor- suppressor gene *p53*. Additionally, approximately the same proportion have overexpression of *COX-2*. In the colon, tumors with upregulation of this gene have suppressed apoptosis, more angiogenesis, and higher metastatic potential. Gastric tumors that overexpress *COX-2* are more aggressive tumors. Recently, a germline mutation in the CDH1 gene encoding for E-cadherin was shown to be associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered in patients with these mutations.⁹⁰

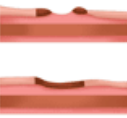

Table 26-16 Genetic Abnormalities in Gastric Cancer		
Abnormalities	Gene	Approximate Frequency %
Deletion/suppression	<i>p53</i>	60–70
	<i>FHIT</i>	60
	<i>APC</i>	50
	<i>DCC</i>	50

Premalignant Conditions of the Stomach

Figure 26-52 shows the prevalence of some premalignant conditions associated with the development of early gastric cancer in a series of 1900 cases from Tokyo. By far the most common precancerous lesion is atrophic gastritis.

1900 Cases		
Precancerous lesion	Number of cases	%
Hyperplastic polyp	 10	0.53
Adenoma	 47	2.47
Chronic ulcer	 13	0.68
Atrophic gastritis	 1802	94.84
Verrucous gastritis	 26	1.37
Stomach remnant	 2	0.11
Aberrant pancreas	 0	0
Total 1900		100

N.C.C.H., Tokyo April 1988

Precancerous lesions of the stomach.

[Reproduced with permission from Ming S-C, Hirota T: Malignant epithelial tumors of the stomach, in Ming S-C, Goldman H (eds): *Pathology of the Gastrointestinal Tract*, 2nd ed. Baltimore: Williams & Wilkins, 1998, p 607.]

Polyps

There are five types of gastric epithelial polyps: inflammatory, hamartomatous, heterotopic, hyperplastic, and adenoma. The first three types have negligible malignant potential. Adenomas can lead to carcinoma, just like in the colon, and should be removed when diagnosed. Occasionally, hyperplastic polyps can be associated with carcinoma. Patients with familial adenomatous polyposis have a high prevalence of gastric adenomatous polyps (about 50%), and are 10 times more likely to develop adenocarcinoma of the stomach than the general population.⁹¹ Screening EGD is indicated in these families. Patients with hereditary nonpolyposis colorectal cancer may also be at risk for gastric cancer.⁹²

Atrophic Gastritis

Chronic atrophic gastritis (Fig. 26-53) is by far the most common precursor for gastric cancer, particularly the intestinal subtype (see Fig. 26-52). The prevalence of atrophic gastritis is higher in older age groups, but it is also common in younger people in areas with a high incidence of gastric cancer. In many patients, it is likely that *H. pylori* is involved in the pathogenesis of atrophic gastritis. Correa described three distinct patterns of chronic atrophic gastritis: autoimmune (involves the acid-secreting proximal stomach), hypersecretory (involving the distal stomach), and environmental (involving multiple random areas at the junction of the oxyntic and antral mucosa).⁸⁶

Chronic atrophic gastritis.

(Reproduced with permission from <http://www.epathologies.com>.)

Intestinal Metaplasia

Gastric carcinoma often occurs in an area of intestinal metaplasia. Furthermore, an individual's risk of gastric cancer is proportional to the extent of intestinal metaplasia of the gastric mucosa. These observations strongly suggest that intestinal metaplasia is a precursor lesion to gastric cancer. There are different pathologic subtypes of intestinal metaplasia in the stomach, based upon the histologic and biochemical characteristics of the changed mucosal glands. In the complete type of intestinal metaplasia, the glands are completely lined with goblet cells and intestinal absorptive cells (Fig. 26-54). These cells are indistinguishable histologically and biochemically from their small bowel counterparts, and are not seen in the normal stomach. There is evidence that eradication of *H. pylori* infection leads to significant regression of intestinal metaplasia and improvement in atrophic gastritis. Therefore, treatment of *H. pylori* infection is a reasonable recommendation for patients with these pathologic diagnoses and *H. pylori* infection.

Benign Gastric Ulcer

Although once considered a premalignant condition, it is likely that the older literature was confounded by mistakenly labeling inadequately biopsied ulcers and healing ulcers as "benign," when, in fact, they were malignant to begin with. It is now generally recognized that all gastric ulcers are cancer until proven otherwise with adequate biopsy and follow-up. Even today, carcinomas are occasionally found when adequately biopsied "benign" ulcers are resected for nonhealing. It is more than likely that the factors just discussed above are more significant etiologically in the development of gastric cancer than the history of a benign gastric ulcer.

Gastric Remnant Cancer

It has long been recognized that stomach cancer can develop in the gastric remnant, usually years following distal gastrectomy for PUD. The risk is controversial, but the phenomenon is real. Most tumors develop >10 years following the initial operation, and they usually arise in an area of chronic gastritis, metaplasia, and dysplasia. This is often near the stoma, but many of these tumors are quite large at presentation, and are equally divided between intestinal and diffuse subtypes. Most cases have been reported following Billroth II gastroenterostomy, but there also have been cases following Billroth I gastroduodenostomy. Whether simple loop gastrojejunostomy increases a patient's risk of gastric cancer, and whether a Roux-en-Y anastomosis following gastric resection lowers their risk of gastric cancer is unknown. Stage for stage, the prognosis for gastric stump cancer is similar to proximal gastric cancer.⁹³

Other Premalignant States

A mutated E-cadherin gene is associated with hereditary diffuse gastric cancer. Prophylactic total gastrectomy should be considered.⁹⁰ Obviously, a myriad of genetic and environmental factors will affect members of the same family, and up to 10% of gastric cancer cases appear to be familial without a clear-cut genetic diagnosis. First-degree relatives of patients with gastric cancer have a two- to threefold increased risk of developing the disease. Patients with hereditary nonpolyposis colorectal cancer have a 10% risk of developing gastric cancer, predominantly the intestinal subtype. The mucous cell hyperplasia of Ménétrier's disease is generally considered to carry a 5 to 10% risk of adenocarcinoma. Periodic surveillance EGD is prudent in all the above conditions. The glandular hyperplasia associated with gastrinoma is not premalignant, but ECL hyperplasia and/or carcinoid tumors can occur.

PATHOLOGY

Dysplasia

It is generally accepted that gastric dysplasia is the universal precursor to gastric adenocarcinoma. Patients with severe dysplasia should be considered for gastric resection if the abnormality is widespread or multifocal, or EMR if the severe dysplasia is localized. Patients with mild dysplasia should be followed with endoscopic biopsy surveillance, and *Helicobacter* eradication.

Early Gastric Cancer

Early gastric cancer is defined as adenocarcinoma limited to the mucosa and submucosa of the stomach, regardless of lymph node status. The entity is common in the Orient, where gastric cancer is a common cause of cancer death, and where aggressive surveillance programs have therefore been established. Approximately 10% of patients with early gastric cancer will have lymph node metastases. There are several types and subtypes of early gastric cancer (Table 26-17 and Fig. 26-55). Approximately 70% of early gastric cancers are well differentiated, and 30% are poorly differentiated. The overall cure rate with adequate gastric resection and lymphadenectomy is 95%. In some Japanese centers, 50% of the gastric cancers treated are early gastric cancer. In the United States, less than 20% of resected gastric adenocarcinomas are early gastric cancer. Small intramucosal lesions can be treated with EMR.⁹⁴

Table 26-17 Early Gastric Cancer	
Type I	Exophytic lesion extending into the gastric lumen
Type II	Superficial variant
IIA	Elevated lesions with a height no more than the thickness of the adjacent mucosa
IIB	Flat lesions
IIC	Depressed lesions with an eroded but not deeply ulcerated appearance
Type III	Excavated lesions that may extend into the muscularis propria without invasion of this layer by actual cancer cells

Gross Morphology and Histologic Subtypes

There are four gross forms of gastric cancer: polypoid, fungating, ulcerative, and scirrhous. In the first two, the bulk of the tumor mass is intraluminal. Polypoid tumors are not ulcerated; fungating tumors are elevated intraluminally, but also ulcerated. In the latter two gross subtypes, the bulk of the tumor mass is in the wall of the stomach. Ulcerative tumors are self-descriptive; scirrhous tumors infiltrate the entire thickness of the stomach and cover a very large surface area. Scirrhous tumors (linitis plastica) have a particularly poor prognosis, and commonly involve the entire stomach. Although these latter lesions may be technically resectable with total gastrectomy, it is common for both the esophageal and duodenal margins of resection to show microscopic evidence of tumor infiltration. Death from recurrent disease within 6 months is common.

The location of the primary tumor in the stomach is important in planning the operation. Several decades ago, the large majority of gastric cancers were in the distal stomach. Recently, there has been a proximal migration of tumors, so that currently, the distribution is closer to 40% distal, 30% middle, and 30% proximal.

Histology

The most important prognostic indicators in gastric cancer are both histologic: lymph node involvement and depth of tumor invasion. Tumor grade (degree of differentiation: well, moderately, or poorly) is also important prognostically.

There are several histologic classifications of gastric cancer. The World Health Organization recognizes several histologic types (Table 26-18). The Japanese classification is similar but more detailed. The commonly used Lauren classification separates gastric cancers into intestinal type (53%), diffuse type (33%), and unclassified (14%). The intestinal type is associated with chronic atrophic gastritis, severe intestinal metaplasia, and dysplasia, and tends to be less aggressive than the diffuse type. The diffuse type of gastric cancer is more likely to be poorly differentiated and is associated with younger patients and proximal tumors. The Ming classification also is useful and easy to remember, with only two types—expanding (67%) and infiltrative (33%).

Pathologic Staging

Ultimately, prognosis is related to pathologic stage. The most widespread system for staging of gastric cancer is the tumor-node-metastasis (TNM) staging system based on depth of tumor invasion, extent of lymph node metastases, and presence of distant metastases. This system was developed by the American Joint Committee on Cancer and the International Union Against Cancer, and has undergone several modifications since it was originally conceived (Table 26-19).

Table 26-19 TNM Staging of Gastric Cancer by the International Union Against Cancer and American Joint Committee on Cancer			
T: Primary tumor			
Tis	Carcinoma in situ; intraepithelial tumor without invasion of lamina propria		
T1	Tumor invades lamina propria or submucosa		
T2	Tumor invades muscularis propria or subserosa		
T3	Tumor penetrates serosa (visceral peritoneum) without invasion of adjacent structures		
T4	Tumor invades adjacent structures		
N: Regional lymph node			
N0	No regional lymph node metastasis		
N1	Metastasis in 1 to 6 regional lymph nodes		
N2	Metastasis in 7 to 15 lymph nodes		
N3	Metastasis in more than 15 regional lymph nodes		
M: Distant metastasis			
M0	No distant metastasis		
M1	Distant metastasis		
Stage grouping			
Stage	T	N	M
0	Tis	N0	M0
IA	T1	N0	M0
IB	T1	N1	M0
II	T2	N0	M0
	T1	N2	M0
	T2	N1	M0
	T3	N0	M0
IIIA	T2	N2	M0
	T3	N1	M0
	T4	N0	M0
IIIB	T3	N2	M0

CLINICAL MANIFESTATIONS

Most patients who are diagnosed with gastric cancer in the United States have advanced stage III or IV disease at the time of diagnosis. The most common symptoms are weight loss and decreased food intake due to anorexia and early satiety. Abdominal pain (usually not severe and often ignored) also is common. Other symptoms include nausea, vomiting, and bloating. Acute GI bleeding is somewhat unusual (5%), but chronic occult blood loss is common and manifests as iron deficiency anemia and heme-positive stool. Dysphagia is common if the tumor involves the cardia of the stomach. Paraneoplastic syndromes such as Trousseau's syndrome (thrombophlebitis), acanthosis nigricans (hyperpigmentation of the axilla and groin), or peripheral neuropathy are rarely present.

Physical examination usually is normal. Other than signs of weight loss, specific physical findings usually indicate incurability. A focused examination in a patient in whom gastric cancer is a likely part of the differential diagnosis should include an examination of the neck, chest, abdomen, rectum, and pelvis. Cervical, supraclavicular (on the left referred to as Virchow's node), and axillary lymph nodes may be enlarged, and today can be sampled in the office with fine-needle aspiration cytology. There may be a metastatic pleural effusion, or aspiration pneumonitis in a patient with vomiting and/or obstruction. An abdominal mass could indicate a large (usually T4 incurable) primary tumor, liver metastases, or carcinomatosis (including Krukenberg's tumor of the ovary). A palpable umbilical nodule (Sister Joseph's nodule) is pathognomonic of advanced disease, or there may be evidence on exam of malignant ascites. Rectal exam may reveal heme-positive stool and hard nodularity extraluminally and anteriorly, indicating so-called *drop metastases*, or rectal shelf of Blumer in the pouch of Douglas.

DIAGNOSTIC EVALUATION

Distinguishing between peptic ulcer and gastric cancer on clinical grounds alone is usually impossible. Patients over the age of 45 years old who have new-onset dyspepsia, as well as all patients with dyspepsia and alarm symptoms (weight loss, recurrent vomiting, dysphagia, evidence of bleeding, or anemia) or with a family history of gastric cancer should have *prompt upper endoscopy and biopsy* if a mucosal lesion is noted. Essentially, all patients in whom gastric cancer is part of the differential diagnosis should have endoscopy and biopsy. If suspicion for cancer is high and the biopsy is negative, the patient should be re-endoscoped and more aggressively biopsied. In some patients with gastric tumors, upper GI series can be helpful in planning treatment. Although a good *double-contrast barium upper GI examination* is sensitive for gastric tumors (up to 75% sensitive), in most centers, endoscopy has become the gold standard for the diagnosis of gastric malignancy.

Preoperative staging of gastric cancer is best accomplished with abdominal/pelvic CT scanning with IV and oral contrast. MRI is probably comparable. The best way to stage the tumor locally is via EUS, which gives fairly accurate (80%) information about the depth of tumor penetration into the gastric wall, and can usually show enlarged (>5 mm) perigastric and celiac lymph nodes. In some centers, if the tumor is transmural (T3) or involves lymph nodes (enlarged nodes can usually be needled under ultrasound guidance), preoperative (neoadjuvant) chemotherapy is given. However, there are limitations to tumor staging with EUS. It largely is operator dependent and may underestimate lymph node involvement because normal-sized nodes (<5 mm) can harbor metastases. EUS is most accurate in distinguishing early gastric cancer (T1) from more advanced tumors.

Positron Emission Tomography Scanning

Whole-body PET scanning uses the principle that tumor cells preferentially accumulate positron-emitting ^{18}F -fluorodeoxyglucose. This modality is most useful in the evaluation of distant metastasis in gastric cancer but can also be useful in locoregional staging. PET scan is most useful when combined with spiral CT (PET-CT)⁹⁵ and should be considered before major surgery in patients with particularly high-risk tumors or multiple medical comorbidities.

Staging Laparoscopy and Peritoneal Cytology

To some extent, the usefulness of these modalities depends on the individual patient's situation as well as the treatment philosophy of the cancer team. The fundamental question is "will it make a difference to this patient's management?" Patients with gastric cancer who undergo R0 resection (i.e., no gross residual disease) and are found to have positive peritoneal cytology (no gross carcinomatosis) have a much worse prognosis than the cytology negative group (median survival 14.8 months vs. 98.5 months).⁹⁶ It is controversial how much this information adds prognostically to that of pathologic staging (TNM). Whether this poor prognosis can be improved postresection with aggressive adjuvant treatment (systemic, or local intraperitoneal hyperthermic chemotherapy) is unknown. Unfortunately, it is also unclear how much these patients benefit from gastric resection. Currently peritoneal cytology information is unlikely to change the treatment of patients with gastric cancer, and most patients without detectable distant metastases will have (and should have) gastric resection regardless of the peritoneal cytology results. A quick laparoscopic examination can occasionally reveal small peritoneal implants or liver metastases that were not detected on preoperative imaging studies and, in some patients (e.g., high risk for surgery or impressive carcinomatosis), this will change the operative plan and avoid a major but futile surgical procedure. Laparoscopy may be most useful in patients with proximal tumors or with adenopathy on spiral CT scan.⁹⁷ An extensive laparoscopic staging procedure, although quite accurate, has not been widely

adopted.

TREATMENT

Surgical resection is the only curative treatment for gastric cancer^{98,99} and most patients with clinically resectable locoregional disease should have gastric resection. Obvious exceptions include patients who cannot tolerate an abdominal operation, and patients with overwhelming metastatic disease.

The goal of curative surgical treatment is resection of all tumor (i.e., R0 resection). Thus, all margins (proximal, distal, and radial) should be negative and an adequate lymphadenectomy performed. Generally, the surgeon strives for a grossly negative margin of at least 5 cm. Some gastric tumors, particularly the diffuse variety, are quite infiltrative and tumor cells can extend well beyond the tumor mass; thus, gross margins beyond 5 cm may be desirable.

Frozen section confirmation of negative margins is important when performing operation for cure, but it is less important in patients with nodal metastases beyond the N1 nodal basin. It should be strongly emphasized that many patients with positive lymph nodes are cured by adequate surgery. It should also be stressed that often lymph nodes that appear to be grossly involved with tumor turn out to be benign or reactive on pathologic examination. More than 15 resected lymph nodes are required for adequate staging.¹⁰⁰ Therapeutic nihilism should be avoided and, in the low-risk patient, an aggressive attempt to resect all tumor should be made. The primary tumor may be resected en bloc with adjacent involved organs (e.g., distal pancreas, transverse colon, or spleen) during the course of curative gastrectomy. Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.^{99,101}

Extent of Gastrectomy

The standard operation for gastric cancer is radical subtotal gastrectomy. Unless required for R0 resection, total gastrectomy confers no additional survival benefit and may have adverse nutritional or quality-of-life consequences, and higher perioperative morbidity and mortality.^{98,99} Subtotal gastric resection typically entails ligation of the left and right gastric and gastroepiploic arteries at the origin, as well as the en bloc removal of the distal 75% of the stomach, including the pylorus and 2 cm of duodenum, the greater and lesser omentum, and all associated lymphatic tissue (Fig. 26-56). Reconstruction is usually by Billroth II gastrojejunostomy, but if a small gastric remnant is left (<20%), a Roux-en-Y reconstruction is considered. The operative mortality is around 2 to 5%. Radical subtotal gastrectomy is generally deemed to be an adequate cancer operation in most Western countries, provided that the contingencies stated result in tumor-free margins, >15 lymph nodes, and the resection of all gross tumor. In the absence of involvement by direct extension, the spleen and pancreatic tail are not removed.

Total gastrectomy with Roux-en-Y esophagojejunostomy may be required for R0 resection (Fig. 26-57), and may be the best operation for patients with proximal gastric adenocarcinoma. The construction of a jejunal pouch may be beneficial nutritionally, particularly for those patients with a good prognosis.¹⁰² Proximal subtotal gastric resection, a technically feasible alternative to total gastrectomy for some proximal gastric tumors, requires an esophagogastrostomy to a vagotomized distal gastric remnant. Pyloroplasty in this setting virtually guarantees bile esophagitis, and if the pylorus is left intact, gastric emptying may be problematic. An isoperistaltic jejunal interposition (Henley loop) between the esophagus and antrum could be considered as an alternative reconstruction, but, all things considered, total gastrectomy usually results in superior functional, if not oncologic, results for most patients with proximal gastric cancer.

Extent of Lymphadenectomy

The Japanese Research Society for Gastric Cancer has numbered the lymph node stations that potentially drain the stomach (see Fig. 26-4). Generally these are grouped into level D1 (i.e., stations 3 to 6), level D2 (i.e., stations 1, 2, 7, 8, and 11), and level D3 (i.e., stations 9, 10, and 12) nodes. Generally, D1 nodes are perigastric, D2 nodes are along the hepatic and splenic arteries, and D3 nodes are the most distant. The operation described above (radical subtotal gastrectomy in the Extent of Gastrectomy section), which is by far the most commonly performed procedure in the United States for gastric cancer, is called a D1 resection because it removes the tumor and the perigastric D1 nodes. The standard operation for gastric cancer in Asia and specialized U.S. centers is the D2 gastrectomy, which involves a more extensive lymphadenectomy (removal of the D1 and D2 nodes). In addition to the tissue removed in a D1 resection, the standard D2 gastrectomy removes the peritoneal layer over the anterior mesocolon and selectively over the pancreas, along with nodes along the hepatic and splenic arteries, and the crural nodes. Splenectomy and distal pancreatectomy are not routinely performed, because this clearly has been shown to increase the morbidity of the operation. The purported survival advantage of D2 gastrectomy in gastric cancer is shown in Table 26-20, which shows the 5-year survival rates for gastric cancer stratified by pathologic stage for the United States and Japan. Unfortunately, the randomized prospective trials that have been performed have not confirmed this survival advantage, but the morbidity and mortality in the D2 group was higher (Table 26-21).^{103,104} This was mostly attributable to the splenectomy and distal pancreatectomy, which are no longer routinely done as part of the D2 gastrectomy.

Table 26-20 Gastric Cancer 5-Year Survival and Operative Mortality in the USA and Japan

	Maruyama (Japan), 1971–1985	American College of Surgeons, 1982–1987	Memorial Sloan Kettering, 1985–1994
No. patients	3176	18,365	675
Stage I	91%	50%	84%
Stage II	72%	29%	61%
Stage III	44%	13%	29%
Stage IV	9%	3%	25%
Operative mortality	1%	7%	3%

Table 26-21 Randomized Trials Comparing D1 and D2 Gastrectomy for Gastric Cancer

		D2	46	13	33

Source: Data from Bonenkamp JJ, Hermans J, Sasako M, et al: Extended lymph node dissection for gastric cancer. *N Engl J Med* 340:908, 1999; and Cuschieri A, Fayers P, Fielding J, et al: Postoperative morbidity and mortality after D1 and D2 resections for gastric cancer: Preliminary results of the MRC randomized controlled surgical trial. The Surgical Cooperative Group. *Lancet* 347:995, 1996.

Some experts have argued that the D2 operation is simply a better staging procedure, and that the apparent improved survival with this more extensive dissection is simply an epiphenomenon of improved pathologic staging. This stage shift suggests that many patients in the U.S. series treated with D1 gastrectomy really had metastatic nodes at the D2 level that went unresected and undetected. Therefore, in the U.S. series, there were patients classified as stage I, who, if they had undergone a D2 gastrectomy, would be classified as stage II; and there were patients classified as stage II, who, if they had undergone a D2 gastrectomy, would be classified as stage III. The stage I survival in the United States would then actually be closer to the (more accurately staged) stage II survival in Japan, because this group includes some patients who really *are* stage II, but the nodes were not found in the D1 resection. All experts would agree that to avoid understaging of gastric cancer, a minimum of 15 nodes should be resected with the gastrectomy specimen.

Chemotherapy and Radiation for Gastric Cancer

In general, the actuarial 5-year survival for resected gastric adenocarcinoma stages 1, 2, and 3 is about 75%, 50%, and 25%, respectively. Because most surgical patients have stage 2 disease or greater, it is common to refer gastric cancer patients postoperatively to a medical and/or radiation oncologist. Unfortunately, the existing data suggest that the incremental survival benefit attendant to adjuvant treatment is marginal, particularly in those patients who have had an adequate resection.^{98,99} In one prospective randomized study, adjuvant treatment with chemotherapy (5-fluorouracil and leucovorin) and radiation (4500 cGy) has demonstrated a survival benefit in resected patients with stage II and III adenocarcinoma of the stomach.¹⁰⁵ Unfortunately, only 10% of patients entered in the study actually had D2 gastrectomy, and most (54%) had less than an adequate D1 gastrectomy. Because adequacy of lymphadenectomy has clearly been shown to impact survival, particularly in patients with stage III gastric cancer,^{99,100} it has been suggested that the benefits of adjuvant chemoradiation shown in this study would be vitiated by an adequate operation. Clearly further studies are needed.

A recently published study from the Japan Clinical Oncology Group showed a 69% overall 5-year survival rate in patients with clinically curable T2b, T3, and T4 gastric cancer, treated with D2 gastrectomy alone (no chemotherapy).¹⁰⁶ There was no incremental benefit from para-aortic lymph node dissection. There is no indication for the routine use of radiation alone in the adjuvant setting, but in certain patients, it can be effective palliation for bleeding or pain. In patients with gross unresectable, metastatic, or recurrent disease, palliative chemotherapy has not been demonstrated to conclusively prolong survival, but occasionally, a patient has a dramatic response. These patients should be considered for clinical trials. Agents that have shown activity against gastric cancer include 5-fluorouracil, cisplatin, doxorubicin, and methotrexate. Neoadjuvant treatment of gastric adenocarcinoma is being evaluated, particularly in patients with clinical T3 or N1 disease.

Endoscopic Resection

It has been demonstrated initially at numerous East Asian centers that some patients with early gastric cancer can be adequately treated by an EMR. Small tumors (<3 cm) confined to the mucosa have an extremely low chance of lymph node metastasis (3%), which approaches the operative mortality rate for gastrectomy. If the resected specimen demonstrates no ulceration, no penetration of the muscularis mucosae, no lymphatic invasion, and size <3 cm, then the risk of lymph node metastases is less than 1%. Thus, some patients with early gastric cancer might be better treated with the endoscopic technique. Currently, this should be limited to patients with tumors <2 cm in size that are node negative and confined to the mucosa on EUS, in the absence of other gastric lesions. The addition of laparoscopic lymph node sampling may be considered in selected patients.

PROGNOSIS

The 5-year survival for gastric adenocarcinoma has increased from 15 to 22% in the United States over the past 25 years. Survival is dependent on pathologic stage (TNM stage) and degree of tumor differentiation. Other important prognostic factors are sex, age, primary gastric site, tumor size, and tumor depth.

Palliative gastrectomy may be indicated in some patients with obviously incurable disease, but most patients presenting with stage IV gastric cancer can be managed without major operation.^{99,101}

SCREENING FOR GASTRIC CANCER

In Japan, it clearly has been shown that patients participating in gastric cancer screening programs have a significantly decreased risk of dying from gastric

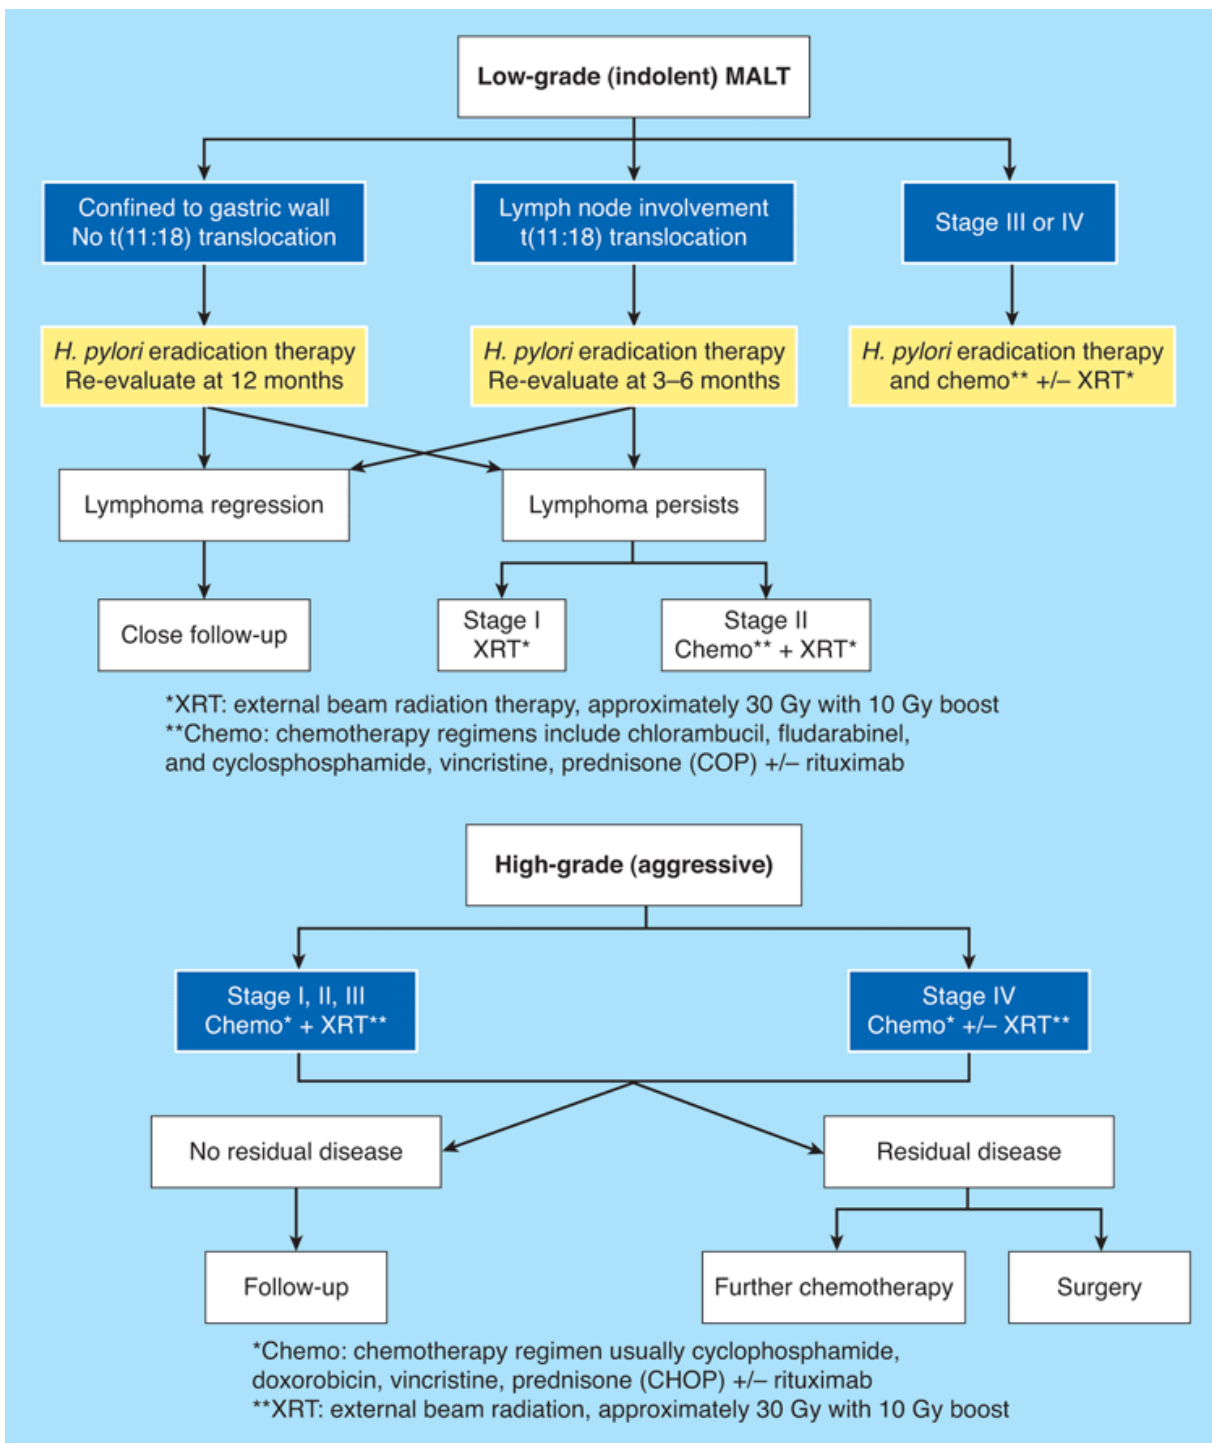

cancer. Thus screening is effective in a high-risk population. Screening the general population in the United States (a low-risk country) does not make sense, but patients clearly at risk for gastric cancer probably should have periodic endoscopy and biopsy. This includes patients with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, gastric adenomas, Ménétrier's disease, intestinal metaplasia or dysplasia, and remote gastrectomy or gastrojejunostomy.

Gastric Lymphoma

Gastric lymphomas generally account for about 4% of gastric malignancies. Over half of patients with non-Hodgkin's lymphoma have involvement of the GI tract. The stomach is the most common site of primary GI lymphoma, and over 95% are non-Hodgkin's type. Most are B-cell type, thought to arise in MALT, although most high-grade gastric lymphomas are without any characteristics of the low-grade MALT neoplasm.¹⁰⁷ About half of gastric lymphomas are histologically low grade, and about half are high grade. Interestingly, the normal stomach is relatively devoid of lymphoid tissue. However, in the setting of chronic gastritis, the stomach acquires MALT, which can undergo malignant degeneration. Again, *H. pylori* is thought to be the culprit. In populations with a high incidence of gastric lymphoma, there is a high incidence of *H. pylori* infection; patients with gastric lymphoma also usually have *H. pylori* infection.

Low-grade MALT lymphoma, essentially a monoclonal proliferation of B cells, presumably arises from a background of chronic gastritis associated with *H. pylori*. These relatively innocuous tumors then undergo degeneration to high-grade lymphoma, which is the usual variety seen by the surgeon. Remarkably, when the *H. pylori* is eradicated and the gastritis improves, the low-grade MALT lymphoma often disappears. Thus low-grade MALT lymphoma is not a surgical lesion. Careful follow-up is necessary particularly in those lesions with a t(11:18) translocation, thought to be a risk factor for a more aggressive MALT lesion. If low-grade lymphoma persists after *H. pylori* eradication, radiation should be considered for disease clinically confined to the stomach (stage I), while chemotherapy with or without radiation is used for more advanced lesions (Fig. 26-58).

Algorithm for the treatment of gastric lymphoma. MALT = mucosa-associated lymphoid tissue.

(Reproduced with permission from Yoon SS, Coit DG, Portlock CS, et al: The diminishing role of surgery in the treatment of gastric lymphoma. *Ann Surg* 240:28, 2004.)

Patients with high-grade gastric lymphoma require aggressive oncologic treatment for cure and present with many of the same symptoms as gastric cancer patients. However, systemic symptoms such as fever, weight loss, and night sweats occur in about 50% of patients with gastric lymphoma. The tumors may bleed and/or obstruct. Lymphadenopathy and/or organomegaly suggest systemic disease. Diagnosis is by endoscopy and biopsy. Much of the tumor may be submucosal, and an assiduous attempt at biopsy is necessary. Primary lymphoma is usually nodular with enlarged gastric folds. A diffusely infiltrative process akin to linitis plastica is more suggestive of secondary gastric involvement by lymphoma. A diligent search for extragastric disease is necessary before the diagnosis of localized primary gastric lymphoma is made. This includes EUS; CT scanning of the chest, abdomen, and pelvis; and bone marrow biopsy. Most patients with high-grade gastric lymphoma are currently treated with chemotherapy and radiation, without surgical resection.

Treatment-related perforation or bleeding is unusual but recognized. For disease limited to the stomach and regional nodes, radical subtotal D2 gastrectomy may be performed, especially for bulky tumors with bleeding and/or obstruction. Palliative gastrectomy for tumor complications also has a role. Certainly, a multidisciplinary team should be involved with the treatment plan for patients with primary gastric lymphoma.

Gastrointestinal Stromal Tumor

GISTs arise from interstitial cells of Cajal (ICC) and are distinct from leiomyoma and leiomyosarcoma, which arise from smooth muscle.^{108,109} Prognosis in patients with GIST tumors depends mostly on tumor size and mitotic count, and metastasis, when it occurs, is typically by the hematogenous route. Any lesion >1 cm can behave in a malignant fashion and may recur. Thus, all GISTs are best resected along with a margin of normal tissue. Almost all GISTs (and almost no smooth muscle tumors) express c-KIT (CD117) or the related PDGFRA, as well as CD34; almost all smooth muscle tumors (and almost no GISTs) express actin and desmin. These markers can often be detected on specimens obtained by fine-needle aspiration¹¹⁰ and are useful in differentiating between GIST and smooth muscle tumor histopathologically. Lesions that are definitively leiomyoma by current histopathologic criteria are adequately treated by enucleation. Lesions that are definitively GIST or leiomyosarcoma are best treated by resection with negative margins. Most equivocal lesions should be resected provided that the patient is a reasonable operative risk.

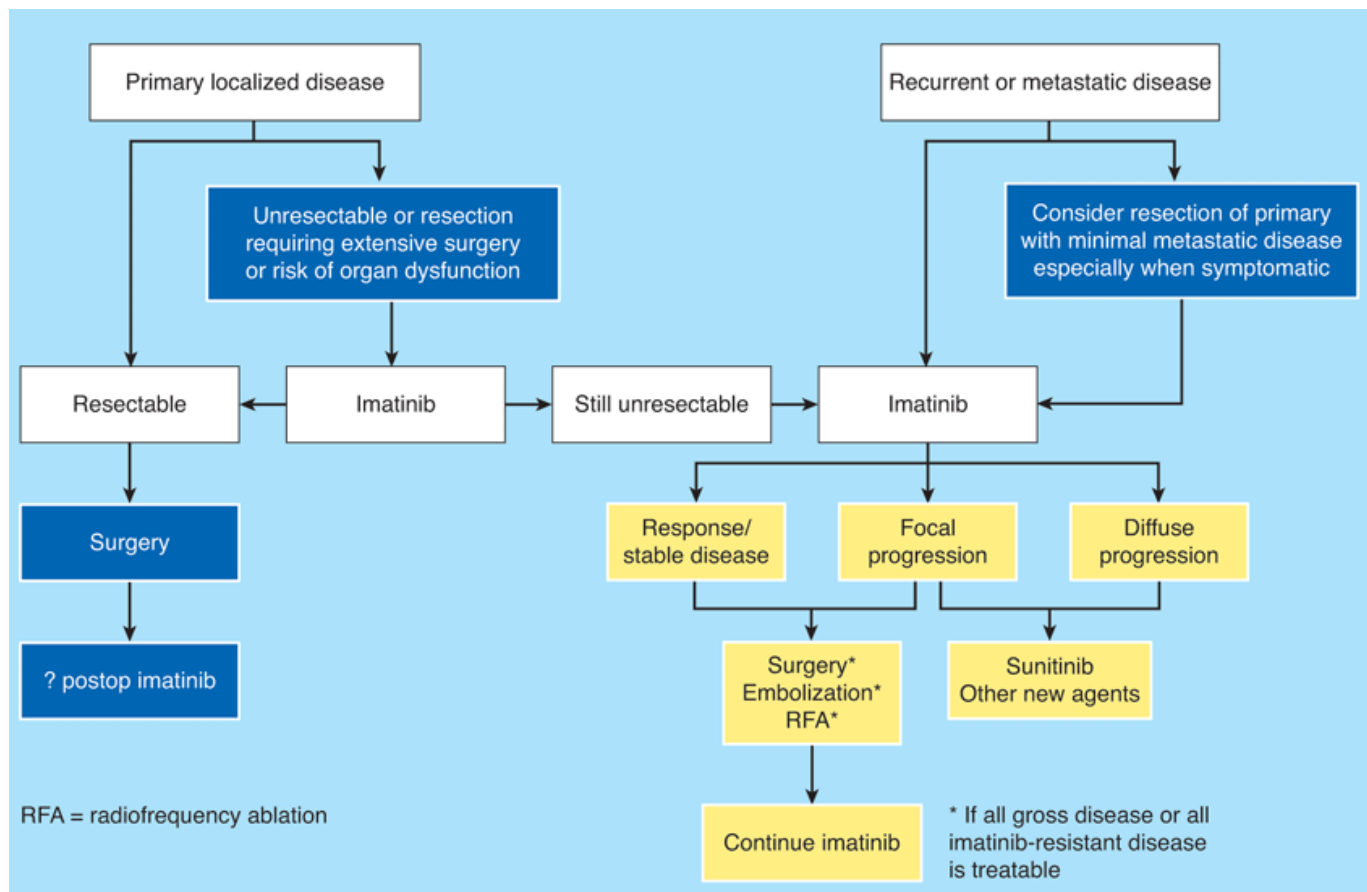

Two thirds of all GISTs occur in the stomach. Epithelial cell stromal GIST is the most common cell type arising in the stomach, and cellular spindle type is the next most common. The glomus tumor type is seen only in the stomach.

GISTs are submucosal tumors that are slow growing. Smaller lesions are usually found incidentally, although they occasionally may ulcerate and cause impressive bleeding. Larger lesions generally produce symptoms of weight loss, abdominal pain, fullness, early satiety, and bleeding. An abdominal mass may be palpable. Metastasis is by the hematogenous route, often to liver and/or lung, although positive lymph nodes are occasionally seen in resected specimens.

Diagnosis is by endoscopy and biopsy, although the interpretation of the latter may be problematic. EUS may be helpful, but symptomatic tumors and tumors >1 cm in size should be removed. Metastatic work-up entails CT of the chest, abdomen, and pelvis (chest x-ray may suffice in lieu of CT of the chest). Most gastric GISTs occur in the body of the stomach, but they also can occur in the fundus or antrum. They are almost always solitary. Wedge resection with clear margins is adequate surgical treatment. True invasion of adjacent structures by the primary tumor is evidence of malignancy. If safe, en bloc resection of involved surrounding organs is appropriate to remove all tumor when the primary is large and invasive. Five-year survival following resection for GIST is about 50%. Most patients with low-grade lesions are cured (80% 5-year survival), but most patients with high-grade lesions are not (30% 5-year survival).

GISTs are usually positive for the protooncogene, *c-kit*, a characteristic shared with the ICC. Imatinib (Gleevec), a chemotherapeutic agent that blocks the activity of the tyrosine kinase product of *c-kit*, yields excellent results in many patients with metastatic or unresectable GIST. Up to 50% of treated patients develop resistance to imatinib by 2 years, and several newer agents show promise for patients with refractory disease. An algorithm for the treatment of patients with GIST is shown in Fig. 26-59.

Gastric Carcinoid Tumors^{111–113}

Compared to midgut and hindgut locations, carcinoid tumors of the stomach are rather unusual. Gastric carcinoids comprise about 1% of all carcinoid tumors and less than 2% of gastric neoplasms. They arise from gastric enterochromaffin-like (ECL) cells and clearly have malignant potential. The apparent incidence of gastric carcinoids is increasing, perhaps related to the more common use of upper endoscopy and/or the increasing use of acid suppressive medication. The latter may cause hypergastrinemia, and gastrin has a recognized trophic effect on gastric ECL cells.

Gastric carcinoids are classified into one of three different types. Type I is the most common type of gastric carcinoid, accounting for about 75% of patients. Type I carcinoids occur in patients with chronic hypergastrinemia secondary to pernicious anemia or chronic atrophic gastritis. These lesions occur more frequently in women, are often multiple and small, and have low malignant potential (<5% metastasize). The role of long-term acid suppression with resultant hypergastrinemia in the pathogenesis of type I gastric carcinoids is unclear.

Type II gastric carcinoids are associated with MEN1 and ZES. These lesions also tend to be small and multiple, but have a somewhat higher malignant potential than type I lesions (10% metastasize). Type II gastric carcinoids are more strongly associated with MEN1; they are quite uncommon in patients with sporadic ZES without MEN1. Gastric acid hypersecretion, hypergastrinemia, and gastric carcinoid imply gastrinoma until proven otherwise.

Type III gastric carcinoids are sporadic tumors. They are usually solitary (usually >2 cm) and occur more commonly in men. They are not associated with hypergastrinemia and biopsy shows a heterogeneous cell population. Most patients have nodal or distant metastases at the time of diagnosis, and some present with symptoms of carcinoid syndrome.

Gastric carcinoids are usually diagnosed with endoscopy and biopsy. Some tumors are submucosal and may be quite small. They are often confused with heterotopic pancreas or small leiomyomas. Biopsy may be difficult because of the submucosal location, and EUS can be helpful in defining the size and depth of the lesion. Plasma chromogranin A levels are elevated in patients with gastric carcinoid. CT scan and octreotide scan are useful for staging.

Gastric carcinoids should be resected. Small lesions confined to the mucosa (typically type I or type II lesions) may be treated endoscopically with EMR if

there are only a few lesions (<5) and if margins are histologically negative. Careful follow-up is necessary. Larger lesions should be removed by D1 or D2 gastrectomy. Survival is excellent for node-negative patients (>90% 5-year survival); node-positive patients have a 50% 5-year survival. Gastrinoma should be resected if located in patients with type II carcinoid. The 5-year survival for patients with type I gastric carcinoid is close to 100%; for patients with type III lesions, the 5-year survival is less than 50%. Somatostatin analogue treatment is useful in controlling the symptoms of carcinoid syndrome but apparently does not prolong survival in patients with metastatic gastric carcinoid. Surgical debulking may have a role in selected patients with metastatic disease. Because somatostatin has an antiproliferative effect on gastric ECL cells, there may be a possible primary treatment role for octreotide in poor-risk surgical patients with gastric carcinoid.

BENIGN GASTRIC NEOPLASMS

Polyps

Epithelial polyps are the most common benign tumor of the stomach (Table 26-22). There are essentially five types of benign epithelial polyps (Table 26-23): adenomatous, hyperplastic (regenerative), hamartomatous, inflammatory, and heterotopic (e.g., ectopic pancreas). The most common gastric polyp (about 75% in most series) is the hyperplastic or regenerative polyp, which frequently occurs in the setting of gastritis and has a low malignant potential. Adenomatous polyps may undergo malignant transformation, similarly to adenomas in the colon. They constitute about 10 to 15% of gastric polyps. Hamartomatous, inflammatory, and heterotopic polyps have negligible malignant potential (including fundic gland polyps). Polyps that are symptomatic, >2 cm, or adenomatous should be removed, usually by endoscopic snare polypectomy. Consideration should also be given to removing hyperplastic polyps, especially if large. Repeat EGD for surveillance should be done following removal of adenomatous polyps, and, perhaps, after removal of hyperplastic polyps as well.

Table 26-22 Benign Polypoid Lesions of the Stomach		
Type of Lesion	Total Number	Percent
Epithelial polyp	252	40.9
Leiomyoma	230	37.3
Inflammatory polyp	29	4.7
Heterotopic tissue	25	4.1

Leiomyoma

The typical leiomyoma is submucosal and firm. If ulcerated, it has an umbilicated appearance and may bleed. Histologically, these lesions appear to be of smooth muscle origin. Lesions <2 cm are usually asymptomatic and benign. Larger lesions have greater malignant potential and a greater likelihood to cause symptoms such as bleeding, obstruction, or pain. Asymptomatic lesions <2 cm may be carefully observed or enucleated if fine-needle aspiration and immune markers confirm smooth muscle tumor; larger lesions and symptomatic lesions should be removed by wedge resection (often possible laparoscopically). When lesions thought to be leiomyoma are observed rather than resected, the patient should be made aware of their presence and the small possibility for malignancy.

Lipoma

Lipomas are benign submucosal fatty tumors that are usually asymptomatic, found incidentally on upper GI series or EGD. Endoscopically, they have a characteristic appearance; there also is a characteristic appearance on EUS. Excision is unnecessary unless the patient is symptomatic.

Gastric Motility Disorders

Gastric motility disorders include delayed gastric emptying (gastroparesis), rapid gastric emptying, and motor and sensory abnormalities (e.g., functional dyspepsia). Surgically relevant secondary disorders of gastric motility (e.g., dumping, gastric stasis, and Roux syndrome) are discussed below under Postgastrectomy Problems. Gastroparesis is the most surgically relevant primary disorder of gastric motility.^{114,115}

Most patients with primary gastroparesis present with nausea and vomiting. Bloating, early satiety, and abdominal pain are common. Eighty percent of these patients are women; some are diabetic. Postprandial vomiting significantly complicates the management in the latter group: Frequently, the patient takes parenteral insulin, eats and then vomits, becoming dangerously hypoglycemic. In patients with gastroparesis, it is important to rule out mechanical gastric outlet obstruction, and small-bowel obstruction. An upper GI series may suggest slow gastric emptying and relative atony, or it may be normal. EGD may show bezoars, but is frequently normal. Gastric emptying scintigraphy shows delayed solid emptying, and often delayed liquid emptying. Gastroparesis can be a manifestation of a variety of problems (Table 26-24). Medical treatment includes promotility agents, antiemetics, and, perhaps, botulinum injection into the pylorus.

Surgeons need to understand the role of surgery in primary gastroparesis. If appropriate, the patient with severe diabetic gastroparesis should be evaluated for pancreas transplant before any invasive abdominal procedure, because some patients improve substantially after pancreas transplant. If the diabetic gastroparetic patient is not a candidate for pancreas transplant, both gastrostomy (for decompression) and jejunostomy tubes (for feeding and prevention of hypoglycemia) can be effective. Infection and wound problems are more common in diabetics with transabdominal tubes than in nondiabetics. Other surgical options include implantation of a gastric pacemaker, and gastric resection. Generally, gastric resection should be done infrequently, if at all, for primary gastroparesis.

Massive Upper Gastrointestinal Bleeding

Although there have been arbitrary definitions of "massive" upper GI bleeding put forth, perhaps the most practical definition in the current era would be acute bleeding proximal to the ligament of Treitz, which requires blood transfusion. In multiple series, the stomach and proximal duodenum is by far the most common source of pathology associated with this diagnosis.^{65,116} The most common causes of acute GI bleeding in emergency room or hospitalized patients are peptic ulcer, gastritis, Mallory-Weiss syndrome, and esophagogastric varices. Less common causes include benign or malignant neoplasm, angiodysplasia, Dieulafoy's lesion, portal gastropathy, Ménétrier's disease, and watermelon stomach. Arterioenteric fistula should always be considered in the patient who has an aortic graft or who has undergone repair of a visceral artery aneurysm.

The most important issues in the early hospital management of patients with acute upper GI bleeding are resuscitation and risk stratification. Large-bore IV access and Foley catheterization is accomplished, and nasogastric intubation is considered. Risk stratification is essentially accomplished by answering the following questions:

1. What is the magnitude and acuity of the hemorrhage? Hypotension, tachycardia, oliguria, low hematocrit, pallor, altered mentation, and/or hematemesis suggest a large blood loss that has occurred over a short period of time. This is a high-risk situation.

2. Does the patient have significant chronic disease, particularly lung, liver, kidney, and/or heart disease, which compromises physiologic reserve? If yes, this is a high-risk situation.
3. Is the patient anticoagulated, or immunosuppressed? If yes, this is a high-risk situation.
4. On endoscopy, is the patient bleeding from varices, or is there active bleeding, or is there a visible vessel, or is there a deep ulcer overlying a large vessel (e.g., posterior duodenal ulcer overlying the gastroduodenal artery)? Could the patient be bleeding from an arterioenteric fistula? If yes, this is a high-risk situation.

If judged to be low risk, most patients will stop bleeding with supportive treatment and IV PPI. Selected patients may be discharged from the emergency room and managed on an outpatient basis.

If the patient is judged to be high risk based on one or more of the questions above, then the following should be done immediately:

1. Type and crossmatch for transfusion of blood products.
2. Admit to ICU or monitored bed in specialized unit.
3. Consult surgeon.
4. Consult gastroenterologist.
5. Start continuous infusion of PPI.
6. Perform upper endoscopy within 12 hours, after resuscitation and correction of coagulopathy. Endoscopic hemostasis should be considered in most high-risk patients with acute upper GI bleeding.

Although the surgeon should be involved early in the hospital course of all high-risk patients with acute upper GI bleeding, most of these patients will be adequately managed without operation. Mucosal lesions can usually be controlled with endoscopic hemotherapy and medical management. Occasionally, arteriography can be helpful.¹¹⁷ Operation for bleeding ulcer is discussed above (see Operation for Bleeding Peptic Ulcer and Fig. 26-43).

Isolated Gastric Varices

Isolated gastric varices are those that occur in the absence of esophageal varices and are classified as type 1 (fundic) or type 2 (distal to fundus including proximal duodenum).¹¹⁸ The presence of isolated gastric varices is usually associated with portal hypertension or splenic vein thrombosis. Although there is a significant bleeding risk from isolated gastric varices on long-term follow-up, there is no indication for the routine application of prophylactic measures.

Patients with acute upper GI bleeding from isolated gastric varices should be considered high risk. Although data are limited, octreotide and/or vasopressin infusion may decrease bleeding, if tolerated. Balloon tamponade with a Sengstaken-Blakemore tube may provide temporary control of exsanguinating hemorrhage from type 1 isolated gastric varices, but if this is used, endotracheal intubation for airway protection is prudent. Endoscopic treatment with sclerotherapy or varix ligation is less successful than in esophageal varices, but should be considered. Interventional radiology should be consulted and balloon occluded retrograde transvenous obliteration considered. A transjugular intrahepatic portosystemic shunt may be useful if there is nonsegmental portal hypertension. If the patient has splenic vein thrombosis and left-sided (sinistral) or segmental portal hypertension, splenectomy is quite effective in controlling bleeding from isolated gastric varices. The operative mortality is 5%. Liver transplantation should always be considered in the cirrhotic patient before any abdominal operation.

Hypertrophic Gastropathy (Ménétrier's Disease)

There are two clinical syndromes characterized by epithelial hyperplasia and giant gastric folds: ZES and Ménétrier's disease. The latter is characteristically associated with protein-losing gastropathy and hypochlorhydria. There are large rugal folds in the proximal stomach, and the antrum is usually spared. Mucosal biopsy shows diffuse hyperplasia of the surface mucus-secreting cells and usually decreased parietal cells (Fig. 26-60). It has recently been suggested that Ménétrier's disease is caused by local overexpression of transforming growth factor alpha in the gastric mucosa, which stimulates the epidermal growth factor receptor, a receptor tyrosine kinase, on gastric SECs. This results in the selective expansion of surface mucous cells in the gastric body and fundus. A few patients with this unusual disease have been successfully treated with the epidermal growth factor receptor blocking monoclonal antibody cetuximab.¹¹⁹

Most patients with Ménétrier's disease are middle-aged men who present with epigastric pain, weight loss, diarrhea, and hypoproteinemia. There may be an increased risk of gastric cancer. Sometimes, the disease regresses spontaneously. Gastric resection may be indicated for bleeding, severe hypoproteinemia, or cancer.

Watermelon Stomach (Gastric Antral Vascular Ectasia)

The parallel red stripes atop the mucosal folds of the distal stomach give this rare entity its sobriquet. Histologically, gastric antral vascular ectasia is characterized by dilated mucosal blood vessels that often contain thrombi, in the lamina propria. Mucosal fibromuscular hyperplasia and hyalinization often are present (Fig. 26-61). The histologic appearance can resemble portal hypertensive gastropathy, but the latter usually affects the proximal stomach, whereas watermelon stomach predominantly affects the distal stomach. Beta blockers and nitrates, useful in the treatment of portal hypertensive gastropathy, are ineffective in patients with gastric antral vascular ectasia. Patients with the latter diagnosis are usually elderly women with chronic GI blood loss requiring transfusion. Most have an associated autoimmune connective tissue disorder, and at least 25% have chronic liver disease. Nonsurgical treatment options include estrogen and progesterone, and endoscopic treatment with the neodymium yttrium-aluminum garnet (Nd:YAG) laser or argon plasma coagulator.¹²⁰ Antrectomy may be required to control blood loss, and this operation is quite effective but carries increased morbidity in this elderly patient group. Patients with portal hypertension and antral vascular ectasia should be considered for transjugular intrahepatic portosystemic shunt.

Gastric antral vascular ectasia (watermelon stomach).

Dieulafoy's Lesion

Dieulafoy's lesion is a congenital arteriovenous malformation characterized by an unusually large tortuous submucosal artery. If this artery is eroded, impressive pulsatile bleeding may occur. To the operating surgeon, this appears as a stream of arterial blood emanating from what appears grossly to be a normal gastric mucosa. The lesion typically occurs in middle-aged or elderly men and may be more common in patients with liver disease.¹²¹ Patients typically present with upper GI bleeding, which may be intermittent, and endoscopy can miss the lesion if it is not actively bleeding. Treatment options include endoscopic hemostatic therapy, angiographic embolization, or operation. At surgery, the lesion may be oversewn or resected.

Bezoars/Diverticula

Bezoars are concretions of undigestible matter that accumulate in the stomach. Trichobezoars, composed of hair, occur most commonly in young women who swallow their hair (Fig. 26-62). Phytobezoars are composed of vegetable matter and, in the United States, are usually seen in association with gastroparesis or gastric outlet obstruction. They also are associated with persimmon ingestion. Most commonly, bezoars produce obstructive symptoms, but they may cause ulceration and bleeding. Diagnosis is suggested by upper GI series and confirmed by endoscopy. Treatment options include enzyme therapy (papain, cellulase, or acetylcysteine), endoscopic disruption and removal, or surgical removal.

Gastric diverticula are usually solitary and may be congenital or acquired. Congenital diverticula are true diverticula and contain a full coat of muscularis propria, whereas acquired diverticula (perhaps caused by pulsion) usually have a negligible outer muscle layer. Most gastric diverticula occur in the posterior cardia or fundus (Fig. 26-63). Most of the time gastric diverticula are asymptomatic. However, they can become inflamed and may produce pain or bleeding. Perforation is rare. Asymptomatic diverticula do not require treatment, but symptomatic lesions should be removed. This can often be done laparoscopically.

Gastric diverticulum.

[Reproduced with permission from Ellis H: Diverticula, volvulus, superior mesenteric artery syndrome, and foreign bodies, in Schwartz SL, Ellis H, Husser WC (eds): *Maingot's Abdominal Operations*, 9th ed. East Norwalk, Connecticut: Appleton & Lange, 1989, p 577.]

Foreign Bodies

Ingested foreign bodies are usually asymptomatic. Removal of sharp or large objects should be considered. This can usually be done endoscopically, with an overtube technique. Recognized dangers include aspiration of the foreign body during removal, and rupture of drug-containing bags in "body packers." Both complications can be fatal. Surgical removal is recommended in body packers, and in patients with large jagged objects. Corrosive objects (e.g., watch batteries) should be removed promptly.

Mallory-Weiss Syndrome

The Mallory-Weiss lesion is a longitudinal tear in the mucosa of the GE junction.¹²² It is presumably caused by forceful vomiting and/or retching, and is commonly seen in alcoholics. It commonly presents with impressive upper GI bleeding, often with hematemesis. Endoscopy confirms the diagnosis and may be useful in controlling the bleeding, but 90% of patients stop bleeding spontaneously. Other options to control the bleeding include balloon tamponade, angiographic embolization, or selective infusion of vasopressin, systemic vasopressin, and operation. Surgical treatment consists of oversewing the bleeding lesion through a long gastrotomy.

Volvulus

Gastric volvulus is a twist of the stomach that usually occurs in association with a large hiatal hernia. It also can occur in patients with an unusually mobile stomach without hiatal hernia. Typically, the stomach twists along its long axis (organoaxial volvulus), and the greater curvature flips up (Fig. 26-64C). If the stomach twists around the transverse axis, it is called *mesenteroaxial rotation* (Fig. 26-64A and Fig. 26-64B). Usually, volvulus is a chronic condition that can be surprisingly asymptomatic. In these instances, expectant nonoperative management is usually advised, especially in the elderly. The risk of strangulation and infarction has been overestimated in asymptomatic patients. Symptomatic patients should be considered for operation, especially if the symptoms are severe and/or progressive. Patients usually present with symptoms of pain and pressure related to the intermittently distending and poorly emptying twisted stomach. Pressure on the lung may produce dyspnea, pressure on the pericardium may produce palpitations, and pressure on the esophagus may produce dysphagia. Symptoms are often relieved with vomiting or passage of a nasogastric tube. Gastric infarction is a surgical emergency, and the patient often presents moribund. Elective operation for gastric volvulus usually involves reduction of the stomach and repair of hiatal hernia, with or without gastropexy. Gastropexy alone may be considered for high-risk patients. A laparoscopic approach should be considered and, if possible, the herniated portion of the stomach should be reduced and secured in the abdomen.

GASTROSTOMY

A gastrostomy is performed either for alimentation or for gastric drainage/decompression. Gastrostomy may be done percutaneously, laparoscopically, or via open technique.^{123,124} Currently, percutaneous endoscopic gastrostomy is the most common method used. The open techniques include the Stamm method (Fig. 26-65), the Witzel method (Fig. 26-66), and the Janeway method (Fig. 26-67). The latter is meant to create a permanent stoma that can be intubated as needed, but does not drain spontaneously. The Janeway gastrostomy is more complicated than the other open techniques, and is rarely necessary. By far the most common technique is the Stamm gastrostomy, which can be performed open or laparoscopically.

Complications of gastrostomy include infection, dislodgment, and aspiration pneumonia. Although gastrostomy tubes usually do prevent tense gastric dilatation, they may not adequately drain the stomach, especially when the patient is bedridden.

Postgastrectomy Problems^{125,126}

A variety of abnormalities affect some patients after a gastric operation that has usually been performed because of ulcer or tumor or severe obesity. Some of the more common disorders result from disturbance of the normal anatomic and physiologic mechanisms that control gastric motor function, and a discussion of these follows.

Dumping Syndrome

Dumping is a phenomenon caused by the destruction or bypass of the pyloric sphincter.¹²⁷ However, other factors undoubtedly play a role because dumping can occur after operations that preserve the pylorus, such as parietal cell vagotomy. The appropriate stimulus can provoke dumping symptoms, even in some patients who have not undergone surgery. Clinically significant dumping occurs in 5 to 10% of patients after pyloroplasty, pyloromyotomy, or distal gastrectomy, and consists of a constellation of postprandial symptoms ranging in severity from annoying to disabling. The symptoms are thought to be the result of the abrupt delivery of a hyperosmolar load into the small bowel. This usually is due to ablation of the pylorus, but decreased gastric compliance with accelerated emptying of liquids (e.g., after highly selective vagotomy) is another accepted mechanism. About 15 to 30 minutes after a meal, the patient becomes diaphoretic, weak, light-headed, and tachycardic. These symptoms may be ameliorated by recumbence or saline infusion. Crampy abdominal pain is not uncommon and diarrhea often follows. This is referred to as *early dumping*, and should be distinguished from postprandial (reactive) hypoglycemia, also called *late dumping*, which usually occurs later (2 to 3 hours following a meal), and is relieved by the administration of sugar. A variety of hormonal aberrations have been observed in early dumping, including increased VIP, CCK, neurotensin, peripheral hormone peptide YY, renin-angiotensin-aldosterone, and decreased atrial natriuretic peptide. Late dumping is associated with hypoglycemia and hyperinsulinemia.

The medical therapy for the dumping syndrome consists of dietary management and somatostatin analogue (octreotide). Often, symptoms improve if the patient avoids liquids during meals. Hyperosmolar liquids (e.g., milk shakes) may be particularly troublesome. There is some evidence that adding dietary fiber compounds at mealtime may improve the syndrome. If dietary manipulation fails, the patient is started on octreotide, 100 µg subcutaneously twice daily. This can be increased up to 500 µg twice daily if necessary. The long-acting depot octreotide preparation is useful. Octreotide not only ameliorates the abnormal hormonal pattern seen in patients with dumping symptoms, but also promotes restoration of a fasting motility pattern in the small intestine (i.e., restoration of the MMC). The α-glucosidase inhibitor acarbose may be particularly helpful in ameliorating the symptoms of late dumping.

Only a small percentage of patients with dumping symptoms ultimately require surgery. Most patients improve with time (months and even years), dietary management, and medication. Therefore, the surgeon should not rush to reoperate on the patient with dumping symptoms. Multidisciplinary nonsurgical management must be optimized first. Before reoperation, a period of inhospital observation is useful to define the severity of the patient's symptoms. Patient compliance with dietary and medical therapy also can be assessed.

The results of remedial operation for dumping are variable and unpredictable. There are a variety of surgical approaches, none of which work consistently well. Additionally, there is not a great deal of experience reported in the literature with any of these methods. Long-term follow-up is rare. Operations performed to treat disabling dumping syndrome include pyloric reconstruction, takedown of gastrojejunostomy, interposition of a 10-cm reversed intestinal segment between the stomach and duodenum, conversion of Billroth II to Billroth I anastomosis, and conversion to Roux-en-Y anastomosis.

Patients with disabling dumping after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that there is some vagal innervation to the antrum, and the pyloric channel is open endoscopically. The reversed intestinal segment is rarely used today—and rightly so. This operation interposes a 10-cm reversed segment of intestine between the stomach and the proximal small bowel. This slows gastric emptying, but often leads to obstruction, requiring reoperation. Isoperistaltic interposition (Henley loop) has not been successful in ameliorating severe dumping over the long term. The Roux-en-Y gastrojejunostomy is associated with delayed gastric emptying, probably on the basis of disordered motility in the Roux limb. Taking advantage of this disordered physiology, surgeons have used this operation successfully in the management of the dumping syndrome. Although this is probably the procedure of choice in the small group of patients requiring operation for severe dumping following gastric resection, gastric stasis may result, particularly if a large gastric remnant is left. In the presence of significant gastric acid secretion, marginal ulceration is common after both jejunal interposition and Roux-en-Y procedures; thus concomitant vagotomy and hemigastrectomy should be considered. The theoretical possibility of treating postpyloroplasty dumping with a Roux-en-Y to the proximal duodenum (the duodenal switch, a potentially reversible operation) has not been reported (Fig. 26-68). Because pyloric ablation seems to be the dominant factor in the etiology of dumping, it is not surprising that conversion of Billroth II to Billroth I anastomosis has not been successful in the treatment of dumping.

Diarrhea

Diarrhea following gastric surgery may be the result of truncal vagotomy, dumping, or malabsorption. Truncal vagotomy is associated with clinically significant diarrhea in 5 to 10% of patients. It occurs soon after surgery and usually is not associated with other symptoms, a fact that helps to distinguish it from dumping. The diarrhea may be a daily occurrence, or there may be significant periods of relatively normal bowel function. The symptoms tend to improve over the months and years after the index operation. The cause of postvagotomy diarrhea is unclear. Possible mechanisms include intestinal dysmotility and accelerated transit, bile acid malabsorption, rapid gastric emptying, and bacterial overgrowth. The latter problem is facilitated by decreased gastric acid secretion and (even small) blind loops. Although bacterial overgrowth can be confirmed with the hydrogen breath test, a simpler test is an empirical trial of oral antibiotics. Some patients with postvagotomy diarrhea respond to cholestyramine, while in others codeine or loperamide may be useful. Another theoretical cause of diarrhea following gastric surgery is fat malabsorption due to acid inactivation of pancreatic enzymes or poorly coordinated mixing of food and digestive juices. This can be confirmed with a qualitative test for fecal fat and treated with acid suppression. Postvagotomy diarrhea usually does not respond to treatment with pancreatic enzymes. In the rare patient who is debilitated by postvagotomy diarrhea that is unresponsive to medical management, the operation of choice is a 10-cm reversed jejunal interposition placed in continuity 100 cm distal to the ligament of Treitz. Another option is the onlay antiperistaltic distal ileal graft. Both operations can cause obstructive symptoms and/or bacterial overgrowth.

Gastric Stasis^{128,129}

Gastric stasis following surgery on the stomach may be due to a problem with gastric motor function or be caused by an obstruction. The gastric motility abnormality may have been pre-existing and unrecognized by the operating surgeon. Alternatively, it may be secondary to deliberate or unintentional vagotomy, or resection of the dominant gastric pacemaker. An obstruction may be mechanical (e.g., anastomotic stricture, efferent limb kink from adhesions or constricting mesocolon, or a proximal small-bowel obstruction) or functional (e.g., retrograde peristalsis in a Roux limb). Gastric stasis presents with vomiting (often of undigested food), bloating, epigastric pain, and weight loss.

The evaluation of a patient with suspected postoperative gastric stasis includes EGD, upper GI series, gastric emptying scan, and gastric motor testing. Endoscopy shows gastritis and retained food or bezoar. The anastomosis and efferent limb should be evaluated for stricture or narrowing. Endoscopy may be facilitated by reviewing a recent upper GI series to help define the anatomy and to look for an area of obstruction. A dilated efferent limb suggests chronic stasis, either from a motor abnormality (e.g., Roux syndrome) or mechanical obstruction (e.g., chronic adhesion). Gastric emptying is best

quantified clinically with scintigraphic techniques, which give a half-time for liquid and solid emptying. The former may be fairly normal, while the latter is profoundly delayed. If the problem is thought to be primarily a disorder of intrinsic motor function, newer techniques such as EGG and GI manometry should be considered. It should, however, be remembered that chronic mechanical obstruction may result in disordered motility in the proximal organ.

Once mechanical obstruction has been ruled out, medical treatment is successful in most cases of motor dysfunction following previous gastric surgery. This consists of dietary modification and promotility agents. Intermittent oral antibiotic therapy may be helpful in treating bacterial overgrowth, with its attendant symptoms of bloating, flatulence, and diarrhea.

Gastroparesis following V+D may be treated with subtotal (75%) gastrectomy. Billroth II anastomosis with Braun enteroenterostomy may be preferable to Roux-en-Y reconstruction. This latter option may be associated with persistent emptying problems that will subsequently require near-total or total gastrectomy, a nutritionally unattractive option. Delayed gastric emptying following ulcer surgery (V+D or V+A) may represent an anastomotic stricture (often due to recurrent ulcer), or proximal small bowel obstruction. The latter should be dealt with at reoperation. Recurrent ulcer usually responds to medical therapy. Endoscopic dilation is occasionally helpful. Gastroparesis following subtotal gastric resection is best treated with near-total (95%) or total gastric resection and Roux-en-Y reconstruction. If total gastrectomy is performed, a jejunal reservoir should be fashioned. Gastric pacing is promising, but it has not achieved widespread clinical usefulness in the treatment of postoperative gastric atony.

Bile Reflux Gastritis

Most patients who have undergone ablation or resection of the pylorus have bile in the stomach on endoscopic examination, along with some degree of gross or microscopic gastric inflammation. Therefore, attributing postoperative symptoms to bile reflux is problematic because most asymptomatic patients have bile reflux as well. However, it is generally accepted that a small subset of patients have bile reflux gastritis, and present with nausea, bilious vomiting, and epigastric pain, and *quantitative evidence* of excess enterogastric reflux. Curiously, symptoms often develop months or years after the index operation. The differential diagnosis includes afferent or efferent loop obstruction, gastric stasis, and small-bowel obstruction. Plain abdominal x-rays, upper endoscopy, upper GI series, abdominal CT scan, and gastric emptying scans are helpful in evaluating these possibilities.

Bile reflux may be quantified with gastric analysis or, more commonly, with scintigraphy (bile reflux scan). Typically, enterogastric reflux is greatest after Billroth II gastrectomy or gastrojejunostomy, and least after vagotomy and pyloroplasty, with Billroth I gastrectomy giving intermediate values. Patients who are well into the abnormal range may be considered for remedial surgery if symptoms are severe. Remedial surgery will eliminate the bile from the vomitus and may improve the epigastric pain, but it is quite unusual to render these patients completely asymptomatic, especially if they are narcotic dependent.

Bile reflux gastritis after distal gastric resection may be treated by one of the following options: Roux-en-Y gastrojejunostomy; interposition of a 40-cm isoperistaltic jejunal loop between the gastric remnant and the duodenum (Henley loop); or Billroth II gastrojejunostomy with Braun enteroenterostomy. To avoid bile reflux into the stomach, the Roux limb should be at least 45 cm long. The Braun enteroenterostomy should be placed a similar distance from the stomach. Excessively long limbs may be associated with obstruction or malabsorption. All operations can result in marginal ulceration on the jejunal side of the gastrojejunostomy, and thus are combined with a generous distal gastrectomy. If this has already been done at a previous operation, the Roux or Braun operations may be attractively simple. Whether truncal vagotomy is necessary is controversial in the current era of excellent acid-suppressing medications. The benefits of decreased acid secretion following vagotomy may be outweighed by problems with vagotomy-associated dysmotility in the gastric remnant. The Roux operation may be associated with an increased risk of emptying problems compared to the other two options, but controlled data are lacking. Patients with debilitating bile reflux after gastrojejunostomy can be considered for simple takedown of this anastomosis provided that (a) there is some vagal innervation to the antrum and (b) the pyloric channel is open.

Primary bile reflux gastritis (i.e., no previous operation) is rare, and may be treated with the duodenal switch operation, essentially an end-to-end Roux-en-Y to the proximal duodenum (see Fig. 26-68). The Achilles' heel of this operation is, not surprisingly, marginal ulceration. Thus, it should be combined with highly selective vagotomy, and/or acid suppressive medication.

Roux Syndrome

A subset of patients who have had distal gastrectomy and Roux-en-Y gastrojejunostomy will have great difficulty with gastric emptying in the absence of mechanical obstruction. These patients present with vomiting, epigastric pain, and weight loss. This clinical scenario has been labeled the *Roux syndrome*. Endoscopy may show bezoar formation, dilation of the gastric remnant, and/or dilation of the Roux limb. An upper GI series confirms these findings and may show delayed gastric emptying. This is better quantified by a gastric emptying scan, which always shows delayed solid emptying, and may show delayed liquid emptying as well.

GI motility testing shows abnormal motility in the Roux limb, with propulsive activity toward, rather than away from, the stomach.¹³⁰ Gastric motility also may be abnormal. Presumably, the disordered motility in the Roux limb occurs in all patients with this operation. Why only a subset develops the Roux

syndrome is unclear. Perhaps those patients with disordered gastric motility are at most risk. The disorder seems to be more common in patients with a generous gastric remnant. Truncal vagotomy also has been implicated.

Medical treatment consists of promotility agents. Surgical treatment consists of paring down the gastric remnant. If gastric motility is severely disordered, 95% gastrectomy should be done. The Roux limb should be resected if it is dilated and flaccid, unless doing so puts the patient at risk for short bowel problems. GI continuity may be re-established with another Roux, a Billroth II with Braun enteroenterostomy, or an isoperistaltic jejunal interposition between the stomach and the duodenum (Henley loop). Truncal vagotomy should probably not be done. Long-term acid suppression may be necessary.

Gallstones

Gallstone formation following gastric surgery generally is thought to be secondary to vagal denervation of the gallbladder with attendant gallbladder dysmotility. Presumably, vagotomy causes stasis of gallbladder bile with subsequent sludge and stone formation. Other possible but incompletely investigated possibilities include postoperative ampullary dysfunction and changes in bile composition. It is unclear whether simply dividing the hepatic branches of the anterior vagal trunk (as is frequently done during antireflux and bariatric operations, as well as subtotal gastric resection) increases gallstone formation. Although prophylactic cholecystectomy is not justified with most gastric surgery, it should be considered if the gallbladder appears abnormal, especially if subsequent cholecystectomy is likely to be difficult. If preoperative evaluation reveals sludge or gallstones, or if intraoperative evaluation reveals stones, cholecystectomy should be done if it appears straightforward and the gastric operation has gone well.

Weight Loss

Patients who have an operation on the stomach commonly lose weight. In the case of bariatric surgery, this is intentional and meant to be a permanent effect of the operation. In antireflux surgery, this is usually transient, and attributed to the temporary dietary modification required in the first few postoperative weeks as the patient compensates for mild dysphagia and early satiety. Severe (>10% ideal body weight) or permanent weight loss after antireflux surgery indicates a significant problem and should prompt a diagnostic work-up. Possible causes include a tight or slipped wrap, gastric stasis (due to vagal injury or a missed motor disorder), bacterial overgrowth and malabsorption, or an unrecognized preoperative problem (commonly a motor disorder).

Weight loss is common in patients who have had a vagotomy and/or gastric resection. The degree of weight loss tends to parallel the magnitude of the operation. It may be insignificant in the large person, or devastating in the asthenic female. The surgeon should always consider the possible consequences before performing a gastric resection for benign disease in a thin female. The causes of weight loss after gastric surgery generally fall into one of two categories: altered dietary intake or malabsorption. If a stool stain for fecal fat is negative, it is likely that decreased caloric intake is the cause. This is the most common cause of weight loss after gastric surgery, and may be due to small stomach syndrome, postoperative gastroparesis, or self-imposed dietary modification because of dumping and/or diarrhea. Consultation with an experienced dietitian may prove invaluable.

Anemia

Iron absorption takes place primarily in the proximal GI tract, and is facilitated by an acidic environment. Intrinsic factor, essential for the enteric absorption of vitamin B₁₂, is made by the parietal cells of the stomach. Vitamin B₁₂ bioavailability also is facilitated by an acidic environment.

With this as background, it is easy to understand why patients who have had a gastric operation are at risk for anemia. Anemia is the most common metabolic side effect in patients who have had a gastric bypass for morbid obesity. It also occurs in up to one third of patients who have had a vagotomy and/or gastric resection. Iron deficiency is the most common cause, but vitamin B₁₂ or folate deficiency also occurs, even in patients who have not had total gastrectomy. Of course, patients who have had a total gastrectomy will all develop B₁₂ deficiency without parenteral vitamin B₁₂. Gastric bypass patients should be given oral iron supplements, and monitored for iron, B₁₂, and folate deficiency. Patients who have had a vagotomy and/or gastrectomy should be similarly monitored with periodic determination of hematocrit, red blood cell indices, iron and transferrin levels, B₁₂, and folate levels. Marginal nutrient status should be corrected with oral and/or parenteral supplementation.

Bone Disease

Gastric surgery sometimes disturbs calcium and vitamin D metabolism. Calcium absorption occurs primarily in the duodenum, which is bypassed with gastrojejunostomy. Fat malabsorption may occur because of blind loop syndrome and bacterial overgrowth, or because of inefficient mixing of food and digestive enzymes. This can significantly affect the absorption of vitamin D, a fat-soluble vitamin. Both abnormalities of calcium and vitamin D metabolism can contribute to metabolic bone disease in patients following gastric surgery. The problems usually manifest as pain and/or fractures years after the index operation. Musculoskeletal symptoms should prompt a study of bone density. Dietary supplementation of calcium and vitamin D may be useful in preventing these complications. Routine skeletal monitoring of patients at high-risk (e.g., elderly males and females and postmenopausal females) may prove useful in identifying skeletal deterioration that may be stopped with appropriate treatment.

LAPAROSCOPIC GASTRIC OPERATIONS

Perhaps the most common laparoscopic gastric operations performed today are for GERD and obesity (see Chap. 27, The Surgical Management of Obesity). However, all of the gastric operations described here can be performed with minimally invasive techniques.¹³¹ Some are technically difficult (e.g., partial or total gastric resection) or are of debatable merit. The operations described in this chapter that lend themselves most readily to minimally invasive techniques are highly selective vagotomy, vagotomy and gastrojejunostomy, and gastrostomy. Laparoscopic wedge resection often is possible for GI stromal tumors, lipomas, or gastric diverticula. Combined endoscopic and laparoscopic techniques occasionally are useful. Diagnostic laparoscopy may prevent a futile laparotomy in some patients with gastric cancer. Robotic gastric operations have been described, but have not yet been widely adopted.¹³² The transgastric route figures prominently in animal models of natural orifice transluminal endoscopic surgery,⁶ but the clinical future of this new frontier is unclear.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 27. The Surgical Management of Obesity >

KEY POINTS

1. Surgical therapy is the only effective and proven therapy for patients with severe obesity (body mass index of ≥ 35 kg/m²). Bariatric operations prolong survival and resolve comorbid medical conditions associated with severe obesity.
2. Bariatric surgery is also metabolic surgery, treating the varied metabolic consequences of the comorbid diseases arising from severe obesity. Some operations are particularly effective treatments for such metabolic consequences, such as gastric bypass for type 2 diabetes.
3. Bariatric operations involve either restriction of caloric intake or malabsorption of nutrients, or both. Long-term follow-up is essential before the merits of an operation can be confirmed.
4. During the years 1999 to 2003, here called the *bariatric revolution*, the availability of a laparoscopic approach for bariatric operations caused major changes in the field, including a major increase in the number of procedures performed as well as an increased public and professional awareness and understanding of the field.
5. Laparoscopic gastric bypass is the most common procedure in the United States. The laparoscopic adjustable gastric band procedure is the most popular procedure performed outside the United States and is increasing in popularity in the United States.
6. Patients who develop a bowel obstruction after laparoscopic gastric bypass require surgical and not conservative therapy due to the high incidence of internal hernias and the potential for bowel infarction.
7. Malabsorptive operations are highly effective in producing durable weight loss but have considerable nutritional side effects. Patients undergoing such procedures require close follow-up and must take appropriate nutritional supplements.
8. All bariatric operations are tools that serve to allow the patient to lose weight, become healthier, and improve quality of life. These changes are maintained long term especially if the patient permanently adopts the new eating patterns and exercise habits that are taught and expected in the early year(s) after surgery.

THE DYNAMIC FIELD OF BARIATRIC SURGERY

The focus of this chapter is the surgical treatment of obesity. Bariatric surgery has been a dynamic surgical field, and changes have continued in recent years. The most substantial change is now the focus within the field on the recognized ability of surgical therapy to treat the metabolic consequences of obesity and not just obesity itself. Although the goal of bariatric surgery has always been to improve the medical condition of all patients for whom it is performed, a major emphasis is now being placed on the fact that resolution of the metabolic conditions that in severe obesity cause a variety of medical problems is as important as the actual amount of weight lost. This emphasis has been publicly recognized by the renaming of the professional society in the United States focusing on the surgical treatment of obesity from the American Society for Bariatric Surgery to the American Society for Metabolic and Bariatric Surgery.

Other major changes in the field of bariatric surgery in the United States since the last edition of this text include the increased popularity of the laparoscopic adjustable gastric banding procedure, the introduction of the sleeve gastrectomy as a primary weight loss operation, and the solidification of the laparoscopic approach to bariatric surgery as the optimal approach. The bariatric surgery community also has focused on improvement of outcomes and treatment for patients as well as documentation of the efficacy of bariatric surgery. A number of very important studies in front-line journals that have generated considerable public and medical attention have further confirmed the efficacy of bariatric surgery for producing durable long-term weight loss, improved survival, and improved resolution of comorbid medical

problems compared with medical therapy. In an effort to encourage optimal outcomes at centers performing bariatric surgery, establishment of a "center of excellence" designation for institutions evolved from concept to reality. The process of institutional application for such center of excellence status has served to emphasize that many centers are now achieving outstanding outcomes for their bariatric operations, outcomes that are characterized by considerably lower rates of morbidity and mortality than were found in many studies whose results were previously published in the literature.

THE DISEASE OF OBESITY

Obesity is the second leading cause of preventable death in the United States, currently outranked only by smoking. However, this statement itself demonstrates the still incomplete appreciation of obesity as a disease entity, a concept that is still poorly understood. Obesity *is* a disease, and as such is in many respects not preventable. The components of this disease likely include a combination of environmental and genetic factors. The recent rapid rise in the incidence of obesity in less than a generation's time suggests that genetic causes alone cannot be responsible for the disease. Nevertheless, the multifactorial contributions to the disease increase the difficulty in understanding its causes.

The degrees of obesity are defined by body mass index, or BMI (calculated as weight in kilograms divided by height in meters squared), which correlates body weight with height. Patients are classified as overweight, obese, or severely obese (sometimes referred to as *morbidly obese*) (Table 27-1). Severely obese individuals generally exceed ideal body weight by 100 lb or more or are 100% over ideal body weight. A more metric, internationally accepted definition of severe or morbid obesity is a BMI of ≥ 35 kg/m². *Superobese* is a term sometimes used to describe individuals who have a BMI of >50 kg/m².

Table 27-1 Classification of Obesity by Body Mass Index (BMI)	
Classification	BMI Range (kg/m ²)
Normal weight	20–25
Overweight	26–29
Obese	30–34
Severely obese	35–49
Superobese	≥ 50

Prevalence and Contributing Factors

Severe obesity is reaching epidemic proportions in the United States. Since 1960, surveys of the prevalence of obesity have been conducted every decade by the National Center for Health Statistics. Obesity statistics have been updated annually since 1985. Twenty-five percent of adult Americans were overweight in 1980; by 1990 that number had risen to 34%. By 2004, 32.2% of adults were *obese*.¹ In 1990, conservative estimates put the number of Americans with a BMI between 35 and 40 kg/m² at 4 million, with an additional 4 million having a BMI exceeding 40 kg/m². Current estimates suggest that the population of patients with severe obesity (BMI >35 kg/m²) is greater than 15 million. Despite the expenditure of more than \$30 billion annually on weight loss products, the prevalence of obesity is dramatically increasing. Obesity is most common in minorities, low-income groups, rural populations, and women, but is increasing in all socioeconomic groups.

The increase in obesity is multifactorial. Genetics plays an important role in the development of obesity. Although the children of parents of normal weight have a 10% chance of becoming obese, the children of two obese parents have an 80 to 90% chance of developing obesity by adulthood. The weight of adopted children correlates strongly with the weight of their birth parents. Furthermore, concordance rates for obesity in monozygotic twins are double those in dizygotic twins.²

Diet and culture are important factors as well. These environmental factors contribute significantly to the epidemic of obesity in the United States, because the rapid increase in obesity during the past two decades cannot be explained by any genetic cause.

Other factors appear to contribute significantly to severe obesity. Intermittent or consistent excessive caloric intake occurs. The lack of satiety, on a consistent or intermittent basis, appears to be strongly correlated with such episodes of excessive caloric ingestion. As yet the physiologic basis for such a lack of satiety is not understood. Other factors commonly suggested to play a role in the disease of obesity include decreased energy expenditure from reduced metabolic activity, reduction in the thermogenic response to meals, an abnormally high set point for body weight, and a decrease in the loss of heat energy. Another factor that may influence absorption of ingested food is the composition of the intraluminal bacteria of the intestinal tract. Recent studies have documented a difference in the composition of the intestinal flora of obese individuals compared with those of normal weight.³

Obese individuals have excessive adipose cells, in both size and number. The number of such cells often is determined early in life; adult-onset obesity is largely a product of an increase in adipose cell size. In children, however, weight gain results from increase in adipose cell size and cell number. Adipose tissue may be deposited in large quantities in the subcutaneous layer of the abdominal wall or the viscera. Males tend to have central visceral fat distribution, whereas females more often have a peripheral or gluteal fat distribution. Central or visceral fat distribution is associated with metabolic diseases such as diabetes, hypertension, and the metabolic syndrome.⁴

Concurrent Medical and Social Problems

The severely obese patient often has chronic weight-related problems, detailed later. However, the single most difficult aspect of the disease of severe obesity for those who have it is the discrimination they face from the rest of the population in terms of social stigmatization. This prejudice against obesity remains the last type of discrimination without legislative remedy. Obese individuals are routinely discriminated against in terms of employment. The design of public facilities often does not allow them to participate in activities. Examples include the inadequate size of airline seats and bathrooms, the lack of availability of appropriate clothing options, and the insufficient size of automobile cabins. Severely obese individuals are thought of by much of the public as being lazy or gluttonous and lacking self-discipline. They often endure not only discrimination and prejudice but also outright ridicule and disrespect. Consequently, the stigma of severe obesity has a major impact on social function and emotional well-being. Psychologic diseases such as depression therefore have an extraordinarily high incidence in this population compared with the general public. Poor self-image is almost universal among these individuals as well.

Significant comorbidities, defined as medical problems associated with or caused by obesity, are numerous. The most prevalent and acknowledged of these include degenerative joint disease, low back pain, hypertension, obstructive sleep apnea, gastroesophageal reflux disease (GERD), cholelithiasis, type 2 diabetes, hyperlipidemia, hypercholesterolemia, asthma, hypoventilation syndrome of obesity, fatal cardiac arrhythmias, right-sided heart failure, migraine headaches, pseudotumor cerebri, venous stasis ulcers, deep vein thrombosis, fungal skin rashes, skin abscesses, stress urinary incontinence, infertility, dysmenorrhea, depression, abdominal wall hernias, and an increased incidence of various cancers such as those of the uterus, breast, colon, and prostate.⁵

Rarely conditions other than exogenous obesity cause excess body weight. Among these is Cushing's syndrome, which is associated with hirsutism, skin lesions, and wound-healing problems, and in rare cases has remained undiagnosed and is identified as the cause of obesity when the patient is evaluated for surgical therapy. After finding no elevated cortisol levels in obese patients in 15 years, we abandoned this screening blood test as being cost inefficient. In children, intractable eating can be associated with Prader-Willi syndrome. This syndrome has been refractory to all known bariatric operations.

Prognosis

Obesity has a profound effect on overall health and life expectancy, largely secondary to weight-related comorbidities. It is estimated that a man who is severely obese at age 21 will live 12 years less than a nonobese individual, and a severely obese woman will live 9 years less. The incidence of severe obesity in the population is comparable for females younger and older than 50 years of age, whereas for men the incidence of severe obesity declines above age 50. This is largely due to the fact that severely obese men often are dead of comorbid medical conditions, especially cardiac arrhythmias and coronary artery disease, by age 50. A study carried out by the Veterans Administration showed a 12-fold increase in mortality among 200 morbidly obese men aged 25 to 34 years and a 6-fold increase among those aged 35 to 44 years over a 7-year follow-up period.⁶ Decreased quality of life also results from severe obesity. Most patients

seeking surgical treatment of severe obesity do so because of the medical issues they face from comorbid conditions or the decreased quality of life they are experiencing as a result of severe obesity. As will be shown later, bariatric surgery can significantly prolong the life span of a severely obese individual as well as improve the quality of his or her life.

MEDICAL MANAGEMENT

Medical treatment for severe obesity is aimed at reducing body weight through a combination of decreased caloric intake and accompanying increases in energy expenditure from moderate exercise. This method of weight loss is the safest possible and may work well for obese individuals who have modest amounts of weight to lose to regain normal body weight or to return to being simply overweight instead of obese. For the severely obese individual, however, who usually must lose at least 75 lb or more to achieve elimination of obesity, this is a daunting and extremely difficult task. The success rate among severely obese patients who try dieting and exercise as a means of losing enough weight to no longer be obese and maintaining that weight loss is only approximately 3%.

Although success rates are limited with diet and exercise alone, all severely obese individuals are asked to attempt this route of weight loss before undertaking any surgical therapy. There are two main reasons for this. The first is to allow those who can achieve such weight loss through the safest possible means to do so. The second, and by far the more practical, is to have the severely obese individual begin to appreciate and practice the lifestyle changes that must ultimately become routine once weight loss is achieved, by whatever means. The adjustment of the patient's lifestyle to include these measures is valuable to long-term success with any bariatric operation.

The treatment of severe obesity should begin with simple lifestyle changes, including moderate reduction of caloric intake and initiation of an exercise plan. Walking is the most common choice of exercise in this population of patients, who may be unable to perform extremely vigorous exercise initially. Medical comorbidities must be identified and treated. Usually the patient's primary care physician will have already accomplished this, but we do at times identify obesity-related comorbidities on initial history taking and physical examination in our clinic.

The severely obese patient will usually have been given dietary counseling by his or her primary care physician and often will have been placed on a medically supervised diet. Most patients also have attempted commercially sponsored diets and diet plans. Success after starting such a program is not unusual, but sustained weight loss for more than a year after stopping the program is rare. Although primary care physicians usually do an outstanding job of identifying and treating comorbid medical problems, their offices usually do not have the related support staff of nutritionists and psychologists who often are very helpful in providing services to severely obese patients undergoing significant lifestyle changes.

Lifestyle changes involving diet, exercise, and behavior modification constitute the first tier of therapy for obesity. Dietary restriction and exercise can each independently create a caloric deficit. A daily energy deficit so created of 500 kcal/d, resulting in a weekly deficit of 3500 kcal, results in the loss of 1 lb of fat weekly. It has been shown that low-calorie diets (800 to 1500 kcal/d) are as effective as very-low-calorie diets at 1 year but result in a lower rate of nutritional deficiencies.⁷ Such diets may produce an average of 8% body weight loss over a 6-month period. Longer follow-up shows recidivism. Moderate daily physical activity can produce a 2 to 3% body weight loss.⁸

A behavioral modification program that provided desirable rewards for meeting short-term dietary or exercise requirements, used in combination with diet and exercise, produced as much as a 10% weight loss at 6 months in one study. This weight loss was only sustained in 60% of patients at 40 weeks,⁹ and at 1 year the average sustained weight loss was decreased to 8.6%.¹⁰

Dietary, exercise, or behavior modification therapy is appropriate treatment for patients who are overweight (BMI <30 kg/m²) and is highly recommended for patients with a BMI between 30 and 35 kg/m². Most of the studies looking at dietary therapy do not include a patient population that is largely obese (BMI >30 kg/m²). Dietary therapy can be effective in producing improvements in comorbid conditions such as diabetes mellitus, with weight loss of 2.3 to 3.7% influencing the disease.¹¹ Thus lifestyle changes can be effective in improving the health of the nonobese. Efficacy for the obese population is not as well documented, and there are no studies published to date that demonstrate significant, long-term efficacy of medical therapy for the severely obese.

Pharmacologic therapy is also an option for patients attempting to lose weight. Unfortunately, the number of effective pharmacologic

agents is small compared with the number of products sold with assertions that they will promote or support weight loss. Pharmacotherapy is normally used only after lifestyle changes and dietary therapies have failed. It is used either alone as the primary therapy or in conjunction with simultaneous diet and exercise therapy. Currently there are only two drugs approved by the U.S. Food and Drug Administration for the treatment of obesity that promote weight loss. Sibutramine is a noradrenaline and 5-hydroxytryptamine reuptake inhibitor that works as an appetite suppressant. Orlistat inhibits gastric and pancreatic lipase enzymes that promote lipid absorption in the intestine.¹² Either of these drugs may produce a weight loss of between 6 and 10% of body weight after 1 year, but cessation of the drug usually results in prompt regaining of lost weight.¹³ Pharmacotherapy is recommended as an adjunctive or supplementary therapy to lifestyle changes, including diet and exercise or behavioral therapy, by the National Institutes of Health (NIH) consensus guidelines for treatment of obesity.¹⁴

Because medical therapies are almost uniformly ineffective for patients with severe obesity, the severely obese patient tends to continue to gain weight. The number and strength of prescribed medications slowly increases as the medical comorbidities become increasingly worse. Unfortunately, for the majority of severely obese patients, this process continues unabated until death results eventually from the comorbidities. Until recently, <1% of severely obese patients underwent surgical treatment for obesity annually. That number has now increased but still is not over 2% of individuals. Even when one counts patients referred for surgery and felt to be poor candidates, it is likely that <5% of patients with severe obesity are referred on an annual basis. Part of the issue may be patient aversion to surgical therapy. Because of societal messages, the patient may feel self-blame for being obese and hence feel that surgery is either too drastic or an admission of weakness.

The recent national advertising campaign for laparoscopic adjustable gastric banding has produced an increased interest in surgery on the part of the severely obese patient population. Most of this interest is based on the belief that this procedure is less invasive than other bariatric surgeries. Not surprisingly, minimally invasive therapy has proven to be a more attractive surgical option to individuals with severe obesity. Over the past two decades, lack of information about bariatric surgery as an option for the severely obese patient has decreased dramatically as a reason why patients would not seek surgical therapy. It is difficult to say whether the persistent lack of attraction of surgical therapy or the currently limited access to surgical care is the more important factor preventing individuals with severe obesity from obtaining surgical therapy. Limited access to care is a result of either a patient's lack of health insurance or the insurance carrier's elimination of coverage for bariatric surgery from the policy. In states where such an elimination is unlawful, such as Virginia, insurance companies have successfully circumvented the intention of the law by attaching riders imposing severe financial penalties to the policies of employers who wish their employees to receive the benefits of coverage for bariatric surgery. Despite endorsement of bariatric surgery as standard of care treatment for severe obesity by many scientific and government organizations (Table 27-2), a majority of private insurance carriers in the U.S. do not provide coverage for bariatric surgery as a standard benefit.

OVERVIEW OF BARIATRIC SURGERY

Bariatric operations produce weight loss through two mechanisms. The most common is restriction of intake. Malabsorption of ingested food is the second mechanism. Restrictive operations may include no or only a modest malabsorptive component. Malabsorptive operations may have some restrictive component, but it is secondary to the malabsorptive aspect of the operation. Table 27-3 describes the common currently performed operations listed by mechanism of action.

Table 27-3 Types of Commonly Performed Bariatric Operations by Mechanism of Action

Restrictive
Laparoscopic adjustable gastric banding (LAGB)
Sleeve gastrectomy (SG)
Vertical banded gastroplasty (VBG) ^a
Malabsorptive
Biliopancreatic diversion (BPD)
Jejunioileal bypass (JIB) ^a
Combined restrictive and malabsorptive
Roux-en-Y gastric bypass (RYGB)
BPD with duodenal switch (DS)

^a Now rarely performed and of historic interest only.

This chapter focuses on the operations listed in Table 27-3 regardless of whether they are done using a laparoscopic or an open incision approach. Although other procedures are known and available, they are performed very infrequently or are not yet approved for coverage by insurance providers, so they are not discussed in detail. Sleeve gastrectomy is now included because the operation has been shown to have medium-range efficacy, and its safety and effectiveness are now supported by a number of studies published in the literature.¹⁵ In 2008 the American Society for Metabolic and Bariatric Surgery declared sleeve gastrectomy to be an appropriate first-line surgical therapy for weight loss. Vertical banded gastroplasty, although still one of the approved operations for the surgical treatment of severe obesity based on the NIH Consensus Conference of 1991,¹⁴ is now so infrequently performed, and has such poor results on long-term follow-up,¹⁶ that it is of historic interest only and has therefore been eliminated from this basic text as a standard of surgical care.

Evolution of Bariatric Surgery

During the 1950s, operations were first performed to treat severe hyperlipidemia with associated obesity.¹⁷ These were ileocolic bypass operations to limit absorption and were associated with severe nutritional complications and liver failure postoperatively. The jejunioileal bypass was then devised and popularized in the mid-1970s.¹⁸ It was also a malabsorptive operation but bypassed only a portion of the small intestine. Complications after this procedure were slower to manifest themselves but included severe diarrhea, electrolyte disturbances, protein/calorie malnutrition, renal stones, and liver failure.

In 1969, Mason and Ito performed the first gastric bypass, in which a loop of jejunum was connected to a transverse proximal gastric pouch.¹⁹ Bile reflux esophagitis was severe postoperatively, which caused Griffin to develop the Roux-en-Y modification of the gastric bypass in 1977.²⁰ The gastric pouch was altered from transverse to vertical using the upper lesser curvature as well.

During the 1970s, the dismal failure of the jejunioileal bypass resulted in a very bad reputation in general for bariatric surgery among general surgeons who had performed the procedure or cared for patients experiencing its complications. Its reputation was not enhanced by the many variations of gastric stapling which then became commonplace during that time and in the early 1980s. Such operations

often consisted of placing a few rows of staples partially across the upper stomach for restrictive purposes. Because the procedure was easily done, some surgeons performed it in prolific numbers. Staple breakdown predictably occurred months to years later, with subsequent regaining of weight. These procedures added to the string of failures of bariatric operations.¹⁸

In 1980, Mason²¹ described vertical banded gastroplasty (VBG), a restrictive procedure in which stapling was used to create a proximal gastric pouch of the upper lesser curvature of the stomach, with placement of a restrictive band to form its outlet to the rest of the stomach. This operation produced excellent initial weight loss (50% of excess weight or more) with low morbidity and mortality. It rapidly became the most commonly performed bariatric operation in the United States during the 1980s. By the early 1990s, however, it had become clear that patients who underwent VBG tended to adopt a diet of high-calorie liquids and regained weight.²² A significant incidence of stenosis at the band was also a problem. Long-term weight loss was poor,¹⁶ and by the 1990s in the United States Roux-en-Y gastric bypass (RYGB) became the procedure of choice for bariatric surgery.

In Italy, in the meantime, Scopinaro had developed and popularized the biliopancreatic diversion (BPD) procedure in the late 1970s.²³ This procedure, described in more detail later, along with its modification to include a duodenal switch (DS), has been the only major malabsorptive operation to enjoy long-term success. BPD and DS are both still used by a fairly select few surgeons throughout the world and both in the past and today represent <5% of operations performed in the United States.

Fixed banding of the stomach, aside from the VBG procedure, was also reported by other surgeons in the 1980s and 1990s. Kuzmak is credited with describing the fixed gastric band procedure that later led to the development of the adjustable gastric banding operation.²⁴

The laparoscopic approach to bariatric surgery became available in the 1990s. Belachew and colleagues performed the first laparoscopic adjustable gastric banding (LAGB) operation in 1994.²⁵ Wittgrove and Clark performed the first laparoscopic Roux-en-Y gastric bypass (LRYGB) the same year.²⁶ Because the former operation is technically much easier than the latter, it was not surprising that it became very popular and was frequently performed in Europe and Australia during the late 1990s. In 2001 LAGB was approved for use in the United States by the U.S. Food and Drug Administration. Since then it has represented an increasingly larger percentage of bariatric operations performed in this country, with 2007 estimated figures suggesting that it accounts for at least 25% if not a higher percentage of bariatric operations performed. Its popularity seems to have been rapidly increasing due to significant national advertising campaigns. In the period since 1994, LRYGB, a much more technically difficult operation, saw a very slow adoption into common practice. Four years after the initial report, only a handful of medical centers had any significant experience with the procedure.

The Bariatric Revolution

The *bariatric revolution* is the term applied to the 5-year period from 1998 to 2003 in which the number of gastric bypass operations performed in the United States, membership in American Society for Metabolic and Bariatric Surgery, and public recognition and interest in and professional respect for the field dramatically increased. Few medical centers in the United States offered a laparoscopic approach to bariatric surgery before 1998, but many bariatric surgeons at that point were interested in learning to perform bariatric operations laparoscopically. Several centers, then began numerous programs to teach many bariatric surgeons the procedure.

General surgeons had demonstrated throughout the 1990s the improvements in outcomes that could result from performing operations laparoscopically rather than using an open incision. Bariatric surgeons were eager to extend laparoscopy to bariatric surgery. Once limitations in the availability of laparoscopic instruments for bariatric procedures had been overcome, and once the procedure was taught to leading bariatric surgeons at bariatric surgery centers (more than a few newly formed), the field literally exploded in terms of growth. Figure 27-1 illustrates the volume of RYGB procedures performed during the years before and during the bariatric revolution. The number of bariatric procedures recorded increased by nearly eightfold, and membership in the American Society for Bariatric Surgery tripled during these years. The number of fellowships in minimally invasive surgery offered to graduating residents, most of which included bariatric surgical procedures as a major component of the case load, increased from a few to 125 during these years. Public recognition of the procedure markedly increased because some public figures in the media underwent bariatric surgery. The wide availability of the Internet to prospective patients allowed much more information to be relayed. Patients who had or were contemplating surgery were able to communicate via the Internet. Videos of bariatric operations became available through several media outlets, including television and the

Internet. Many U.S. surgical departments that had previously shunned the field of bariatric surgery recruited bariatric surgeons and set up programs. Hospitals without programs recruited surgeons so they could offer the service. Bariatric surgery presentations at national surgical meetings became commonplace instead of rare or limited to bariatric meetings. In just 5 years, the field experienced greater growth than the field of general surgery had experienced during the introduction of laparoscopy a decade earlier—and underwent just as absolute a change.

Indications

The indications for performing bariatric surgery remain as described by the NIH Consensus Conference of 1991.¹⁴ The only major difference is in which procedures are now recognized as standard procedures. The standard procedures were defined by the Centers for Medicare and Medicaid Services in 2005 as those listed in Table 27-3, with the exception of sleeve gastrectomy. The latter, although still often not covered by insurance policies in many areas, seems destined to take its place, among the available options for bariatric surgery. Vertical banded gastroplasty, although still listed as a standard procedure and still covered by many insurance policies, has fallen from favor. For this reason, as noted earlier, a detailed description of it has been eliminated from this text. The indications for performing bariatric surgery are summarized in Table 27-4.

Table 27-4 Indications for Bariatric Surgery
Patient must:
1. Have body mass index (weight in kilograms/height in square meters) of ≥ 40 with or without comorbid medical conditions associated with obesity
2. Have body mass index of 35–40 with comorbid medical conditions
In addition it is expected that patients:
3. Have failed attempt at other weight loss treatments
4. Be psychologically stable

Source: Adapted from 1991 NIH Consensus Conference.¹⁴

Contraindications

Of all the reasons preventing a patient who desires bariatric surgery from having an operation, inadequate insurance coverage, or lack

thereof, is the most common. Assuming that the patient does have insurance coverage or the financial means to qualify for surgery, then application of the NIH criteria is the next step. Once a patient qualifies according to those criteria, then medical, social, and psychologic issues are considered to identify any possible reasons to avoid surgical therapy.

The NIH criteria do not set limits for age, and surgeon opinion on this issue varies widely. One of us (BS) observes a general upper limit of about 60 years of age for LRYGB and at most 65 years for LAGB. Rare exceptions are made for patients who appear younger than their chronologic age. However, most patients who are severely obese have been that way for decades, with concurrent deterioration of major vital organ systems as a result. Thus few of them are physiologically "younger" than their chronologic age, and the reverse is more often true. The rationale for age restriction is twofold: a large number of younger patients are interested in and eligible for bariatric surgery, and there is a greater likelihood of a longer period of postoperative benefit in terms of improved quality of life and longevity with younger patients. Although this represents something of a triage approach, until the vast majority of patients who qualify for surgery can obtain it, this approach can be justified. More details on bariatric surgery for both the old and the young are provided later in this chapter.

Medical issues that preclude patients from being good surgical candidates include the presence of American Society of Anesthesiologists class IV disease of a type that makes surgical therapy associated with an extraordinarily high risk. Psychologic instability or the inability to understand the implications of the proposed operation and what changes will result from it in terms of the patient's lifestyle is also a contraindication. Known and documented drug or alcohol addiction is a contraindication to surgery. Smoking is a relative contraindication, and the requirement for cessation of smoking varies by surgical practice. An ongoing eating disorder, especially bulimia, is also a contraindication to surgery. Nonambulatory status is a relative contraindication to surgery, especially if it results from such severe obesity that the patient cannot normally perform self-care or would not likely be able to do so after surgery. In our experience, not only do such patients have excessive morbidity, but placement in care facilities postoperatively after recovery from surgery is often difficult due to their size and limitations of physical ability. Some patients view the bariatric operation as a "magic bullet" for which they must only show up and after which they will not be required to make any substantive changes in eating or lifestyle. Although it may be hard to detect this attitude in a single visit, an accumulation of evidence suggests that such a view on the part of the patient is a very valid reason to deny surgery. Similarly, inappropriate, uncooperative, or intimidating behavior during the preoperative interval often is a harbinger of postoperative problems and may constitute a reason to deny surgical care. Finally, the lack of sufficient social support, an extremely poor or unsupportive home environment, or hostile spouse or relatives can be contraindications to surgical care, because a supportive environment is important to optimize outcomes once the patient is discharged from the hospital. Table 27-5 summarizes relative contraindications for surgery.

Table 27-5 Relative Contraindications for Bariatric Surgery ^a
1. Severe medical disease that makes anesthesia or surgery prohibitively risky (American Society of Anesthesiologists class IV)
2. Mental incompetence that prevents the patient from understanding the procedure
3. Inability or unwillingness of the patient to change lifestyle postoperatively
4. Drug, alcohol, or other substance addiction
5. Uncontrolled bulimia or other eating disorder
6. Psychologic instability
7. Nonambulatory status
8. Patient view of surgery as a "magic bullet"
9. Antagonistic family, unsupportive home environment
10. Noncompliant behavior

^a These relative contraindications should be weighed against the potential benefits of surgery which may be the only treatment likely to yield significant weight loss and clinical improvement in the high-risk patient.

PREOPERATIVE ISSUES

Patient Selection

Patient selection for surgery should be based on a multidisciplinary team evaluation. The patient has usually been screened by his or her primary care physician before referral, with major medical issues addressed before referral. Determining whether the patient meets the NIH criteria and whether insurance coverage is available can be handled by office administrators and confirmed and documented before the first appointment.

The preoperative assessment of the patient for bariatric surgery must include input from the nutritionist as an important independent evaluation. Careful assessment of the patient's eating habits, knowledge, self-awareness, and insight are important. An estimation of the patient's motivation to change eating habits is important. An experienced bariatric nutritionist can be helpful in predicting which patients will be compliant or noncompliant with recommended lifestyle changes postoperatively. Specific nutritional counseling and education is required based on the operation to be performed.

Psychologic assessment is required by some insurance carriers. In our opinion, the major benefit of the psychologic assessment is to determine how the patient views the operation and whether the patient has a realistic understanding of the changes in lifestyle that are needed for optimal outcomes. The psychologist or psychiatrist often diagnoses previously unappreciated depression, which is detected in nearly 40% of our preoperative patients when they are carefully screened. Treatment of the depression is felt to improve postoperative outcomes.

Most of the patients referred to us for surgery who have been screened for qualification according to the NIH standards are appropriate candidates for bariatric surgery. Some will decide against the procedure after completing thorough educational and counseling sessions. We advocate detailed written information and a multihour verbal presentation by our multidisciplinary team to educate patients preoperatively regarding bariatric surgical procedures and expected outcomes and potential complications. Informed and prepared patients will be much more compliant with requested perioperative and postoperative behavioral and eating changes. Some patients who decide against the procedure will return for re-evaluation in the future after their obesity comorbidities worsen.

Preoperative Preparation

Preoperatively, current comorbidities and other medical problems are reviewed and optimized. Potentially undiagnosed medical problems are recognized and treated. Screening for hidden diseases such as coronary artery disease in patients >50 years of age is important. For such patients, or those with known cardiovascular disease, we advocate a preoperative cardiology consultation. Such consultation usually involves electrocardiography, echocardiography, stress test, and perhaps even cardiac catheterization. Another condition often underdiagnosed preoperatively in the severely obese patient population is obstructive sleep apnea. Patients who give a history of loud snoring, morning tiredness on waking, and falling asleep easily while driving or sitting likely have obstructive sleep apnea. A diagnostic sleep study is indicated. One report suggests that the incidence of sleep apnea in severely obese patients, when all routinely undergo sleep studies, may approach 80%.²⁷ Once diagnosed with sleep apnea, patients should use a positive airway pressure device as treatment. Use of this system in the immediately postoperative period is especially important to prevent episodes of hypoxia and the cardiac arrhythmias that can potentially result. Asthma and hypoventilation syndrome of obesity are other significant pulmonary diseases often requiring preoperative management. Hypoventilation syndrome of obesity is defined as a resting partial pressure of arterial oxygen of <55 mmHg and a resting partial pressure of arterial carbon dioxide of >47 mmHg, with accompanying pulmonary hypertension and polycythemia. Pulmonary consultation is indicated for patients with hypoventilation syndrome. Postoperative intensive care unit hospitalization, rarely used after bariatric surgery, is usually indicated for these patients in our opinion.

For patients with active GERD taking medication, a preoperative screening upper endoscopy to rule out Barrett's esophagus and intrinsic lesions of the stomach or duodenum is recommended. This is especially true for patients planning LRYGB, in which the distal stomach and duodenum will be precluded from easy inspection postoperatively. Several studies have documented the considerable incidence of preoperative pathology identified on flexible upper endoscopy in this patient population, as well as a small but not insignificant incidence of pathology resulting in alteration of the originally planned surgical procedure.^{28,29} At the University of Virginia Medical Center, our experience was that such pathology was found on 4.6% of examinations.³⁰

In patients who are taking anticoagulants for prosthetic cardiac valves or recent venous thromboembolism, anticoagulation therapy must be managed perioperatively. Options include total cessation of oral warfarin therapy 5 days before surgery, then administration of subcutaneous low molecular weight heparin until resumption of warfarin postoperatively. Alternatively, one can proceed with preoperative hospital admission for IV heparin anticoagulation therapy, which is then stopped 6 hours before surgery.

Patients who have a strong history of venous thromboembolism or who are felt to have multiple risk factors for postoperative venous thromboembolism are potential candidates for preoperative placement of a temporary inferior vena cava filter. Such filters are placed the day before surgery by our interventional radiology colleagues and removed 3 to 6 weeks postoperatively. Our results with such therapy have been excellent, with little morbidity and effective prevention of any significant pulmonary embolism in such patients.

We routinely perform screening ultrasound of the abdomen in patients planning to undergo LRYGB who have an intact gallbladder to rule out the presence of gallstones. Should gallstones be discovered, we currently recommend simultaneous laparoscopic cholecystectomy. Another approach is to defer cholecystectomy until after LRYGB if the patient is symptomatic. Recent analysis of our experience with this approach at the University of Virginia has shown an average increase in operative time of approximately 30 minutes for both LRYGB and RYGB with no increase in hospitalization time or morbidity.³¹ An earlier study at Pittsburgh did demonstrate an increased length of hospitalization for patients undergoing simultaneous cholecystectomy.³² When a patient does not have gallstones as determined by preoperative ultrasound, we have followed the recommendations of a previous study which showed that prophylactic administration of ursodiol at a dosage of 300 mg bid will decrease the incidence of gallstone formation after RYGB to approximately 4%.³³ Controversy currently exists as to the proper role of simultaneous laparoscopic cholecystectomy at the time of LAGB. The conservative approach is not to perform such an operation, given the small potential for gallbladder bile spillage, which can result in infection of the prosthesis. Insufficient data have been published on the subject for a more evidence-based recommendation to be made. Another value of preoperative ultrasound of the abdomen is the assessment of liver size and composition. An ultrasound finding of a large fatty liver in a patient planning to undergo either LAGB or LRYGB should alert the surgeon to the high potential for technical difficulty in liver retraction and exposure. We have converted to an open procedure and even deferred persisting with the operation altogether when confronted with an excessively large liver. Knowledge of this before surgery allows the patient to follow a low-calorie diet to shrink the liver preoperatively.

Some surgeons require patients to follow a low-calorie diet in the immediately preoperative period, insisting on weight loss before proceeding with surgery. Some data indicate that preoperative weight loss by patients may improve outcomes. Such studies suffer from the fact that the patients who are most compliant and lose weight preoperatively may also be the most compliant postoperatively, which may account for the improved outcomes. Preoperative weight loss is not necessary to achieve good outcomes from surgery, because many practices do not require such preoperative weight loss and still achieve good outcomes. Requiring preoperative weight loss raises the dilemma of whether patients who do not achieve weight loss should then be denied the benefit of surgical therapy.

Other routine preparation for surgery in our practice includes measurement of baseline arterial blood gas values. This is especially important in any patient with significant pulmonary disease or hypoventilation syndrome of obesity, because a baseline value of "normal" *for that patient* must be known if ventilator management is necessary postoperatively.

Baseline evaluation of thyroid function is recommended preoperatively, because hypothyroidism is not uncommon in this patient population. Serum chemical analysis, liver function tests, and the usual screening blood tests are performed. Blood tests to determine baseline nutritional parameters commonly reveal abnormally low iron and vitamin D levels. The former finding is common in the menstruating female population, obese or not, whereas the latter has also been noted.³⁴ Whether to treat low vitamin D levels preoperatively is unclear, because its influence on clinical outcomes remains undefined.

Preoperative patient education is important to re-emphasize important events of the perioperative period, expected postoperative course, and instructions for postoperative activity and diet. Expectations we have for patients include ambulating on the day of surgery, adhering to postoperative dietary instructions, taking recommended vitamin and mineral supplements, and following a regular exercise plan.

Anesthesiology Issues

A preoperative anesthesiology assessment is indicated for all patients undergoing bariatric surgery. This assessment confirms that ongoing comorbid medical problems are being optimally evaluated and managed. It also includes the aforementioned cardiopulmonary evaluation to identify any underlying pathology that requires preoperative treatment to decrease perioperative morbidity from cardiopulmonary complications.

It is important that the anesthesiologist for the bariatric surgical procedure be experienced in carrying out general anesthesia management for the bariatric patient. There is no question that the consistent participation of a few selected and experienced anesthesiologists who specialize in the care of the bariatric patient will minimize morbidity in surgical outcomes. Perioperative and intraoperative communication between the anesthesiology team and the surgical team is particularly important during bariatric operations to facilitate the smooth flow of the operation and avoid complications from the procedure.

Two major difficulties the anesthesiologist faces when administering a general anesthetic to a severely obese patient are vascular access and airway management. Both are significantly more difficult in the obese patient population than in the normal-weight population. Central venous access is at times the only available route for establishment of reliable IV access. Access to both arms during the procedure is standard in our operating rooms; this allows for additional larger-bore IV access should an episode of intra-abdominal hemorrhage occur. Jugular cannulation is often very difficult due to neck adipose tissue. Subclavian access is used when other central access routes are not feasible.

Management of the airway in the severely obese patient is often a major challenge for the anesthesiologist and must be done well to avoid potentially significant morbidity. Videotelescopic intubation systems are successfully used in some institutions to accomplish difficult airway intubation. Fiber-optic laryngoscopy is more commonly used for difficult intubations should standard laryngoscopy provide an inadequate view. For the most difficult class IV or even class III airways, fiberoptically guided intubation is used. Experience again is key in accomplishing smooth intubation of this patient population. Significant preoxygenation for 3 minutes or longer before intubation is performed in the severely obese patient to provide a longer safe duration for intubation should difficulties be encountered. However, desaturation must be addressed immediately with re-establishment of oxygenated ventilation, because this patient group does not tolerate any prolonged desaturation without potential adverse cardiopulmonary consequences.

The anesthesiologist must be adept at understanding and managing alterations in cardiopulmonary function from the use of a pneumoperitoneum during laparoscopic bariatric procedures. These alterations include the effects of carbon dioxide absorption on required minute ventilation, the potential for bradyarrhythmias, and the potential for decreased systemic pH with longer procedures in patients with pre-existing cardiopulmonary disease. Arterial monitoring of the latter group of patients by the anesthesiology team is necessary, and placement of a radial arterial line is standard for such patients.³⁵

Drug pharmacokinetics differ in severely obese patients as well. Factors affecting changes in volume of distribution include smaller-than-normal fraction of total body water, greater adipose tissue content, altered protein binding, and increased blood volume. Possible changes in renal function and hepatic function must be considered when administering drugs.

Alterations in the metabolism of specific anesthetic drugs in the severely obese include a larger volume of distribution of thiopentone, which results in a prolonged effect of the drug. The dosage should be calculated based on lean body weight. Benzodiazepines also exhibit a prolonged elimination phase, which causes persistence of their effects. Increased pseudocholinesterase activity is present in the severely obese patient, so that increased dosages of pancuronium are required. Enflurane metabolism is increased over that in the average-sized person, so that a lower dosage of this agent must be used.

BARIATRIC SURGICAL PROCEDURES

Laparoscopic vs. Open Procedures

The procedures described later use the laparoscopic approach as the default or typical approach. The Roux-en-Y gastric bypass (RYGB), the biliopancreatic diversion (BPD), and the duodenal switch (DS) are often still performed using an open approach, and such an approach has been well documented to be safe and effective. Decreased wound complications, as well as earlier hospital discharge and lower 30-

day complication rates, have all been demonstrated for the laparoscopic approach, which clearly favors the use of this approach when feasible.^{36–38} In addition, the logical assumption that avoiding the major tissue trauma associated with a long abdominal wall incision is beneficial to patient recovery has been confirmed. Most importantly, patient interest in bariatric surgery increased dramatically once a laparoscopic approach was available for these procedures, especially RYGB. In the United States, the annual number of RYGB procedures in the 1990s was just under 20,000 but by 2003 had reached 130,000 (see Fig. 27-1).³⁹ In the twenty-first century, most prospective bariatric surgery patients are informed enough about the options for surgery to seek out a surgeon who performs laparoscopic bariatric surgery if such a surgeon is available within a reasonable distance of their home.

When an open surgical approach is used for any of these procedures, an upper midline incision is the most commonly used approach. Some surgeons have had excellent success with a left subcostal incision for performing RYGB.⁴⁰ Mechanical retractors afford additional exposure for open surgery, and their use is indicated. Wound closure for midline incisions usually is performed using heavy monofilament suture for the midline fascia, but surgeon preferences vary. Thorough hemostasis and irrigation of the subcutaneous tissues is indicated before secure skin closure. The use of drains has been shown to increase wound infections. We have found that leaving skin staples in place for a longer interval is beneficial to prevent premature skin dehiscence, which in turn can lead to more severe wound infection. Any worrisome drainage from a postoperative open surgical incision line requires opening of the wound in that area to confirm that a more severe deep-seated fascial tissue infection does not exist.

Laparoscopy is the most commonly used approach for bariatric surgical procedures at this time. Table 27-3 lists the operations that are discussed in later sections by mechanism of action. As implied by the name *laparoscopic adjustable gastric banding (LAGB)*, virtually all gastric banding procedures are performed using this approach. The same is true for sleeve gastrectomy, although the nomenclature for that operation does not include the word *laparoscopic*. The majority of gastric bypass operations are now done laparoscopically (LRYGB). BPD and DS, both malabsorptive operations, are performed with relative infrequency in the United States. When performed, they often are still done using an open approach, but some centers do use a laparoscopic approach as well.

Laparoscopic surgery requires a core set of knowledge and skills that have now become a standard part of surgical training. Successful completion of the Fundamentals of Laparoscopic Surgery unit developed by the Society of Gastrointestinal and Endoscopic Surgeons⁴¹ has now become a mandatory requirement for all surgical residents in the United States who wish to become certified by the American Board of Surgery.

Laparoscopy begins with the safe creation of a pneumoperitoneum, often a difficult step in the bariatric patient. We have found the use of a tracheostomy hook inserted through a trocar-sized incision to elevate the fascia in the left subcostal region to be of great assistance in facilitating the insertion of a Veress needle into an appropriate location for pneumoperitoneum creation. In general, the use of a Hasson approach for creating a pneumoperitoneum in the bariatric population is problematic because of the thick body wall. In the patient with an extremely thick body wall, extra long trocar ports can be used for laparoscopic surgery.

The pneumoperitoneum pressure that is used when performing bariatric surgical procedures is generally in the 15- to 18-mmHg range. A high-flow insufflator is mandatory to maintain the pneumoperitoneum for adequate and safe visualization. Use of an angled telescope is quite helpful. Instrumentation for performing laparoscopic bariatric surgery has dramatically improved in the past 15 years and continues to improve. We now favor using certain laparoscopic instruments, such as the staplers and Harmonic scalpel ultrasonic cutting and coagulating device, even if conversion to an open approach is necessary.

Conversion to an open incision is appropriate in circumstances in which patient safety would potentially be compromised by persisting with a laparoscopic approach. Table 27-6 lists appropriate reasons for conversion to an open incision as well as certain conditions that, if known beforehand, are grounds for beginning with open surgery, such as an existing large upper abdominal incisional hernia or known severe intra-abdominal adhesions. Conversion to an open incision should not be viewed as a failure by the surgeon, nor should such an attitude bias the surgeon in favor of persisting with a laparoscopic approach if the operation is not progressing or if a complication is worsening when it could be corrected more quickly using an open approach. Patient safety is the gold standard for determining the timing and appropriateness of conversion. Usually, if conversion is needed, it is best to do so as early in the course of the operation as possible.

Table 27-6 Indications for Conversion from Laparoscopic to Open Surgery

1. Failure to establish an adequate pneumoperitoneum
2. Hemodynamic adverse reaction to pneumoperitoneum
3. Intra-abdominal adhesions precluding safe access or presenting excessive difficulty in accessing abdomen
4. Hepatomegaly such that retraction is not feasible or organ visualization is obscured even with retraction
5. Intraoperative complications such as hemorrhage that are best managed with an open approach
6. Exceedingly thick body wall precluding adequate trocar access or manipulation
7. Existing large upper abdominal wall hernia that optimally can be repaired at the same time using the same incision

Some bariatric surgeons have adopted a hand-assisted approach to performing bariatric surgery. In some cases this technique has been used as a bridge when a surgeon experienced at performing open surgery is transitioning to performing laparoscopic bariatric surgery.⁴² Most bariatric surgeons have found the discomfort of the thick abdominal wall on the forearm of the operating surgeon, the potential for infections and incisional hernias at the hand port site, and the lack of superiority in results compared with those of a total laparoscopic approach to be reasons not to use this approach routinely.

Postoperative Follow-Up

Short-term follow-up is defined as follow-up of up to 2 years. Such follow-up is expected of most if not all of one's bariatric surgical patients. Unfortunately, even in the best of practices in the United States, because of the lack of a centralized health system or registry, 1-year follow-up of 90% or greater is a laudable achievement and is rarely reported in most case series. Recommendations for bariatric centers wishing to be centers of excellence are that 75% of patients be followed for 5 years after restrictive operations and 90% after malabsorptive operations. Those recommendations, however, assume the presence of a system that attempts maximum possible follow-up and therefore should be able to produce such results. Although a system may be in place that generates multiple attempts to have the patient return for postoperative checkups, without patient compliance all such systems are fallible.

The goals of short-term follow-up are to maximize care of the patient in the postoperative period; assist the patient in adjusting to new eating, exercise, and lifestyle patterns; provide early identification of postoperative complications; and recommend measures to limit such complications. Objective data that should be obtained after all bariatric operations include weight loss, change in BMI, resolution or improvement in medical comorbidities, and any adverse events or complications that occur. Optimally, a measure of quality of life, such as the Short Form-36 General Health Survey questionnaire, is also used to help gauge efficacy. Short-term follow-up data give a good reflection of the safety of the procedure, but they provide only an estimate of its efficacy with regard to weight loss and effect on the resolution of medical comorbidities.

Medium-term follow-up, defined as follow-up for 2 to 5 years, and long-term follow-up, defined as that for >5 years, are the only means by which the true long-term efficacy of bariatric surgical operations can be assessed. Operations that initially appeared quite promising, such as VBG or even jejunoileal bypass, were shown with long- and medium-length follow-up, respectively, to have significant deficiencies in efficacy (for the VBG¹⁶) and safety (for the jejunoileal bypass²⁰). Other stapled gastroplasty procedures similarly did not demonstrate efficacy on medium-term follow-up.¹⁸

Unfortunately, to date there has been no standardized method of reporting outcomes after bariatric surgery. The ideal publication includes the number of patients; description of the operative technique; rate of conversion to an open procedure if applicable; number of patients included in follow-up data per year; percentage of patients lost to follow-up; weight loss (usually expressed as percentage of excess weight); initial and subsequent BMI; information on complications, mortality, and resolution of medical comorbidities; and any quality-of-life data. Not all publications have included all these elements. There are also only a few studies that have conducted a prospective randomized comparison either between bariatric surgery and medical management or between different bariatric surgical operations or approaches (e.g., laparoscopic vs. open). Improvement in study design and reporting of more complete data in future publications is needed.

Postoperative follow-up for the various operations to be described later has some common overall themes. These include an initial visit soon after surgery to determine wound healing, tolerance of oral intake, adjustment to the operation, and return to activity, and to confirm the postoperative nutrition and exercise plan. Periodic follow-up is indicated for all procedures, with the goal of documenting the previously listed items for optimal outcomes reporting. A multidisciplinary team approach is as essential postoperatively for follow-up as it was preoperatively, if not more so. Regular counseling sessions with the nutritionist are indicated for at least the first year after surgery. Psychologic support should be available as needed to assist the patient in adjusting to major life changes. Patient-oriented support groups can add significant value to preparation for surgery and adjustment afterward. Geographic proximity to the hospital improves patients' ability to attend such sessions.

Our combined experience of several decades in performing bariatric surgery has led us to conclude that *regardless of what operation is performed, patients can achieve long-term success if they embrace the eating and lifestyle changes that the operation allows them to adopt*. Continuation of exercise as part of the daily lifestyle is associated with a high rate of preservation of weight loss. Diligence to avoid snacking and returning to other poor eating habits is also important. The majority of patients do embrace the metamorphosis that their bariatric operation produces so that they maintain their new eating, lifestyle, and exercise habits to the benefit of their continued improved health, self-image, and well-being. Whether the patient achieves this behavior pattern is, in the opinion of one of us (BS), the main factor that determines the appropriateness of considering any revisional or additional surgery in response to weight gain.

Laparoscopic Adjustable Gastric Banding

BACKGROUND

Laparoscopic adjustable gastric banding (LAGB) involves placement of an inflatable silicone band around the proximal stomach. The band is attached to a reservoir system that allows adjustment of the tightness of the band. This reservoir system is accessed through a subcutaneously placed port, similar in concept to the ports used for chemotherapy via central venous catheters. Figure 27-2 shows the LAGB apparatus in place.

Two major types of bands have been used for this procedure. The original Lap-Band Adjustable Gastric Banding System, most recently marketed by Allergan, has been used most frequently. The Swedish adjustable gastric band, now remarketed as the Realize Adjustable Gastric Band by Ethicon, is slightly wider than the Lap-Band.⁴³ The two both work with a port system, but the ports have differences in profile and method of attachment to the fascia.

TECHNIQUE

Port placement for LAGB has varied among surgeons. Usually some combination of two ports for the surgeon's hands, one or two for the assistant, a port for the telescope, and a liver retractor site are needed.

With the patient placed in reverse Trendelenburg's position, the procedure begins with division of the peritoneum at the angle of His, then division of the gastrohepatic ligament in its avascular area (the pars flaccida) to expose the base of the right crus of the diaphragm. If a hiatal hernia is present, it must be repaired at this point, and a standard posterior esophageal dissection is used to expose the crura and perform suture repair. A grasper (Lap-Band) or specially devised instrument (Realize band) is inserted along the base of the anterior surface of the diaphragmatic crura, from right to left, emerging at the angle of His in the area of the divided peritoneum (Fig. 27-3). The device is then used to pull the band underneath the posterior surface of the gastroesophageal junction. Use of this technique, in which the band is passed through some fibrous tissue in this plane, serves to anchor the band more securely posteriorly. During the initial years of band placement, a retrogastric location of the posterior half of the band in the free space of the lesser sac caused an unacceptably high incidence of slippage and prolapse of the band. The adoption of the pars flaccida technique decreased the incidence of such slippage.⁴⁴

Once the band is passed around the proximal stomach, it is locked into its ring configuration through its own self-locking mechanism. This involves passing the tubing end through the orifice of the buckle for the Lap-Band, and passing through the suture on the end of the flanged end of the band site for the Realize band. Once the band is securely locked in place, the buckle portion of the band is located on the lesser curvature of the stomach (Fig. 27-4A and 27-4B). Now the anterior surface of the fundus and proximal stomach is imbricated over the band using several sutures (Fig. 27-5).

Stomach imbricated over band.

The tubing of the band system is brought out through the desired site for placement of the port portion of the system. Usually this is a trocar site near the upper abdomen or xiphoid region to allow placement of the port most superficially so that it can be palpated postoperatively. The port is secured to the anterior abdominal wall fascia. Access to the port for subsequent addition of fluid to the band system is gained percutaneously using a Huber or noncutting-type needle. The band is initially placed in the fully deflated state.

PATIENT SELECTION AND PREPARATION

Most LAGB procedures are done on an outpatient basis. Technically the operation is not as difficult as the other operations described later. Because the GI tract is not violated, the relative risk of the procedure is lower than that of most other bariatric operations, which makes this procedure more suitable to offer to older, more medically ill, or higher-risk patient populations. However, efficacy of the operation in the superobese (BMI $>50 \text{ kg/m}^2$) is less impressive, with average BMI remaining $>40 \text{ kg/m}^2$ after 5- to 8-year follow-up.⁴⁵ It has been our impression that optimal results occur with this operation in patients who are motivated, need to lose $<50 \text{ kg}$ to achieve a BMI of $<30 \text{ kg/m}^2$, are willing and able to exercise regularly, are amenable to changing eating patterns as recommended, and live within a geographic area close enough for easy follow-up. Patients who are impatient to lose weight, are immobile, are unable to exercise, are confirmed "grazers" or nibblers on high-calorie sweets, and expect to be able to continue their dietary habits without great alteration are not good candidates for this operation. Similarly, patients who have had previous upper gastric surgery, such as a Nissen fundoplication, are relatively poor candidates for LAGB due to the potential tissue compromise in taking down the wrap to place the band.

Important points of preoperative preparation specific to the procedure include placing the patient on nil per os status, providing appropriate venous thromboembolism prophylaxis preoperatively, administering appropriate broad-spectrum IV antibiotics, and ensuring appropriate IV access and monitoring. A Foley catheter is inserted into the bladder and an orogastric tube into the stomach. These preoperative measures are indicated for all the procedures described later as well.

POSTOPERATIVE CARE AND FOLLOW-UP

As noted earlier, the majority of LAGB procedures are performed on an outpatient basis. Insurance requirements and pre-existing medical issues are usually the only reason for overnight hospitalization. Instructions regarding diet, wound care, pain medications, and the time schedule for resuming preoperative medications should be explained to the patient as well as to a family member (who has not just undergone general anesthesia) before discharge. In addition, arrangements should be made for a postoperative follow-up visit, and phone numbers to call in emergencies should be provided, along with an explanation of the indications that should prompt such calls.

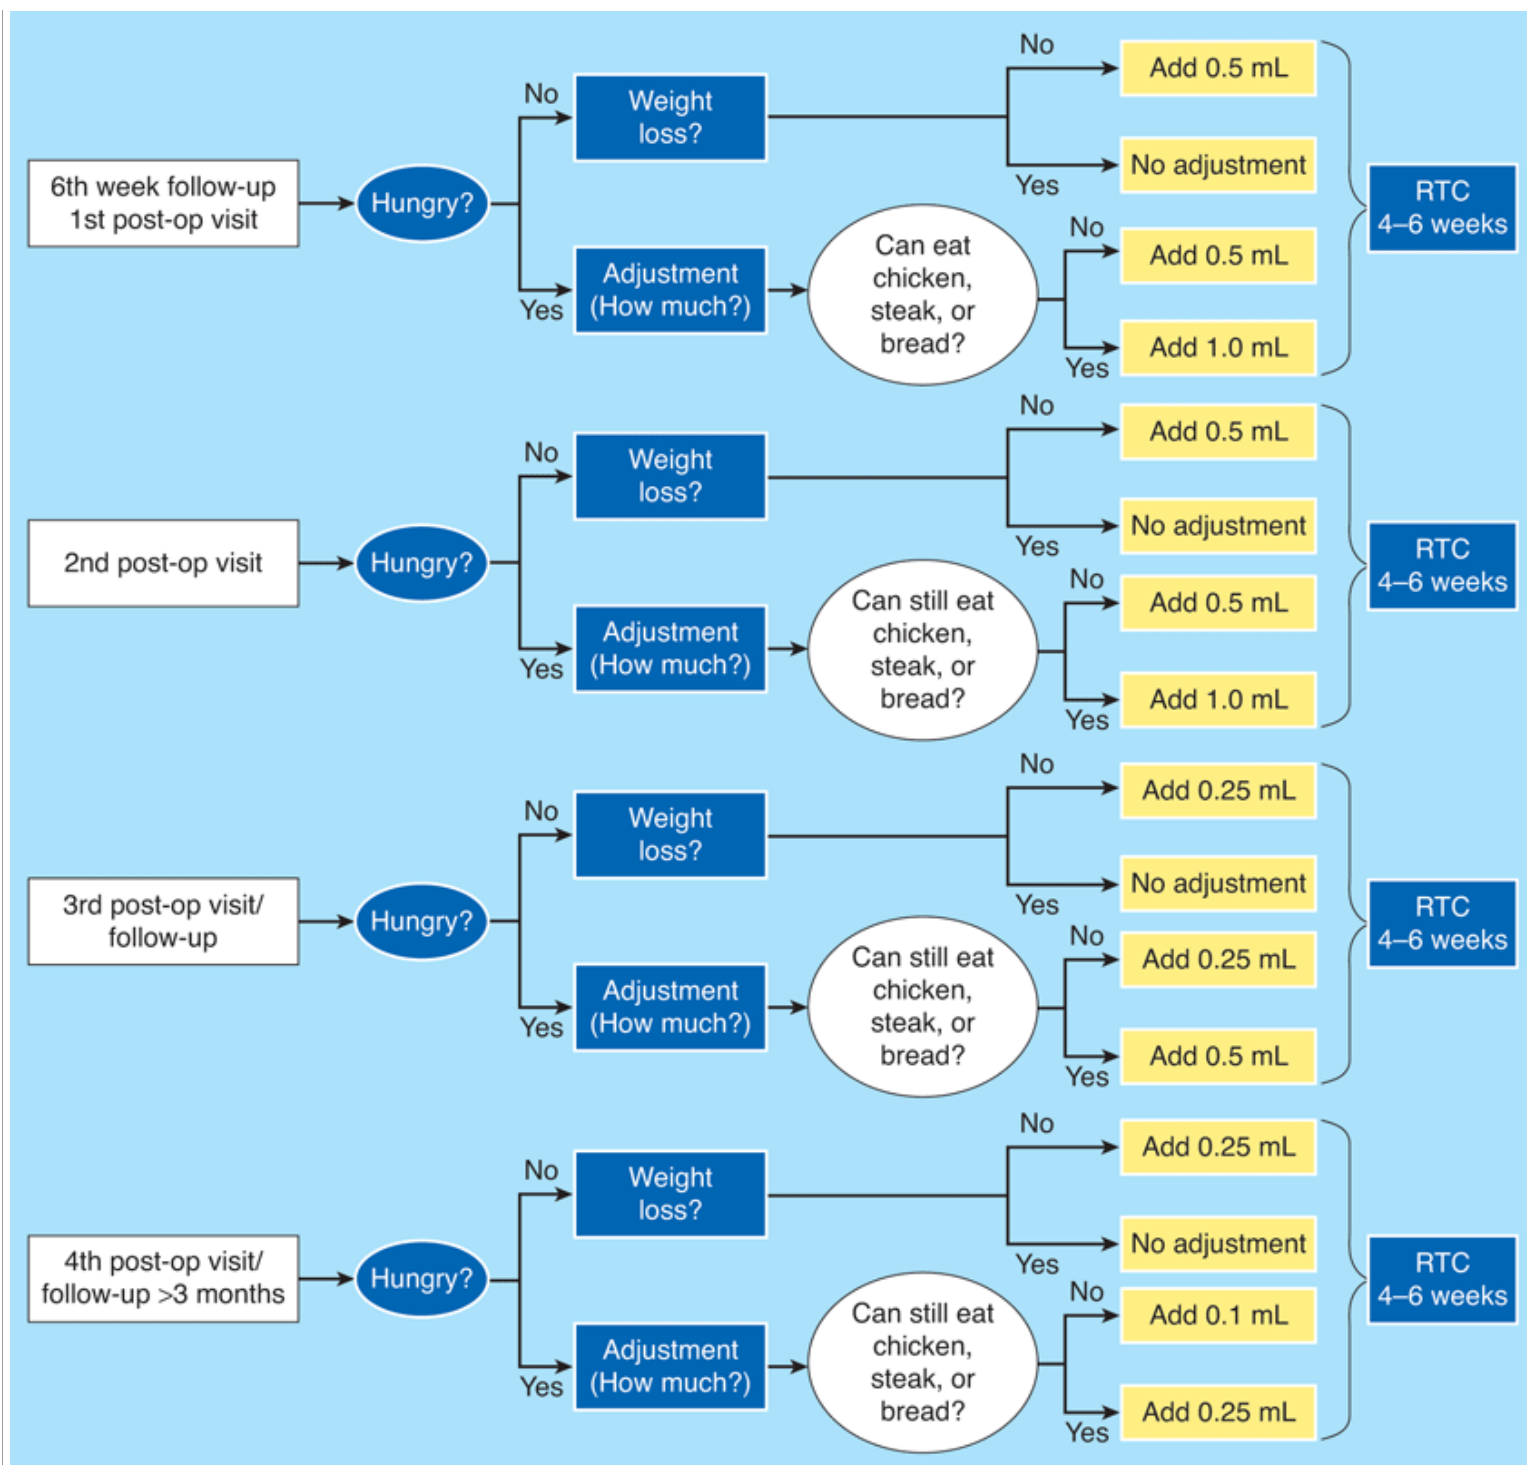

We usually see our LAGB patients 2 weeks after surgery. By this time they have begun to tire of the blenderized diet recommended, are often eager to return to work if they have not already done so, and are amenable to discussions of an exercise plan and diet progression.

plan. Wounds are assessed, as are medical problems, oral intake, and adherence to the prescribed diet. Because LAGB does not preclude absorption of any specific nutrients, we recommend only a multivitamin for patients whose preoperative laboratory results were normal. We have not routinely recommended ursodiol (300 mg bid) for gallstone prophylaxis, because weight loss often does not occur as rapidly after LAGB as after gastric bypass, and data regarding gallstone formation after LAGB are lacking. However, many surgeons do recommend gallstone prophylaxis after LAGB.

Band adjustments and postoperative support group sessions are extremely important for good outcomes after LAGB. Band adjustments are paramount as part of the operation. The actual performance of the LAGB procedure is really just one part of the care of the patient. Frequent postoperative visits, band adjustments as necessary, and participation in an appropriate exercise program are all important for postoperative success for these patients. Recommendations for the timing of band adjustments vary from practice to practice. In general, there is agreement that losing <2 lb/wk is an indication to increase the restriction of the band by adding fluid. Patients who can easily eat most solid foods and have little satiety and a fairly pronounced appetite need additional restriction from the band.

Band fills usually are accomplished in the outpatient clinic setting. Occasionally fluoroscopic radiology is needed to assist in accessing the port, based on the depth of the port from the skin and its ease of palpation. Experience by the person doing the band fill is an important factor in increasing the percentage of patients whose ports can be accessed in the clinic without radiologic assistance. A careful record should be maintained of the amount of fluid in each patient's band. Some surgeons withdraw all the fluid at each fill, reinserting the desired amount. Many just add additional fluid as indicated. The amount of fluid added is based on hunger, weight loss, and ability to eat meat or bread. Figure 27-6 shows an in office algorithm adjustment scheme used by Ren.⁴⁶ Ideally, adjustments are performed over an approximately 2-year period after surgery.

Algorithm for postoperative band adjustment. RTC = return to clinic. The band capacity for this algorithm was 5.0 ml. New bands have larger capacities, and the recommended adjustment amounts should be altered proportionately according to the increased band capacity.

[Reproduced with permission from Ren CJ: Laparoscopic adjustable gastric banding: Postoperative management and nutritional evaluation, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 200.]

An optimal situation for LAGB success is a program in which patients all live within an easy drive of the center, will and do participate in frequently available support groups and use exercise facilities supplied by the program, have access to band adjustment visits as needed, and are carefully selected for appropriateness and motivation for the procedure preoperatively.

OUTCOMES

Medium- to long-term (8-year follow-up) outcomes have been reported for LAGB by Weiner and colleagues.⁴⁷ Published studies have shown that, on average, at 5 and 7 years after LAGB patients had lost 60% and 58% of excess weight, respectively.⁴⁸ The authors point out that the weight loss curve for LAGB approaches that for RYGB after 3 years, because LAGB patients often continue to lose weight for at least 2 and often 3 years after operation, whereas gastric bypass patients lose weight the first year then tend to regain weight with the passage of time. Resolution of comorbidities after LAGB has been reported as very good overall, with hypertension resolving in 55% of patients at 1 year,⁴⁸ observed sleep apnea decreasing from 33 to 2%,⁴⁹ GERD improving in >50% of cases,⁵⁰ and asthma,⁵¹ depression,⁵² and quality of life⁵³ improving for patients after LAGB. Dixon and associates⁵⁴ published a landmark article describing the vastly superior results of LAGB over optimal medical treatment in managing patients with diabetes. Resolution of diabetes was 13% in the medical group vs. 73% in the surgical group after a 2-year follow-up.

Results of large institutional series of LAGB have been published by centers in Europe and Australia reporting excellent results for the Lap-Band.^{55,56} Similarly excellent results have been published for the Swedish adjustable band.⁵⁷ Buchwald and colleagues⁵⁸ performed a meta-analysis of all bariatric surgical papers published from 1990 to 2003. Overall mortality for LAGB was given as 0.1%. Table 27-7 shows the data from this paper for weight loss, morbidity, and mortality for LAGB compared with RYGB and the malabsorptive procedures. Table 27-8 also shows the findings of Buchwald and colleagues⁵⁸ on the percentage of resolution of four major comorbidities associated with obesity after the most common types of bariatric operations, including LAGB. Another contemporary meta-analysis shows similar outcomes for LAGB compared to other bariatric operations.⁵⁹

Table 27-7 Outcomes for Bariatric Operations			
	LAGB	RYGB	BPD/DS
Excess weight loss (%)	47.5	61.6	70.1
Mortality (%)	0.1	0.5	1.1
Morbidity (%)	10–25	13–38	27–33
Nutritional morbidity (%)	0–10	15–25	40–77

BPD/DS = biliopancreatic diversion with duodenal switch; LAGB = laparoscopic adjustable gastric banding; RYGB = Roux-en-Y gastric bypass.

Specific complications that may occur after LAGB include prolapse, slippage, erosion, and port and tubing complications. In addition, just plain failure to lose weight is more commonly seen with this procedure than with other common bariatric procedures.

Prolapse is perhaps the most common emergent complication that requires reoperation after LAGB. The incidence is generally in the 3% range. Postoperative vomiting predisposes to this problem, because the lower stomach can be pushed upward and trapped within the lumen of the band. Typical patient symptoms include immediate dysphagia, vomiting, and inability to take oral food or liquid. Either anterior or posterior prolapse may occur.⁶⁰ Reoperation laparoscopically to reduce the prolapse and resuture the band imbrication is indicated.

Slippage has been greatly reduced by the use of the pars flaccida technique and now occurs in <3% of cases in most series. Laparoscopic

reoperation to reposition the band in the optimal location is the treatment for this problem.

Band erosion is uncommon, reported in 1 to 2% of patients in most series. The patient usually becomes ill but not floridly ill, developing either a port site infection or systemic fever and signs or symptoms suggesting low-grade abdominal inflammatory sepsis. Endoscopy can be diagnostic. The presence of otherwise unexplained free air on computed tomographic scan should alert the surgeon to this diagnosis as well. Laparoscopic removal of the band is indicated, with repair of any gastric perforation. Often the perforation is already sealed by an inflammatory process, but if not, appropriate management of the gastric perforation must be undertaken.⁶⁰

Port and tubing problems occur in approximately 5% of patients undergoing LAGB. These require revision of the port and tubing system to correct perforation or kinking of the tubing or turning of the port so that access to the surface of the port for adding fluid is precluded. Usually a procedure under local anesthesia is all that is required to repair or realign the tubing or port.

The incidence of band removal because of patient dissatisfaction or lack of weight loss is difficult to assess, due to a lack of published data. The figure also is likely related to patient follow-up and may be artificially low if the patient seeks a second surgeon to remove a band. The true incidence probably varies widely, from almost zero in some practices to possibly as high as >10% in others.

An overview of the outcomes of LAGB should note the safety of the procedure. Although complications are now rare, most of them involve non-life-threatening events. Most reoperations can and are performed laparoscopically or under local anesthesia. Nutritional complications are uncommon and easily treated. Based on worldwide data, the results appear to be optimal in those practices and centers in which continued optimal follow-up and encouragement of appropriate behavioral lifestyle changes preserve the excellent weight loss enabled by such conditions. In centers in which suboptimal conditions exist for support and follow-up, the rate of band failure in terms of poor overall weight loss can be significant. Reports in the literature tend to include only those patients who still have their bands in place and to exclude patients who have had their bands removed due to failure to lose weight. Although the number of patients in the latter group probably varies widely from center to center, the trend in many European centers now to perform more LRYGB and fewer LAGB procedures than 5 years ago suggests that the outcomes for LAGB may rest as much on the postoperative support setting as on the operation itself. Centers should reassess their ability to provide such optimal follow-up and should do so if possible for the best long-term results after this operation.

Laparoscopic Roux-En-Y Gastric Bypass

BACKGROUND

The laparoscopic approach to gastric bypass (LRYGB) was first described in 1994,²⁶ but by 1998 only a few centers had accumulated any significant experience with the procedure. Many training programs were conducted in the late 1990s that enabled many surgeons to learn and adopt the laparoscopic approach. By 2001, the number of minimally invasive surgery fellowships had exploded, providing an opportunity for young surgeons to work in an apprentice-type setting for the bariatric surgeons doing laparoscopic bariatric and GI surgery. By 2003, >130,000 gastric bypasses were performed in the United States, with more than half of them being done laparoscopically.

RYGB had been done since the 1960s, and the evolution of that procedure to the current general configuration of LRYGB is described later in the discussion of open RYGB. Figure 27-7 depicts the configuration of the RYGB. The major feature of the operation is the creation of a proximal gastric pouch of small size (often <20 mL) that is totally separated from the stomach. A Roux limb of proximal jejunum is brought up and anastomosed to the pouch. The pathway of that limb can be anterior to the colon and stomach, posterior to both, or posterior to the colon and anterior to the stomach. The length of the biliopancreatic limb from the ligament of Treitz to the distal enteroenterostomy is from 20 to 50 cm, and the length of the Roux limb is 75 to 150 cm.

Fig. 27-7.

Configuration of gastric bypass.

[Reproduced with permission from Austrheim-Smith I, et al: Evolution of bariatric minimally invasive surgery, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 22.]

Although it is an oversimplification, one can say that experience has resolved several controversies about gastric bypass, whereas others are still debated. It is clear that creating the proximal gastric pouch by totally dividing it from the distal stomach is superior to open techniques of simply stapling the stomach, because the latter is associated with a high incidence of staple breakdown.⁶¹ The size of the proximal gastric pouch must be small (<20 mL) to create adequate restriction, and it should exclude the fundus of the stomach to prevent dilation over time. Longer length of the Roux limb is associated with higher short-term weight loss,⁶² but this difference becomes insignificant on long-term follow-up.⁶³ Some surgeons doing LRYGB create a longer (150-cm) Roux limb for patients with a BMI of >60 kg/m² or even >50 kg/m². Antecolic position of the Roux limb was associated with a lower incidence of internal hernias leading to obstruction in most early series.⁶⁴ However, follow-up reports suggest that the incidence of late internal hernia may increase with an antecolic approach.⁶⁵ Despite the overabundance of enthusiasm for reoperative endoscopic narrowing of the gastrojejunostomy opening,^{66,67} there are not yet any good long-term data to confirm what size of gastrojejunostomy can be related to weight loss. The gastrojejunal anastomosis can be constructed in a variety of ways. Smaller-diameter circular stapling (21 mm vs. 25 mm) is associated with a higher incidence of postoperative stenosis, and linear stapling is associated with a lower incidence of stenosis than circular stapling.^{68,69}

TECHNIQUE

The operation generally is performed using five ports plus a site for a liver retractor. Both the surgeon, who stands on the patient's right, and the first assistant, who stands on the patient's left, have two ports for instruments. The telescope requires a port, usually in the supraumbilical region. The assistant's ports are in the left subcostal and flank areas, whereas both of the surgeon's ports may be in the right upper quadrant (Cleveland approach) or one may be on each side of the camera (Virginia approach, Fig. 27-8). Division of the proximal jejunum at 40 to 50 cm distal to the ligament of Treitz is performed with the linear stapler using the white (2.8-mm) stapler

cartridge. Further division of the mesentery at that location is performed either with the stapler or the Harmonic scalpel, so that adequate mobilization of the Roux limb is achieved. A Penrose drain is sutured to the proximal Roux limb (Fig. 27-9).

Creation of the Roux limb during laparoscopic gastric bypass.

The length of the Roux limb to be created (usually 100 to 150 cm) is now measured. A jejunojejunostomy is then created to the proximal end of the biliopancreatic limb at the above-determined location along the Roux limb. A side-to-side stapled anastomosis is performed (Fig. 27-10). Either single- or double-fired staple technique (the latter using a stapler fired in each direction) is used. The stapler defect is optimally closed with sutures but can be closed with a stapler if great care is taken not to narrow the lumen of the alimentary tract at this location. Once the stapler defect is closed, the mesenteric defect is then also closed with running permanent suture.

Fig. 27-10.

Enteroenterostomy of laparoscopic Roux-en-Y gastric bypass.

Passage of the Roux limb toward the stomach is now performed. If an antecolic route is to be used, the end of the Roux limb is brought up so as to confirm its ability to reach the stomach. If a retrocolic route is to be used, a defect is made in the transverse colon mesentery just to the left and slightly above the ligament of Treitz. The Penrose drain and the proximal end of the Roux limb are placed into the retrogastric space (Fig. 27-11).

Fig. 27-11.

Passage of Roux limb.

[Reproduced with permission from Thodiyil PA, et al: Linear stapled technique for gastrojejunal anastomosis, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 266.]

The left lobe of the liver is now retracted using any one of several retractor types. The patient is moved to reverse Trendelenburg's position. The Harmonic scalpel is used to divide the peritoneum in the area of the angle of His. Then it is used to open an area along the lesser curvature of the stomach approximately 3 cm down from the gastroesophageal junction. Another approach for creating access to the lesser curvature of the stomach is to use a white or gray (2.0-mm) cartridge (vascular load) of the stapler and divide the lesser curvature vessels up to the surface of the stomach. Then a blue (3.8-mm) cartridge of the stapler is fired one time transversely from the lesser curvature side partially across the stomach; this is followed by multiple subsequent firings of the stapler upward in the direction of the angle of His to completely separate the proximal gastric pouch from the remainder of the stomach (Fig. 27-12). Use of a Ewald tube passed by the anesthesiologist and maneuvered to lie against the lesser curvature of the proximal stomach can help calibrate the pouch size.

Fig. 27-12.

Source: Brunicaardi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>

Creation of gastric pouch for laparoscopic Roux-en-Y gastric bypass.

[Reproduced with permission from Thodiyil PA, et al: Linear stapled technique for gastrojejunal anastomosis, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 266.]

Once the pouch is created, the Roux limb is brought up to the proximal gastric pouch. For the linear stapled anastomosis, the proximal end of the Roux limb is aligned with the distal gastric pouch end, and the sides of the organs are sutured together to maintain their side-by-side position. A blue stapler cartridge is introduced through a gastrotomy and an enterotomy for the two legs of the stapler, and the anastomosis is created (Fig. 27-13). The stapler defect is closed with sutures and often reinforced with a second layer of sutures. At this point the gastrojejunostomy is tested for security either by injecting methylene blue under pressure through the Ewald tube or by performing flexible upper endoscopy intraoperatively to test for air leakage from the anastomosis. The latter technique has been clearly shown to decrease the incidence and seriousness of anastomotic leaks postoperatively.⁷⁰ The final step of the operation involves suture closure of all mesenteric defects using permanent suture.

Fig. 27-13.

Gastrojejunostomy in laparoscopic Roux-en-Y gastric bypass.

[Reproduced with permission from Thodiyil PA, et al: Linear stapled technique for gastrojejunal anastomosis, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 267.]

Circular anastomosis for the gastrojejunostomy is accomplished by placing the anvil of the stapler through the anterior wall of the proximal gastric pouch. This is done either by pulling the anvil transorally via an endoscopically placed guidewire (Fig. 27-14), making a gastrotomy in the pouch that is later closed, or by creating a gastrotomy in the lower stomach before completing gastric division to form the pouch, which allows the anvil to be placed into the lumen of the stomach and then be brought through the anterior stomach in an area that is subsequently included in the proximal gastric pouch (Fig. 27-15).

A hand-sewn gastrojejunostomy is usually created using two layers of absorbable suture to anastomose an approximately 1-cm gastrotomy and enterotomy.

PATIENT SELECTION AND PREPARATION

LRYGB is an appropriate operation to consider for most patients eligible for bariatric surgery. Relative contraindications to LRYGB include previous gastric surgery, previous antireflux surgery, severe iron deficiency anemia, distal gastric or duodenal lesions that require ongoing future surveillance, and Barrett's esophagus with severe dysplasia. Contraindications to a laparoscopic approach to RYGB should cause the surgeon to choose an open RYGB or other open procedure instead.

Preoperative flexible upper endoscopy for all patients contemplating RYGB is advocated by some to rule out lesions of the stomach or duodenum noted earlier. Preoperative consumption of a low-calorie diet by patients with hepatomegaly can decrease liver size and thereby improve the chances of completing the operation laparoscopically. We use a mechanical bowel preparation to decrease bowel weight and protect against complications due to an inadvertent tear caused by the laparoscopic graspers.

POSTOPERATIVE CARE AND FOLLOW-UP

Patients undergoing LRYGB usually are hospitalized for 2 to 3 days. Major concerns on the night of surgery include adequate analgesia, adequate fluid resuscitation to provide adequate urine output, and early ambulation. We routinely perform a postoperative oral contrast study on the first postoperative day to rule out a leak. Some studies have advocated abandoning this practice due to its lack of accuracy and cost effectiveness, while others have shown that it can lead to earlier identification of leaks.^{71–73} The study's value to us has been to alert us to an early asymptomatic leak or to edema or stenosis of the enteroenterostomy or to any other obstructive pattern of the proximal bowel. Obstruction of the enteroenterostomy or beyond can result in distal gastric dilatation over a period as short as several hours, which if untreated can cause distal gastric staple line rupture with fatal consequences.

In addition to early ambulation, postoperative prophylaxis against venous thromboembolism includes use of compression devices and SC administration of low molecular weight heparin. Discharge on a blenderized diet is standard for our practice.

Diet advancement occurs after the first clinic visit, usually approximately 3 weeks after surgery. At that time an exercise plan is initiated if not already started.

Patients taking insulin for type 2 diabetes and those taking antihypertensive medications should be monitored to determine if reduction of their medication is indicated. Subsequent follow-up visits are usually scheduled for 3 months, 6 months, and 1 year after surgery, then annually after that. The focus of later postoperative visits is documentation of outcomes and testing for postoperative nutritional deficiencies.

OUTCOMES

Patients undergoing LRYGB usually lose between 60 and 80% of excess body weight during the first year after surgery. This has held true since the earliest large series of this operation was reported.⁷⁴ Resolution of comorbidities varies depending on the disease but is >90% for GERD and venous stasis ulcers, and >80% for type 2 diabetes of <5 years' duration. Hyperlipidemias are almost always improved and resolve totally in approximately 70% of cases. Hypertension is resolved in 50 to 65% of cases (Table 27-8). Even superobese patients who do not achieve an ultimate BMI of <35 kg/m² can experience significant improvements in comorbidities after LRYGB or open RYGB.⁷⁵

Mortality after LRYGB is consistently <1% in most large reported series. Recent data from centers applying to be bariatric surgery centers of excellence show a mortality of approximately 0.3% overall.⁷⁶

Overall morbidity after LRYGB has been acceptably low and in non-Veterans Administration National Surgical Quality Improvement Program centers generally is reported in the 15% range.⁷⁷ LRYGB avoids most wound and incisional hernia problems. Complications that

do occur include anastomotic leak (1 to 2% incidence), venous thromboembolism (1 to 3% incidence with a <1% incidence of pulmonary embolism), wound infections or problems (3 to 5% incidence), marginal ulcers (3 to 15% incidence), bowel obstruction (an approximately 7% incidence), need for postoperative transfusion (a 4% incidence), and anastomotic stenosis (1 to 19% incidence based on the type of anastomosis created).

Postoperative nutritional complications after LRYGB include iron deficiency in 20 to 40% of patients, iron deficiency anemia in 20%, vitamin B₁₂ deficiency in 15%, and vitamin D deficiency in at least 15%, which usually is present preoperatively.

Several complications that are specific to the LRYGB procedure must be emphasized. The most important is small-bowel obstruction. This complication must be treated differently from obstruction in the average general surgery patient, in whom it is usually caused by adhesions and often will resolve with conservative, nonoperative therapy. Patients who have undergone LRYGB who have symptoms of obstruction *require surgical therapy on an emergent basis* (see Table 27-9). This is because the cause of the bowel obstruction after LRYGB is often an internal hernia from inadequate closure or nonclosure of the mesenteric defects by the surgeon at the time of operation. Treatment for these patients therefore differs from that for most patients with small-bowel obstruction. The *single most important point* made in this chapter is to caution general surgeons to be aware of the need to operate emergently on patients who present with small-bowel obstruction after LRYGB. Currently centers that perform small-bowel transplantation are finding that the leading patient group referred for that procedure is patients who had small-bowel obstruction after LRYGB, developed infarction of most of the bowel from the internal hernia, and have short-gut syndrome. Patients for whom surgery is delayed and in whom the bowel infarcts often do not survive. When the surgeon does encounter bowel obstruction after LRYGB, he or she can expect to see proximally dilated bowel. Cutoff of passage of contrast medium on computed tomographic scan at the enteroenterostomy is particularly suggestive of this diagnosis (Fig. 27-16). If this particular problem is addressed early in the course of the obstruction, the surgical treatment can be performed laparoscopically. The surgeon must place a trocar for the telescope low enough in the abdomen to adequately survey most of the small intestine. The cecum and terminal ileum are identified, and the bowel is followed in a retrograde direction from the terminal ileum to determine the anatomy. Often much of the small bowel is herniated through a mesenteric defect, and only this technique allows the surgeon to reliably identify the bowel and decompress it appropriately. If the bowel is viable, suturing the mesenteric defect is all that is required for treatment. It should be emphasized that this complication can occur with either an antecolic or retrocolic placement of the Roux limb, because internal hernias can arise with either approach.

Table 27-9 Complications for Which Patients Undergoing Laparoscopic Roux-En-Y Gastric Bypass Require Urgent Surgical Intervention

Obstruction of passage of contrast medium at enteroenterostomy with small-bowel obstruction from internal hernia after laparoscopic Roux-en-Y gastric bypass.

Marginal ulcers are another complication relatively specific to RYGB, either LRYGB or open RYGB. The patient presents with pain in the epigastric region that is not altered by eating. Diagnosis is by endoscopy. Treatment is medical with administration of proton pump inhibitors, which are effective in 90% of cases. Only those with a gastrogastic fistula to the distal stomach or severe stenosis of the lumen of the gastrojejunostomy or non-healing ulcers require surgical therapy.

In our experience stenosis of the gastrojejunostomy has been markedly reduced by the use of a linear stapling technique.⁶⁸ Symptoms of stenosis most commonly appear between 6 and 12 weeks postoperatively but can also occur later. Diagnosis is by upper endoscopy. Treatment is balloon dilatation. Resolution normally occurs with one or two treatments. Fewer than 10% of patients require reoperation, and these are almost always patients with concurrent marginal ulcers.⁷⁸

In the immediately postoperative period, anastomotic leak is the single most feared complication after RYGB, either open or laparoscopic. Careful vigilance and a high index of suspicion for this problem is the only appropriate approach. The presentation of anastomotic leak may be insidious and the patient's demise sudden if the condition is untreated. Tachycardia, tachypnea, fever, and oliguria are the most common symptoms that arouse suspicion of this problem. The treatment is surgical except in circumstances in which a drain is already in place, no hemodynamic or clinical deterioration is present, and the leak is contained.⁷³ Surgical treatment involves oversewing and repair of the leak as feasible along with drainage. A gastrostomy tube in the diverted stomach can provide a reliable feeding access and decompression.

In the first few hours or day after surgery, hematemesis often indicates bleeding from the gastrojejunostomy unless proven otherwise. The dangers to the patient include aspiration, life-threatening hemorrhage, or, more commonly, intraluminal hematoma of the Roux limb and enteroenterostomy, which then causes an obstruction of the biliopancreatic limb leading to distal gastric staple line rupture. In fact, any obstructive symptoms in the first few weeks after surgery or any signs of obstruction of the biliopancreatic limb due to stenosis of the enteroenterostomy on postoperative swallow studies require immediate attention and possible surgical intervention to prevent rupture of the distal gastric staple line. Some reports show that percutaneous decompression of the distal stomach can ameliorate the danger. We have preferred operative therapy to decompress the stomach and treat the obstructive problem.

Overall, LRYGB has the significant advantages over open RYGB of avoiding incisional hernias and severe wound infections. Table 27-10 shows the data on these problems, comparing outcomes for laparoscopic vs. open procedures performed at the University of Virginia. Compared with other bariatric surgical procedures, the LRYGB offers a reliable and powerful operation to allow the severely obese patient to lose weight. The more reliable and greater weight loss after RYGB is accompanied by a higher rate of severe complications than with LAGB. However, recently reported data from scores of medical centers around the United States suggest that the incidence of LRYGB-

related morbidity is decreasing. RYGB is particularly effective in resolving the comorbidities of GERD and type 2 diabetes when compared with LAGB.

Table 27-10 Outcomes for Laparoscopic vs. Open Roux-En-Y Gastric Bypass, University of Virginia, 1994–2004			
Characteristics	LRYGB	ORYGB	P Value
Preoperative body mass index (kg/m ²)	50.9 ± 0.3 ^a	57.5 ± 0.5 ^a	<.001
Number of comorbidities	2.7 ± 0.1 ^a	3.6 ± 0.1 ^a	<.001
30-day mortality	2 (0.3%)	6 (1.7%)	<.02
Overall complications	111 (14.5 %)	208 (57.3%)	<.001
Reoperations	67 (8.8%)	150 (41.3%)	<.001
Incisional hernias	13 (1.7%)	123 (33.9%)	<.001
Wound infections	14 (1.8%)	27 (7.4%)	<.001

LRYGB = laparoscopic Roux-en-Y gastric bypass; ORYGB = open Roux-en-Y gastric bypass.

Open Roux-En-Y Gastric Bypass

BACKGROUND

As mentioned earlier, Mason and Itoh¹⁹ first described gastric bypass and Griffin and colleagues²⁰ described the Roux limb modification. The RYGB procedure has been the most time tested and proven of all bariatric operations. Open RYGB is now done in virtually the same manner as LRYGB, the only difference being the access route to perform it. Experienced bariatric surgeons who do not perform laparoscopic surgery still perform this operation with excellent overall outcomes.⁴⁰ Open RYGB was the most popular bariatric operation performed in the United States in the 1990s but is now far exceeded by LRYGB and LAGB in terms of volume, likely due largely to the preference of patients to undergo a laparoscopic rather than an open procedure. However, for the patient for whom a laparoscopic approach fails, open RYGB must be an operation that the bariatric surgeon can perform with skill.

TECHNIQUE

Open RYGB is performed in essentially the same way as LRYGB. Some surgeons who use an open approach prefer to create the gastric pouch as the first part of the procedure, but in essence the basic procedure is the same. Access for open RYGB is usually through an upper midline incision, although a left subcostal incision has been reported to furnish adequate access as well. Closure of the midline wound is performed using a running monofilament suture. Subcutaneous tissues are thoroughly irrigated, and the skin is closed with a skin stapler.

PATIENT SELECTION AND PREPARATION

Patient selection for open RYGB is essentially the same as for LRYGB, because the operation is the same. Extraordinarily large patients or those who have previously undergone multiple abdominal operations, particularly previous gastric surgery, left colectomy, and splenectomy, often require an open incision to perform RYGB. An especially thick abdominal wall and large liver size are other factors that may require an open incision approach. Patients who have an existing large midline incisional hernia are also candidates for an open approach.

Preparation for open RYGB is identical to that for LRYGB.

POSTOPERATIVE CARE AND FOLLOW-UP

The postoperative care of the patient undergoing open RYGB is very similar to that of the patient undergoing LRYGB. Larger volumes for fluid resuscitation and often more narcotic analgesics are required the day of surgery and frequently the next as well. Greater attention must be paid to the incision site to check for potential infection, because an inadequately treated wound infection in these patients can

extend easily to the fascial level and cause significant tissue loss before it is fully diagnosed. The perioperative care of patients undergoing open RYGB is usually more intense, often because such patients are very large and have severe comorbidities, which puts them at higher risk overall for complications of all types. It is interesting, though, that since the era of LRYGB, patients who still undergo open RYGB (usually due to intraoperative conversion) in our practice often are discharged within 1 day of the laparoscopic patients. The overall length of stay has decreased for our RYGB patients based on the use of postoperative pathways geared toward LRYGB.

Postoperative follow-up visits are similar to those for LRYGB patients, with the first visit being timed appropriately for removal of skin staples. Other visits, follow-up schedule, and blood testing are identical to those for LRYGB.

OUTCOMES

The weight loss statistics and patterns for open RYGB are comparable to those for LRYGB, as would be expected. Postoperative deaths are slightly higher with open RYGB, but this is in part due to the patient population, who are often among the most severely medically compromised preoperatively. Flum and Dellinger⁷⁹ showed that in a patient population with Medicare insurance and hence largely disabled, RYGB had an across-the-board mortality rate of 2.0%. This is considerably higher than the 0.3 to 0.4% incidence that has been reported on average the past 2 years for programs applying for qualification as bariatric centers of excellence and is due in large part to the patient population. Interestingly, in Flum and Dellinger's report, surgeons with the most experience had a patient mortality rate of <1.0% for this patient population, which suggests that surgeon experience and perhaps also patient selection by experienced surgeons influences mortality for RYGB.

One of the most important population studies showing the benefit of bariatric surgery was done in patients undergoing RYGB. Christou and colleagues⁸⁰ showed that, in a 5-year follow-up, mortality was lower among >1000 patients undergoing RYGB than among >5000 severely obese individuals who did not have surgery (0.68 vs. 6.17%). This represents a reduction of 89% in the death rate.

The incidence of postoperative complications is higher for open RYGB than for LRYGB. The major types of increased morbidity are incisional hernias and other wound-related problems. Table 27-10 presents data recently submitted for publication drawn from the Virginia experience after 10 years of follow-up. Findings included a very high incidence of incisional hernias after open RYGB as well as a lower rate of wound infections for LRYGB than for open RYGB. The marked difference in reoperation rates for the laparoscopic and open procedures was due almost exclusively to incisional hernia repairs. However, when considering these data one must keep in mind that the patients undergoing LRYGB also were smaller and had fewer comorbidities during these years. Except for the higher rate of incisional hernias, the long-term results for patients undergoing open RYGB are similar to those for patients undergoing LRYGB with regard to nutritional complications, weight loss, and overall resolution of comorbidities.

Two randomized controlled trials with 5-year follow-up have compared LRYGB with LAGB. Both demonstrate a higher rate of postoperative morbidity for RYGB compared to LAGB (21 vs. 7%) but superior weight loss for RYGB compared to LAGB (67–68 vs. 41–46% EWL). Failure to achieve significant weight greater for LAGB compared to RYGB (17-35 vs. 0-4%).^{81,82}

Biliopancreatic Diversion and Duodenal Switch

BACKGROUND

Biliopancreatic diversion (BPD) was first described by, and remains championed by, Scopinaro and colleagues in Italy.²³ The operation, which is pictured in Fig. 27-17, involves resection of the distal half to two thirds of the stomach and creation of an alimentary tract of the most distal 200 cm of ileum, which is anastomosed to the stomach. The biliopancreatic limb is anastomosed to the alimentary tract either 75 or 100 cm proximal to the ileocecal valve, depending on the protein content of the patient's diet. This operation met with limited international popularity, probably due to the technical difficulty of performing it combined with the significant percentage of nutritional complications that arise postoperatively. However, the procedure did develop a devoted following among a few bariatric surgeons.

One complication that plagued BPD was the high incidence of marginal ulcers postoperatively. Hess and colleagues⁸³ and Marceau and associates⁸⁴ separately described the adaptation of the duodenal switch (DS) operation, originally proposed by DeMeester and colleagues⁸⁵ for the treatment of bile reflux gastritis, to replace the gastric portion of the BPD. This new procedure was originally called *biliopancreatic diversion with duodenal switch*. For ease of description, the term *duodenal switch* is used to indicate this procedure. It is illustrated in Fig. 27-18. Currently BPD and DS together represent <5% of bariatric operations performed in the United States and perhaps as little as 2 to 3%. The lack of a significant number of surgeons offering the operation, especially via a laparoscopic approach, probably has a great deal to do with that statistic. BPD and DS are recognized as standard bariatric operations, however, and are approved for coverage by most insurance companies at this time.

Configuration of the duodenal switch.

[Reproduced with permission from Austrheim-Smith I, et al: Evolution of bariatric minimally invasive surgery, in Schauer PR, et al (eds): *Minimally Invasive Bariatric Surgery*, 1st ed. New York: Springer, 2007, p 22.]

TECHNIQUE

The technique for BPD is described for the open approach, but the laparoscopic approach essentially reproduces what is done with the open approach using different access. Laparoscopic BPD and DS are very technically challenging operations, which is perhaps another factor contributing to the relatively low numbers of surgeons offering these operations.

The BPD operation begins with performance of a distal subtotal gastrectomy. A residual 200-mL gastric pouch is created for superobese patients and a slightly larger pouch for patients with a BMI of $<50 \text{ kg/m}^2$. The terminal ileum is identified and divided 250 cm proximal to the ileocecal valve. The distal end of that divided ileum is then anastomosed to the stomach, creating a 2- to 3-cm stoma. The proximal end of the ileum is then anastomosed side to side to the terminal ileum approximately 100 cm proximal to the ileocecal valve. Some surgeons perform the anastomosis only 50 cm proximal to the valve, but in these patients the likelihood of good protein intake postoperatively should be high. Prophylactic cholecystectomy is performed due to the high incidence of gallstone formation with the malabsorption of bile salts.

The DS procedure differs from BPD only in the proximal gut portion of the operation. Instead of a distal gastrectomy, a resection of all the stomach except for a narrow lesser curvature tube is performed. The diameter of this tube is calibrated with a dilator and, if limited to an approximately 32F (11-mm) diameter, produces the optimal amount of weight loss while still allowing adequate oral intake. The duodenum is now divided in its first portion and an approximately 2-cm length of duodenum is left intact beyond the pylorus. This end of the duodenum is then anastomosed to the distal 250 cm of ileum. This anastomosis is often done in an end-to-end fashion with a circular stapler. It is the most difficult portion of the DS procedure, and leak rates are slightly higher than with other types of anastomosis. The distal bowel configuration and cholecystectomy are similar to those for BPD.

PATIENT SELECTION AND PREPARATION

Patients who undergo either BPD or DS must be prepared for the consequences of a malabsorptive operation. The occurrence of diarrhea after any large amount of oral intake is a given. Patients who undergo this procedure must be willing to accept that and will also usually modify their eating pattern to restrict intake if access to a bathroom will prove difficult. Patients who undergo either operation must be followed closely *by the surgeon*. Internists and family physicians may not appreciate the problems related to protein-calorie malabsorption if they occur and treat the patients instead for congestive heart failure. Results may then be disastrous. Patients must also have the financial means to afford the large number of vitamin and mineral supplements that must be taken to avoid nutritional problems in this patient population. One unofficial estimate from a surgeon who performs these procedures is that the cost of such supplements may be approximately \$1500 per year.

Given the higher incidence of postoperative nutritional and other complications compared with any of the restrictive operations, BPD and DS usually are recommended only for those patients who are superobese or for whom it is reasonable to believe that they will not succeed in meeting the diet and exercise requirements that form the basis for long-term success with restrictive operations. Patients for whom a restrictive operation has failed and who are considering reoperation are candidates for these procedures.

Contraindications to the procedure include significant geographic distance from the surgeon, lack of financial means to afford supplements, and pre-existing deficiencies of calcium, iron, or other vitamins or minerals.

POSTOPERATIVE CARE AND FOLLOW-UP

Patients undergoing BPD or DS must be followed closely and with absolute completeness for nutritional issues long term. Postoperatively, BPD and DS patients face the same potential complications as seen after RYGB. Anastomotic leaks, pulmonary compromise and complications, GI bleeding, anastomotic stenosis or obstruction, and infections are all potential concerns during the index hospitalization. The long gastric staple line and the duodenoileostomy of the DS and the duodenal stump and gastroileostomy of the BPD are all areas of anatomic concern postoperatively. Distal anastomotic problems can occur with either as well. Thorough preoperative and postoperative counseling by a nutritionist well versed in the operation and potential associated nutritional deficiencies is essential. Vitamin and mineral supplements, including oral supplements of iron, calcium, and B₁₂ and a multivitamin, must be taken regularly on follow-up. Fat-soluble vitamins must be supplemented in parenteral form. Careful monitoring of protein intake and serum albumin level is necessary. More frequent follow-up is needed than after RYGB. Checkups at 2-month intervals for the first year and semiannual or more frequent visits thereafter is an appropriate schedule.

OUTCOMES

Weight loss results after BPD or DS are both excellent and are comparable. The losses also are very durable. One 18-year follow-up of patients after BPD showed a mean excess weight loss of 70% persisting for that duration.⁸⁶

Although most of the results reported for BPD or DS are for open operations, one report of laparoscopic DS showed that for 40 patients with an average BMI of 60 kg/m² the mean hospital stay was 4 days, the average operating room time was 3.5 hours, and mean excess weight loss at 9 months was 58%.⁸⁷

Buchwald and colleagues⁵⁸ showed that the average excess weight loss after BPD and DS reported in the literature was >70%; the mortality rate was 1.1%, the complication rate was 27 to 33%, and the nutritional complication rate was 40 to 77% (see Table 27-7).

Complications that occur after BPD include those seen after RYGB, in which intestinal anastomoses and gastric division create potential problems. Scopinaro and associates⁸⁶ reported complication rates of 1.2% for obstruction, a similar rate for wound infections, and 2.8% for marginal ulcers. However, others found the incidence of marginal ulcers to be higher after BPD, which led to the adoption of the DS procedure. Preservation of the pylorus drastically reduces the incidence of significant dumping after BPD (poorly quantitated in most series). The duodenoileostomy of DS also is associated with a very low rate of stomal ulcer, unlike the gastroileostomy of BPD.

Nutritional complications are by far the most frequent and worrisome after both these operations, particularly on long-term follow-up. Scopinaro and colleagues⁸⁶ reported a protein malnutrition rate of 7%, an iron deficiency anemia rate of <5%, and a bone

demineralization rate at 5 years of 53%. Other problems that may arise include alopecia from inadequate protein absorption, night blindness from a lack of vitamin A, and gallstones if the gallbladder is not removed. Of all these nutritional complications, however, protein-calorie malnutrition is the most severe and life-threatening. When it is diagnosed, the treatment is parenteral nutrition. The occurrence of two episodes in which parenteral nutrition is required is usually considered an adequate indication to lengthen the common channel of ileum—the section of ileum between the ileoileostomy connecting the biliopancreatic limb to the alimentary tract and the ileocecal valve. The amount by which the surgeon should lengthen the common channel is poorly documented, but most surgeons will lean toward making it long enough to be certain to avoid recurrence of the problem, such as doubling the length of the common channel, even if it decreases weight loss somewhat.

It cannot be emphasized enough that patients who undergo either BPD or DS must be compliant with the required regimen and understand that lifetime nutritional supplementation and lifetime follow-up are essential to the preservation of good health after one of these operations.

Sleeve Gastrectomy

BACKGROUND

Sleeve gastrectomy (SG) was originally conceived by Gagner's group after they reviewed their results with laparoscopic DS procedures.⁸⁵ Because candidates for DS tended to be superobese and often had significant risk factors for surgery, it was not surprising that a somewhat high mortality rate was seen in this series. Demonstrating that mortality was confined to the patients at very high risk, Gagner recommended doing the procedure in two stages for these patients. The gastric resection, for which the term *sleeve gastrectomy* was coined, was performed as an initial stand-alone procedure for high-risk patients. These patients then underwent the remainder of the DS procedure after they had lost significant amounts of weight from the SG. Mortality was decreased with this two-step operation.⁸⁸

Other surgeons subsequently began to use SG as a primary weight loss operation. Insurance approval was problematic, because until recently few insurance companies would reimburse for this operation unless it was part of a staged DS procedure. Reports in the literature of the success and excellent weight loss after SG have been accumulating for the past few years.^{89,90} One recent report described 750 patients who underwent SG as a primary weight loss procedure.⁹¹

The American Society of Metabolic and Bariatric Surgery recently officially recommended that SG be used in selected patients for whom the results of other weight loss operations were not superior or as part of a staged DS procedure. It thus recognized SG as a standard weight loss operation.

TECHNIQUE

SG is performed laparoscopically under most circumstances, although the word *laparoscopic* is omitted from its description in this chapter. It is assumed that this is the approach. Placement of surgical team members is similar to that for LRYGB. Port placement is comparable or altered slightly to improve the angle of placement of the stapler along the lesser curvature of the stomach. Once a liver retractor is placed, the operation begins with passage by the anesthesiologist of a 32F bougie. The bougie is aligned along the lesser curvature of the stomach and used to size the sleeve pouch. Alternatively, some surgeons use an endoscope (approximately 30F) instead of a bougie to size the sleeve. The surgeon begins the gastric resection by dividing the vessels along the greater curvature of the stomach using the Harmonic scalpel. Division is begun 2 to 3 cm proximal to the pylorus and continued to the angle of His. Clips may be used to additionally secure named vessels. Once the greater curvature of the stomach is completely devascularized, gastric division begins. The stomach is divided approximately 2 to 3 cm proximal to the pylorus starting on the greater curvature side. The stapler is initially equipped with a green (4.5-mm) staple cartridge due to the thickness of the stomach wall in this location. The stapler is fired repeatedly toward the angle of His; after the first or second firing it is placed directly adjacent to the dilator along the lesser curvature to limit sleeve diameter (Fig. 27-19). This spacing continues all the way up the stomach to the angle of His. The specimen is removed in a bag, and the staple line is checked for integrity and hemostasis. Figure 27-20 shows the completed operation.

PATIENT SELECTION AND PREPARATION

Patients undergoing SG tend to fall into two groups. One group is high-risk superobese patients considering eventually undergoing the second procedure to complete the DS operation. The other group is patients who have a BMI of $<50 \text{ kg/m}^2$ and have decided that they prefer the SG operation. Reasons usually include surgeon preference and recommendation, the presence of gastric lesions that require monitoring and have potential consequences (adenomatous polyps), or a desire to undergo a relatively simple restrictive operation not requiring the placement of a foreign body. Preoperative preparation is similar to that for LRYGB. Bowel preparation is not needed, however. Whether or not preoperative upper endoscopy should routinely be performed has yet to be determined.

POSTOPERATIVE CARE AND FOLLOW-UP

SG usually is performed with an overnight stay after surgery. Longer hospitalizations are indicated for patients with more severe medical problems. Absence of signs of bleeding and a documented intact staple line with good gastric emptying are required before discharge. Routine meglumine diatrizoate (Gastrografin) swallow on the first day after surgery is ordered by many surgeons, but its efficacy and cost effectiveness have yet to be documented. Follow-up is similar to that after LRYGB. Few nutritional complications occur unless the patient has difficulty taking in enough nutrients or protein or vitamins due to edema or tightness of the sleeve lumen. Multivitamins are usually prescribed to avert any other potential shortages from dietary vagaries.

OUTCOMES

SG results in excellent short-term weight loss. Depending on body size, weight loss is in the range of 45–50% of excess weight for patients with a BMI of $>60 \text{ kg/m}^2$, but for patients with a BMI of 35 to 50 kg/m^2 with a 32F pouch size, excess weight loss at 3 years was recently reported as being 60%.⁹¹ A report of >1000 operations by this same center described a hospital stay averaging 1.7 days, an operative time <80 minutes, and no conversions to open procedures or mortality. The rate of severe complications was $<5\%$. A recent

systematic review by Brethauer and colleagues of sleeve gastrectomy outcomes involving over 2500 patients (mean BMI = 51.2 kg/m²) with up to 5-year follow-up demonstrated a mean excess weight loss of approximately 55%, a complication rate of approximately 8%, and mortality rate of 0.19%. In half of these studies, SG was used as a staging procedure for high BMI, high-risk patients while in the remainder it was used as a primary procedure.¹⁵

Sleeve gastrectomy is becoming a more commonly accepted bariatric operation either as a staging operation or a stand-alone procedure.

SPECIAL ISSUES RELATING TO THE BARIATRIC PATIENT

Bariatric Procedures in the Adolescent and the Elderly Patient

The incidence of obesity in the U.S. population has risen dramatically during the past 2 decades. This increase has been seen in children and adolescents as well. The incidence of obesity (BMI >30 kg/m²) is estimated to exceed 25% in the adolescent population. Factors felt to contribute to the rise of obesity among adolescents include decreased participation in physical sports and activities, increased time spent playing computer and screen games, and increased consumption of fast food and processed foods.

Obese adolescents have a high likelihood of being obese adults. In one study 75% of adolescents above the 85th percentile for weight were obese as adults.⁹² The social stigmatization of the severely obese adolescent is often brutal. Comorbid medical problems, including hypertension and type 2 diabetes, may already be present in severely obese adolescents. The overwhelming likelihood that a severely obese adolescent will face a lifetime of severe obesity as an adult also implies that an average of 12 years of life for males and 9 years of life for females will be lost due to this medical problem.

The major controversies with regard to performing bariatric surgery in adolescents include the general aversion to subjecting an adolescent to surgery as well as concern about the secondary side effects of bariatric surgery on remaining growth and development. Clearly, the younger the patient, the more relevant the latter concern becomes.

The literature to date regarding the outcomes of bariatric surgery in adolescents is generally quite favorable. However, the data are still limited. Sugerman and colleagues⁹³ reported results for 33 adolescents, 30 of whom underwent RYGB. There were two late deaths at 2 and 6 years of follow-up unrelated to surgery. Complications both early and late numbered 20, including six incisional hernias and five wound infections. Significant weight loss was maintained in the majority of patients for up to 14 years after surgery. Most comorbidities resolved at 1 year after surgery. Self-image was greatly enhanced and social stigmatization greatly decreased. Capella and Capella⁹⁴ reported on 19 adolescent patients treated using a modified version of RYGB in which a vertical band was added to the pouch. After an average of 5.5 years of follow-up, average BMI for the group was 28 kg/m². No deaths occurred, but two patients required revisional surgery. No mortality or morbidity was reported, and all comorbidities resolved. Abu-Abeid and colleagues⁹⁵ treated 11 adolescents with LAGB. No late complications occurred, and after a 4-year follow-up average BMI went from 46.4 to 32.1 kg/m².

The elderly patient population certainly includes those with severe obesity. However, data on the effect of conservative therapies in treating this patient population are lacking. Similarly, it is likely that a patient who becomes obese late in life has a significantly different prognosis from that of an individual who has been severely obese for many years and manages to survive to an older age despite the resulting comorbidities.

There has been an increasing tendency to offer bariatric surgery to patients >60 years of age. Studies have documented that this patient population can enjoy the same good outcomes and resolution of comorbidities as younger patients.⁹⁶ Nehoda and associates⁹⁷ reported equally excellent results for LAGB in patients >50 years of age and those <50 years of age. Excess weight loss of 68%, a reoperation rate of 10%, and a 97% rate of improvement in comorbidities were reported for this age group (>50 years).

Although these data show that in selected older patients excellent results can be obtained, surgeons must be careful to determine which patients have been severely obese for decades and therefore have essentially end-stage organ function in many cases as a result of the comorbid medical conditions that have been present for those years. Flum and Dellinger⁷⁹ showed that the older patient population, especially those few patients >70 years undergoing bariatric surgery, did have an increased incidence of mortality and morbidity after RYGB.

The concept that bariatric surgery confers to patients receiving it an improved quality of life, a longer life, and a life without as many associated medical problems leads to the logical conclusion that the benefits of the operation will be more fully realized the younger the patient. In view of the large number of unserved patients, this philosophy does justify setting age limits for individual surgical practices. Although we do have such age limits, patients near or just over the age limit are often evaluated on an individual basis to determine their appropriateness for surgery. Accumulation of data may also change these limits in the future.

Bariatric Procedures in the Female Patient: Pregnancy and Gynecologic Issues

Hormonal levels in female patients are related to body weight. Obesity alters the levels of estrogen and progesterone available for normal ovulation, which results in abnormal ovulation patterns, amenorrhea, and difficulty conceiving. Should an obese woman become pregnant, the increased chances of gestational diabetes and hypertension make the pregnancy high risk. Macrosomia is increased. There is a twofold to threefold increase in the rate of cesarean sections, with more complications. Fetal mortality does not appear to be changed when maternal weight gain is limited.⁹⁸ With obesity, there is an increased risk for breast and endometrial cancer in the postpartum mother.

Infertility compounds the difficulties of the obese woman who wishes to have an uncomplicated pregnancy and delivery. The same hormonal alterations that cause an increased incidence of cancer, such as increased circulating estrogen levels, also cause infertility. If a severely obese woman becomes pregnant, pregnancy management is made more difficult by the body habitus and the need for more frequent ultrasound imaging as opposed to physical examination, which yields limited information.

Women who become pregnant soon after undergoing bariatric surgery can be at risk due to the ongoing weight loss produced by the operation. However, if the pregnancy is quickly recognized and appropriately managed, patients who have undergone bariatric surgery may actually have a better prognosis than if they had not had surgery. Wittgrove and colleagues⁹⁹ showed that patients who had undergone RYGB had a lower incidence of diabetes, macrosomia, and cesarean section than those who had not had surgery. Iron replacement, though, was cited as a critical need for these pregnant women. Despite these good results, there are issues for the female patient undergoing RYGB who becomes pregnant during the rapid weight loss phase after surgery. Special attention is needed to ensure adequate intake of vitamins and essential nutrients during what otherwise would be a period of rapid weight loss. In our practice, patients undergoing RYGB are cautioned to practice strict birth control during the first year after surgery to avoid becoming pregnant.

Patients who become pregnant after LAGB would seem to have even less likelihood of significant risk to their pregnancy, because the band can be adjusted to allow more food intake during the pregnancy but also limit weight gain to a healthy amount. Dixon and associates¹⁰⁰ wrote that morbidly obese women do have higher risks during pregnancy but that LAGB allows weight loss which reduces such risk. The adjustability of the band makes this an ideal operation for the woman planning to become pregnant.

Weight loss after bariatric surgery can correct the gynecologic problems that occur at high incidence in women with severe obesity. Deitel and associates¹⁰¹ found menstrual irregularities in >40% of patients preoperatively, but menstruation became normal in >95% of patients postoperatively. Infertility problems were present preoperatively in 29% of patients, and medical problems were frequent during previous pregnancies, including hypertension in 26.7%, pre-eclampsia in 12.8%, diabetes in 7%, and deep vein thrombosis in 7%. These problems were virtually eliminated after weight loss. The rate of stress urinary incontinence in the female patients in that study decreased from 61.2% before surgery to 11.6% after bariatric surgery.

Polycystic ovary syndrome is another common hormonal dysfunction associated with severe obesity. It is characterized by infertility, hyperandrogenism, dyslipidemia, anovulation, insulin resistance, and abnormal menses as well as obesity.¹⁰²

Stress urinary incontinence is a frequent problem in the severely obese woman and must be specifically solicited in history taking. The increased intra-abdominal pressure from severe obesity contributes to the high incidence of this problem in the severely obese population. Obesity may also alter the neuromuscular function of the genitourinary tract, contributing to incontinence. Studies have confirmed the increased incidence of obesity in patients with both true stress incontinence and detrusor instability.¹⁰³ Weight loss alone relieves symptoms in many patients with obesity, but if symptoms persist, surgical therapy is still effective for this problem even in the obese patient.

Metabolic Surgery

Probably the single most prominent change in the field of bariatric surgery since the last version of this text is the increased emphasis on and attention to the metabolic aspects of surgery for weight loss. As noted earlier, the obvious indication of this emphasis is the changing of the name of the American Society for Bariatric Surgery to the American Society for Metabolic and Bariatric Surgery, effective as of June 2007. International meetings on the topic of bariatric surgery and its effects on diabetes have been convened during the last few years as well. The entire field of bariatric surgery is now much more focused on the metabolic effects and benefits of bariatric surgery.

Although many comorbidities are improved by bariatric surgery and the resultant weight loss, the metabolic diseases that are most particularly affected are type 2 diabetes, the hyperlipidemias, and the metabolic syndrome. Hypertension and cardiovascular disease are also improved indirectly through metabolic benefits as well as directly through weight loss effects.

TYPE 2 DIABETES

There has been a dramatic increase in the potential application of surgical therapy to treat type 2 diabetes. Much of this stems from the original observations of surgeons performing RYGB that patients who had undergone the operation showed improvement or near resolution of type 2 diabetes well before they had achieved maximum weight loss. Hickey and colleagues¹⁰⁴ highlighted these observations in a landmark paper which confirmed that RYGB was an effective treatment for type 2 diabetes, resolving the condition in 85% of patients who had developed it within the 5 years before surgery. MacDonald and associates,¹⁰⁵ also from the same institution, showed that the use of RYGB to treat patients with type 2 diabetes resulted in a longer life span. Schauer and colleagues¹⁰⁶ showed that the improvement in type 2 diabetes after LRYGB is comparable to that seen in Pories's original work, with fasting insulin levels and glycosylated hemoglobin levels returning to normal values in 83% and improving markedly in 17%.¹⁰⁶ RYGB has been shown to decrease overall long-term mortality related to diabetes in several large population studies.^{107,108}

These results, as well as the observation that type 2 diabetes resolved quickly after RYGB, led to the general belief that the enteric hormonal component of glucose metabolism has an important influence on the disease. Rubino and Marescaux¹⁰⁹ reported the resolution of diabetes in an obese rat model with surgical diversion of the food stream from the duodenum and proximal jejunum. Reversal of the operation led to return of the disease state. The extension of Rubino and Marescaux's findings to humans has now occurred: A duodenojejunal exclusion operation has now been performed and has shown initial safety and efficacy in a small group of patients.¹¹⁰ Although the majority of patients who have type 2 diabetes are obese, approximately 10% of patients with this disease are not obese, and these data from South America may confirm that the resolution of the disease through enteric diversion is not based on associated weight loss.¹¹¹

Surgical therapy that produces weight loss without diversion of the enteric stream also can be quite effective in resolving type 2 diabetes. Dixon and associates⁵⁴ reported that 73% of patients who underwent LAGB and were followed for 2 years experienced resolution of their type 2 diabetes, compared with only 13% in a control group of medically treated patients. An editorial accompanying the article by Dixon and associates advocated that treatment for diabetes be reshaped to include consideration of surgical therapy as an option for patients, especially severely obese patients.¹¹²

Despite these data, there has been resistance from endocrinologists and internists specializing in the medical treatment of diabetes to accept the use of surgical therapy as an optimal treatment for the disease.¹¹³ Only recently have these medical groups shown any recognition of the role of surgery in treating diabetes. However, in recent years there have been an increasing number of joint symposia and meetings between internists and basic scientists, including surgeons, on the topic of the treatment of diabetes. The first International Diabetes Surgery Summit was convened in Rome in 2007. That meeting documented the considerable benefits of surgical therapy for diabetes as well as the reluctance on the part of major groups such as the American Diabetes Association to include surgery as a common treatment option for diabetic patients. In 2009, the American Diabetes Association included bariatric surgery in their position statement on standards of medical care in diabetes. The guideline indicates that "bariatric surgery should be considered for adults with BMI ≥ 35 kg/m² and type 2 diabetes, especially if the diabetes is difficult to control with lifestyle and pharmacologic therapy."¹¹⁴

That surgical therapy is the single best treatment to resolve type 2 diabetes in 80% of severely obese patients who have it is a powerful

fact that one would think would cause a rapid adoption of this treatment. Reasons for its slow penetration may include the stigma associated with obesity and obesity surgery. Obesity currently remains one of the last unaddressed areas of discrimination within society. It must be inferred that some of the bias against obesity is due to the slow acceptance of obesity surgery as a treatment for the diseases common to obesity. The bariatric surgery community is only now beginning to recognize that gastric bypass may best be described to the public and the insurance industry as an operation that corrects the metabolic diseases of severe obesity, such as diabetes.

METABOLIC SYNDROME

Metabolic syndrome is characterized by central obesity, glucose intolerance, dyslipidemia, and hypertension. Metabolic syndrome is a common finding in patients with severe obesity, occurring in 52% of individuals in one report.¹¹⁵ All the associated metabolic problems of metabolic syndrome respond to surgical therapy to produce weight loss. Basic scientists attribute the occurrence of this associated array of diseases to an enhanced inflammatory state in the body resulting from the increased production of cytokines by the adipocyte. These cytokines in turn produce a mild inflammatory reaction that promotes the production of these diseases.

Diabetes and pre-diabetes (fasting plasma glucose of 100–124 mg/dL) are effectively treated by both RYGB and LAGB, as discussed earlier. These operations also are effective in treating the other components of metabolic syndrome. RYGB produced a resolution of metabolic syndrome in 98% of patients 1 year after surgery.¹¹⁶

Dyslipidemias improve in >70% of patients undergoing RYGB. The rate of resolution is >90% after any of the malabsorptive operations (see Table 27-8). Overall lipid profiles also are improved. The degree to which this occurs is in part related to the exercise levels of individuals as well as genetic components of the disease.

CARDIOVASCULAR DISEASE

Hypertension, a component of metabolic syndrome, is one of the cardiovascular diseases that are increased in the setting of obesity. Elevated arterial pressure in patients with obesity-related hypertension is associated with increased cardiac output and total peripheral resistance. The elevated output is related to expanded intravascular volume, which increases cardiopulmonary volume, venous return, and left ventricular preload; the elevated pressure and total peripheral resistance increase afterload. This dual ventricular overload promotes a dimorphic, concentric, and eccentric hypertrophy in response to the volume and pressure overload. Increased myocardial oxygen demand results from the elevated tension in the left ventricular wall, reflecting its increased diameter and pressure, and provides a physiologic rationale for the greater potential for coronary arterial insufficiency and cardiac failure. There is higher renal blood flow and lower renal vascular resistance in patients with obesity-related hypertension at any level of arterial pressure. This may be offset by an increased renal filtration fraction, which may favor protein deposition and glomerulosclerosis.¹¹⁶

Weight loss results in decreased intravascular volume, decreased cardiac output, and decreased arterial pressure. These manifestations occur after all the various bariatric operations that produce weight loss.

Heart failure also is increased in the setting of severe obesity. Much of the risk is secondary to the processes described earlier that produce hypertension and cardiac hypertrophy. Hypertension and obesity each have significant independent associations with left ventricular hypertrophy and cardiac wall thickness. Obesity is particularly strongly associated with left ventricular internal diameter.¹¹⁷

Resolution of Other Comorbid Medical Problems

Bariatric surgery can produce resolution of many if not all of the comorbid medical problems associated with obesity and present at the time of surgery. This is true to some extent for all bariatric procedures, although some are more efficient at reversing specific comorbid problems than others.

Gastroesophageal reflux disease (GERD) is symptomatically present in approximately half of patients with severe obesity and has been objectively proven to be present in 21%.⁷⁵ Unfortunately, obese patients with GERD have a higher chance of failing to obtain symptomatic relief from standard antireflux surgery. The recurrence of symptoms is higher, likely due to a higher incidence of wrap herniation into the mediastinum and other mechanical failure of the fundoplication, which in turn is likely affected by the increased intra-abdominal pressure

occurring in the obese condition. A patient with a BMI of $>35 \text{ kg/m}^2$ who has GERD has a better chance of eliminating symptoms by undergoing LRYGB, which is approximately 95 to 97% effective in the elimination of GERD.¹¹⁸ LRYGB creates such a small gastric pouch that it has a very limited volume for acid production. LAGB also improves GERD but to a considerably lesser extent than RYGB.

Obstructive sleep apnea is a disturbance of sleep associated with obesity. It is a measurable problem, quantitated by polysomnography. In one recent study, of 349 patients considering bariatric surgery who were referred and tested, only 17% had no sleep apnea, whereas 32% had mild, 18% had moderate, and 33% had severe sleep apnea. At a mean time of 11 months after RYGB, the mean Respiratory Disturbance Index for all patients decreased from 51 to 15 ($P < .01$). Of 83 patients requiring continuous positive airway pressure or bilevel positive airway pressure preoperatively, only 31 still required it after surgery and machine settings could be decreased.¹¹⁹ This study illustrates the results generally reported in the literature regarding resolution of this problem after bariatric operations.

Another pulmonary disorder that is commonly seen in severely obese patients is asthma. This comorbidity has been poorly quantitated and studied in this population to date. Observation from our practice shows that, with good weight loss, most nonallergic-type asthma symptoms, possibly related to dyspnea of exertion and secondary mild bronchospasm, do resolve.

Nonalcoholic fatty liver disease (NAFLD) is a metabolically related problem associated with obesity. The disease is a spectrum of liver abnormalities including steatosis, steatohepatitis, and fibrosis and cirrhosis of the liver. It is estimated that 20% of U.S. adults have NAFLD, largely because of the high incidence of obesity. NAFLD is present in an estimated 85% of patients with severe obesity.¹²⁰ Due to the high incidence of this disease, some authorities have advocated routine liver biopsy at the time of bariatric operations. Because the treatment of the disease is weight loss, however, patients with mild forms of the disease need no further treatment or follow-up. Patients whose biopsy report shows any degree of fibrosis should generally undergo further follow-up with a hepatologist. Histologic evaluation of liver biopsies before and after bariatric surgery have demonstrated significant improvements in degrees of steatosis, inflammation, and in some cases even fibrosis.¹²¹ It has also been shown that RYGB does decrease the metabolic abnormalities involved in the pathogenesis of NAFLD and decreases the expression of factors involved in the progression of liver fibrosis.¹²²

Musculoskeletal problems, especially degenerative joint disease and low back pain, are among the most common complaints and comorbid problems of the severely obese population. Quantitation of their severity is often difficult, however, which makes resolution or improvement equally difficult. Symptoms usually improve and often resolve in patients who experience significant weight loss. This is likely a combined effect of the directly decreased workload and some secondary resolution of the inflammatory process in the joints brought on directly and indirectly by obesity.

Plastic Surgery after Weight Loss

Patients who have undergone bariatric surgery are often left with large amounts of hanging skin or rolls of skin and subcutaneous tissue as a result of the weight loss. Related additional problems that arise include skin rashes; maceration under folds in the pannus, thighs, and breasts; body odor; and poorly fitting clothes. Excess skin can be a limiting factor in exercise and sexual activity.

Most such patients wish to be rid of the extra skin and its associated problems. However, the major problem these patients face in accomplishing this is obtaining insurance approval for surgical removal of the excess skin. Most insurance companies consider this "cosmetic" surgery and will not authorize coverage. A few, with appropriate documentation of the conditions and problems caused by excess skin, do provide coverage for surgery. Plastic surgeons who are experienced in abdominoplasty and body contouring can offer these patients an excellent surgical treatment for the problems of excessive skin.

Reconstructive surgery requires careful preoperative planning and is based on the patient's deformities and priorities. Excess tissue of the lower torso is the most common deformity for which patients undergo surgical intervention. A standard abdominoplasty to remove this excessive tissue is performed. More radical body contouring can include a circumferential abdominoplasty and lower body lift.¹²³ This procedure involves excision of tissue from the buttocks and lateral thighs, with skin undermining down the thighs. Circumferential abdominoplasty removes redundant skin of the lower abdomen, flattens the abdomen, and incorporates the lower body lift. It requires central undermining to the xiphoid and minimal lateral undermining of the superior flap. The central abdominal fascia often requires imbrication. If simultaneous abdominal hernia repair is performed, this serves the function of fascial imbrication by creating a repair with

some degree of fascial tension. The closure of the superior flap to the inferior skin edge incorporates lateral tension to narrow the waist and advance the anterolateral thighs. Medial thighplasty also may be needed for patients with significant excess medial thigh skin. This is done transversely.

Excess skin distal to the mid-thighs requires long vertical medial excision of skin. Mid-back and epigastric rolls, along with sagging breasts, are corrected with an upper body lift. The upper body lift is a reverse abdominoplasty, removal of mid-torso excessive skin, and reshaping of the breasts. For highly selected individuals, and with a well-organized team, a single-stage total body lift, which includes a circumferential abdominoplasty, lower body lift, medial thighplasty, upper body lift, and breast reshaping, can be performed safely in <8 hours (Figs. 27-21 and 27-22).¹²⁴ Although many bariatric surgery programs do not have the accompanying volume, experience, and interest to offer such an extensive single-stage operation, most programs do have plastic surgery expertise available for abdominoplasty and removal of excess skin of the extremities as separate procedures. The rising numbers of patients undergoing bariatric surgery have provided an increased flow of patients requesting such services, which in turn should lead to improved outcomes with increasing experience for surgeons performing these procedures.

Endoscopic, Electric, and Other Experimental Procedures

Bariatric surgery has been a field in which a constant succession of procedures have been developed in an attempt to improve safety, minimize invasiveness, and offer better outcomes. Recent experimental procedures include electrical stimulation of the stomach and vagus nerves to produce weight loss.

The implantable gastric stimulation device, initially marketed by Transneuronix, Inc, in the early part of the twenty-first century, was a dual-lead implantable gastric electrical stimulator that theoretically interfered with the stomach's innate myoelectric pattern, causing decreased gastric emptying and nausea. A mean excess weight loss of 23% after implantation was reported at 16-month follow-up for the second U.S. trial study of the device.¹²⁵ Longer-term follow-up for the first European study has shown a 25% excess weight loss in 91 patients over a 2-year follow-up.¹²⁶ The disappointing aspect of this treatment is that a significant number of patients lose little weight, whereas a smaller group seem to respond well to the treatment. The ability to select those patients who will respond remains a challenge for this technology, which still is only a proposed potential operation for weight loss.

Vagal stimulation has recently been proposed as a means of stimulating the neural input to the stomach to achieve decrease in appetite, early satiety, at times nausea, and weight loss. Data to date have been sparse and very preliminary in showing any merits or potential efficacy for this approach.¹²⁷

Endoscopic procedures to decrease gastric pouch size and to limit gastrojejunostomy anastomotic size are currently being performed at several medical centers.^{67,128} These are currently reoperative procedures, not initial procedures for weight loss.

Intragastric balloon placement for weight loss has resurfaced on the bariatric scene in the past few years. The Garren-Edwards bubble of the late 1980s era¹²⁹ proved to be a disastrous failure. Now this concept has been reintroduced by one company, which has marketed a device of this type as a short-term bridge to weight loss to be followed by a more definitive procedure. Although there may be some limited application of this device for such purposes,¹³⁰ its ability to produce durable weight loss is unproven. It may have potential use only as a preliminary procedure before a more definitive one.

Prototype procedures undergoing trial include one that uses an endoscopically placed intraluminal sleeve to limit absorption.¹¹⁰ The

eventual ability to endoscopically create a gastric pouch and hence perform a restrictive operation completely endoscopically is being envisioned. Although these proposed procedures speak to the energy and innovation of today's bariatric surgery community, their actual creation has yet to occur.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 28. Small Intestine >

KEY POINTS

1. The small intestine performs a diverse set of functions.
2. Small bowel obstruction is one of the most common surgical diagnoses.
3. Most cases of small bowel obstruction are due to adhesions from previous surgery.
4. If, following surgical resection, less than 200 cm of small bowel remains, patients are at risk of developing short bowel syndrome.
5. Tumors and malignancies of the small bowel are rare and difficult to diagnose.

AN UNDERRATED ORGAN

The small intestine is the *raison d'être* of the GI tract as it is the principle site of nutrient digestion and absorption.¹ The small intestine is also the body's largest reservoir of immunologically active and hormone-producing cells, and hence can be conceptualized as the largest organ of the immune and endocrine systems, respectively. It achieves this diversity of action through unique anatomical features that provide it with a massive surface area, a diversity of cell types, and a complex neural network to coordinate these functions.

Despite its size and importance, diseases of the small intestine are relatively infrequent, and present diagnostic and therapeutic challenges. Treatments for common conditions such as postoperative ileus are hardly more effective than those used at the dawn of the last century. Mortality rates associated with acute mesenteric ischemia have not improved during the past 50 years.

Despite the introduction of novel imaging techniques such as capsule endoscopy and double balloon endoscopy, diagnostic tests lack sufficient predictive power to definitively guide clinical decision making for individual patients. Furthermore, few high-quality, controlled data on the efficacy of surgical therapies for small bowel diseases are available.

Therefore, sound clinical judgment and a thorough understanding of anatomy, physiology, and pathophysiology remain essential to the care of patients with intestinal disorders.

GROSS ANATOMY

The small intestine is a tubular structure that extends from the pylorus to the cecum. The estimated length of this structure varies depending on whether radiologic, surgical, or autopsy measurements are made. In the living, it is thought to measure 4 to 6 m.² The small intestine consists of three segments lying in series: the duodenum, jejunum, and ileum. The duodenum, the most proximal segment, lies in the retroperitoneum immediately adjacent to the head and inferior border of the body of the pancreas. The duodenum is demarcated from the stomach by the pylorus and from the jejunum by the ligament of Treitz. The jejunum and ileum lie within the peritoneal cavity and are tethered to the retroperitoneum by a broad-based mesentery. No distinct anatomic landmark demarcates the jejunum from the ileum; the proximal 40% of the jejunoileal segment is arbitrarily defined as the jejunum and the distal 60% as the ileum. The ileum is demarcated from the cecum by the ileocecal valve.

The small intestine contains mucosal folds known as *plicae circulares* or *valvulae conniventes* that are visible upon gross inspection. These folds are also visible radiographically and help in the distinction between small intestine and colon, which does not contain them, on abdominal radiographs. These folds are more prominent in the proximal intestine than in the distal small intestine. Other

features evident on gross inspection that are more characteristic of the proximal than distal small intestine include a larger circumference, thicker wall, less fatty mesentery, and longer vasa recta (Fig. 28-1). Gross examination of the small intestinal mucosa also reveals aggregates of lymphoid follicles. Those follicles, located in the ileum, are the most prominent and are designated *Peyer's patches*.

Fig. 28-1.

Gross features of jejunum contrasted with those of ileum. Relative to the ileum, the jejunum has a larger diameter, thicker wall, more prominent plicae circulares, a less fatty mesentery, and longer vasa recta.

Most of the duodenum derives its arterial blood from branches of both the celiac and the superior mesenteric arteries. The distal duodenum, the jejunum, and the ileum derive their arterial blood from the superior mesenteric artery. Their venous drainage occurs via the superior mesenteric vein. Lymph drainage occurs through lymphatic vessels coursing parallel to corresponding arteries. This lymph drains through mesenteric lymph nodes to the cisterna chyli, then through the thoracic duct, and ultimately into the left subclavian vein. The parasympathetic and sympathetic innervation of the small intestine is derived from the vagus and splanchnic nerves, respectively.

HISTOLOGY

The wall of the small intestine consists of four distinct layers: mucosa, submucosa, muscularis externa, and serosa (Fig. 28-2).

Fig. 28-2.

The mucosa is the innermost layer and it consists of three layers: epithelium, lamina propria, and muscularis mucosae. The epithelium is exposed to the intestinal lumen and is the surface through which absorption from and secretion into the lumen occurs. The lamina propria is located immediately external to the epithelium and consists of connective tissue and a heterogeneous population of cells. It is demarcated from the more external submucosa by the muscularis mucosae, a thin sheet of smooth muscle cells.

The mucosa is organized into villi and crypts (crypts of Lieberkühn). *Villi* are finger-like projections of epithelium and underlying lamina propria that contain blood and lymphatic (lacteals) vessels that extend into the intestinal lumen. Intestinal, epithelial cellular proliferation is confined to the *crypts*, each of which carries an average census of 250 to 300 cells. All epithelial cells in each crypt are derived from an unknown number of the yet uncharacterized multipotent stem cells located at or near the crypt's base. Their immediate descendants are amplified by undergoing several cycles of rapid division. These descendants then make a commitment to differentiate along one of four pathways that ultimately yield *enterocytes* and *goblet*, *enteroendocrine*, and *Paneth* cells. With the exception of Paneth cells, these lineages complete their terminal differentiation during an upward migration from each crypt to adjacent villi. The journey from the crypt to the villus tip is completed in 2 to 5 days and terminates with cells being removed by apoptosis and/or exfoliation. Thus, the small intestinal epithelium undergoes continuous renewal, making it one of the body's most dynamic tissues. The high cellular turnover rate contributes to mucosal resiliency but also makes the intestine uniquely susceptible to certain forms of injury such as that induced by radiation and chemotherapy.

Enterocytes are the predominant absorptive cell of the intestinal epithelium. Their apical (lumen-facing) cell membrane contains specialized digestive enzymes, transporter mechanisms, and microvilli that are estimated to increase the absorptive surface area of the small intestine by up to 40-fold. *Goblet cells* produce mucin believed to play a role in mucosal defense against pathogens. *Enteroendocrine cells* are characterized by secretory granules containing regulatory agents and are discussed in greater detail below in the Endocrine Function section. *Paneth cells* are located at the base of the crypt and contain secretory granules containing growth factors, digestive enzymes, and antimicrobial peptides. In addition, the intestinal epithelium contains microfold (M) cells and

intraepithelial lymphocytes. These two components of the immune system are discussed below.

The submucosa consists of dense connective tissue and a heterogeneous population of cells, including leukocytes and fibroblasts. The submucosa also contains an extensive network of vascular and lymphatic vessels, nerve fibers, and ganglion cells of the submucosal (Meissner's) plexus.

The muscularis propria consists of an outer, longitudinally oriented layer and an inner, circularly oriented layer of smooth muscle fibers. Located at the interface between these two layers are ganglion cells of the myenteric (Auerbach's) plexus.

The serosa consists of a single layer of mesothelial cells and is a component of the visceral peritoneum.

DEVELOPMENT

The first recognizable precursor of the small intestine is the embryonic gut tube, formed from the endoderm during the fourth week of gestation. The gut tube is divided into foregut, midgut, and hindgut. Other than duodenum, which is a foregut structure, the rest of the small intestine is derived from the midgut. The gut tube initially communicates with the yolk sac; however, the communication between these two structures narrows by the sixth week to form the vitelline duct. The yolk sac and vitelline duct usually undergo obliteration by the end of gestation. Incomplete obliteration of the vitelline duct results in the spectrum of defects associated with Meckel's diverticula.

Also, during the fourth week of gestation, the mesoderm of the embryo splits. The portion of mesoderm that adheres to the endoderm forms the visceral peritoneum, while the portion that adheres to the ectoderm forms the parietal peritoneum. This mesodermal division results in the formation of a coelomic cavity that is the precursor of the peritoneal cavity.

At approximately the fifth week of gestation, the bowel begins to lengthen to an extent greater than that which can be accommodated by the developing abdominal cavity, resulting in the extracoelomic herniation of the developing bowel. The bowel continues to lengthen during the subsequent weeks and is retracted back into the abdominal cavity during the tenth week of gestation. Subsequently, the duodenum becomes a retroperitoneal structure. Coincident with extrusion and retraction, the bowel undergoes a 270° counterclockwise rotation relative to the posterior abdominal wall. This rotation accounts for the usual locations of the cecum in the right lower quadrant and the duodenojejunal junction to the left of midline (Fig. 28-3).

Developmental rotation of the intestine. **A.** During the fifth week of gestation, the developing intestine herniates out of the coelomic cavity and begins to undergo a counterclockwise rotation about the axis of the superior mesenteric artery. **B** and **C.** Intestinal rotation continues, as the developing transverse colon passes anterior to the developing duodenum. **D.** Final positions of the small intestine and colon resulting from a 270° counterclockwise rotation of the developing intestine and its return into the abdominal cavity.

The celiac and superior mesenteric arteries and veins are derived from the vitelline vascular system, which, in turn, is derived from blood vessels formed within the splanchnopleuric mesoderm during the third week of gestation. Neurons found in the small intestine are derived from neural crest cells that begin to migrate away from the neural tube during the third week of gestation. These neural crest cells enter the mesenchyme of the primitive foregut and subsequently migrate to the remainder of the bowel.

During the sixth week of gestation, the lumen of the developing bowel becomes obliterated as bowel epithelial proliferation accelerates. Vacuoles form within the bowel substance during the subsequent weeks and coalesce to form the intestinal lumen by the ninth week of gestation. Errors in this recanalization may account for defects such as intestinal webs and stenoses. Most intestinal atresias, however, are believed to be related to ischemic episodes occurring after organogenesis has been completed rather than to errors in recanalization.

During the ninth week of gestation, the intestinal epithelium develops intestine-specific features such as crypt-villus architecture. Organogenesis is complete by approximately the twelfth week of gestation.

Elucidation of the fundamental mechanisms regulating patterned intestinal development is an area of active investigation.

PHYSIOLOGY

Digestion and Absorption

The intestinal epithelium is the interface through which absorption and secretion occur. It has features characteristic of absorptive epithelia in general, including epithelial cells with cellular membranes possessing distinct apical (luminal) and basolateral (serosal) domains demarcated by intercellular tight junctions, and an asymmetric distribution of transmembrane transporter mechanisms that promotes vectorial transport of solutes across the epithelium.

Solutes can traverse the epithelium by active or passive transport. Passive transport of solutes occurs through diffusion or convection and is driven by existing electrochemical gradients. *Active transport* is the energy-dependent net transfer of solutes in the absence of or against an electrochemical gradient.

Active transport occurs through transcellular pathways (through the cell), whereas passive transport can occur through either transcellular or paracellular pathways (between cells through the tight junctions). Transcellular transport requires solutes to traverse the cell membranes through specialized membrane proteins, such as channels, carriers, and pumps. The molecular characterization of transporter proteins is evolving rapidly, with different transporter families, each containing many individual genes encoding specific transporters, now identified. Similarly, understanding of the paracellular pathway is evolving. In contrast to what was once believed, it is becoming apparent that paracellular permeability is substrate specific, dynamic, and subject to regulation by specific tight junction proteins.³

WATER AND ELECTROLYTE ABSORPTION AND SECRETION

Eight to 9 L of fluid enter the small intestine daily. Most of this volume consists of salivary, gastric, biliary, pancreatic, and intestinal secretions. Under normal conditions, the small intestine absorbs over 80% of this fluid, leaving approximately 1.5 L that enters the colon (Fig. 28-4). Small intestinal absorption and secretion are tightly regulated; derangements in water and electrolyte homeostasis characteristic of many of the disorders discussed in this chapter play an important role in contributing to their associated clinical features.

Fig. 28-4.

Small intestinal fluid fluxes. Typical quantities (in volume per day) of fluid entering and leaving the small intestinal lumen in a healthy adult are shown.

Water absorption is believed to be driven by osmotic gradients created primarily by active transepithelial Na^+ absorption. Intestinal

water secretion, in contrast, is believed to be driven by osmotic gradients created primarily by transepithelial Cl^- secretion. Most intestinal water transport is believed to occur through the transcellular pathway.⁴ The specific transport mechanisms mediating water absorption are incompletely characterized. Aquaporins (water channels) are expressed in the intestinal epithelium; however, their contribution to overall intestinal water absorption appears to be relatively minor.⁵

The prevailing model for intestinal epithelial Na^+ absorption is shown in Fig. 28-5. Activity of the Na^+/K^+ ATPase enzyme, which is located in the basolateral membrane and exchanges three intracellular Na^+ for every two extracellular K^+ in an energy-dependent process, generates the electrochemical gradient that drives the transport of Na^+ from the intestinal lumen into the cytoplasm of enterocytes. Na^+ ions traverse the apical membrane through several distinct transporter mechanisms including nutrient-coupled sodium transport (e.g., sodium-glucose cotransporter-1, SGLT1), sodium channels, and sodium-hydrogen exchangers. Absorbed Na^+ ions are then extruded from enterocytes through the Na^+/K^+ ATPase located in the basolateral membrane. Similar mechanistic models that account for the transport of other common ions such as K^+ and HCO_3^- also exist.

Substantial heterogeneity, with respect to both crypt-villus and craniocaudal axes, exist for intestinal epithelial transport mechanisms. For example, nutrient-coupled Na^+ transporters are expressed in mature villus cells, but are absent in crypt cells. In contrast, the cystic fibrosis transmembrane regulator (a chloride channel) is expressed to a greater extent in crypt cells. This spatial distribution pattern is consistent with a model in which absorptive function resides primarily in the villus and secretory function in the crypt.

Intestinal absorption and secretion are subject to modulation under physiologic and pathophysiologic conditions by a wide array of hormonal, neural, and immune regulatory mediators (Table 28-1).

CARBOHYDRATE DIGESTION AND ABSORPTION

Approximately 45% of energy consumption in the average Western diet consists of carbohydrates, approximately one half of which is in the form of starch (linear or branched polymers of glucose) derived from cereals and plants. Other major sources of dietary carbohydrates include sugars derived from milk (lactose), fruits and vegetables (fructose, glucose, and sucrose), or purified from sugar cane or beets (sucrose). Processed foods contain a variety of sugars including fructose, oligosaccharides, and polysaccharides. Glycogen derived from meat contributes only a small fraction of dietary carbohydrate.

Pancreatic amylase is the major enzyme of starch digestion, although salivary amylase initiates the process. The terminal products of amylase-mediated starch digestion are oligosaccharides, maltotriose, maltose, and alpha-limit dextrins (Fig. 28-6). These products, as well as the major disaccharides in the diet (sucrose and lactose), are unable to undergo absorption in this form. They must first undergo hydrolytic cleavage into their constituent monosaccharides; these hydrolytic reactions are catalyzed by specific brush border membrane hydrolases that are expressed most abundantly in the villi of the duodenum and jejunum. The three major monosaccharides that represent the terminal products of carbohydrate digestion are glucose, galactose, and fructose.

Fig. 28-6.

Carbohydrate digestion. Dietary carbohydrates, including starch and the disaccharides sucrose and lactose, must undergo hydrolysis into constituent monosaccharides glucose, galactose, and fructose before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by salivary and pancreatic amylase and by enterocyte brush border hydrolases.

Under physiologic conditions, most of these sugars are absorbed through the epithelium via the transcellular route. Glucose and galactose are transported through the enterocyte brush border membrane via intestinal SGLT1 (Fig. 28-7). Fructose is transported through the brush border membrane by facilitated diffusion via glucose transporter-5 (GLUT5, a member of the facilitative glucose transporter family). All three monosaccharides are extruded through the basolateral membrane by facilitated diffusion. Extruded monosaccharides diffuse into venules and ultimately enter the portal venous system.

Hexose transporters. Glucose and galactose enter the enterocyte through secondary active transport via the sodium-glucose cotransporter-1 (SGLT1) located on the apical (brush border) membrane. Fructose enters through facilitated diffusion via glucose transporter-5 (GLUT5). Glucose and galactose are extruded basolaterally through facilitated diffusion via glucose transporter-2 (GLUT2). Fructose is extruded basolaterally via GLUT5.

There is evidence of overexpression of hexose transporters, specifically SGLT1, in disease states such as diabetes.⁶ Several approaches aimed at down-regulation of these transporters are being investigated as a novel therapy for disease states such as diabetes and obesity.⁷

PROTEIN DIGESTION AND ABSORPTION

Ten to 15% of energy consumption in the average Western diet consists of proteins. In addition to dietary proteins, approximately one half of the protein load that enters the small intestine is derived from endogenous sources including salivary and GI secretions and desquamated intestinal epithelial cells. Protein digestion begins in the stomach with action of pepsins. This is not, however, an essential step, because surgical patients who are achlorhydric, or have lost part or all their stomach, are still able to successfully digest proteins. Digestion continues in the duodenum with the actions of a variety of pancreatic peptidases. These enzymes are secreted as inactive proenzymes. This is in contrast to pancreatic amylase and lipase, which are secreted in their active forms. In response to the presence of bile acids, enterokinase is liberated from the intestinal brush border membrane to catalyze the conversion of trypsinogen to active trypsin; trypsin, in turn, activates itself and other proteases. The final products of intraluminal protein digestion consist of neutral and basic amino acids and peptides two to six amino acids in length (Fig. 28-8). Additional digestion occurs through the actions of peptidases that exist in the enterocyte brush border and cytoplasm. Epithelial absorption occurs for both single amino acids and di- or tripeptides via specific membrane-bound transporters. Absorbed amino acids and peptides then enter the portal venous circulation.

Fig. 28-8.

Protein digestion. Dietary proteins must undergo hydrolysis into constituent single amino acids and di- and tripeptides before being absorbed by the intestinal epithelium. These hydrolytic reactions are catalyzed by pancreatic peptidases (e.g., trypsin) and by enterocyte brush border peptidases.

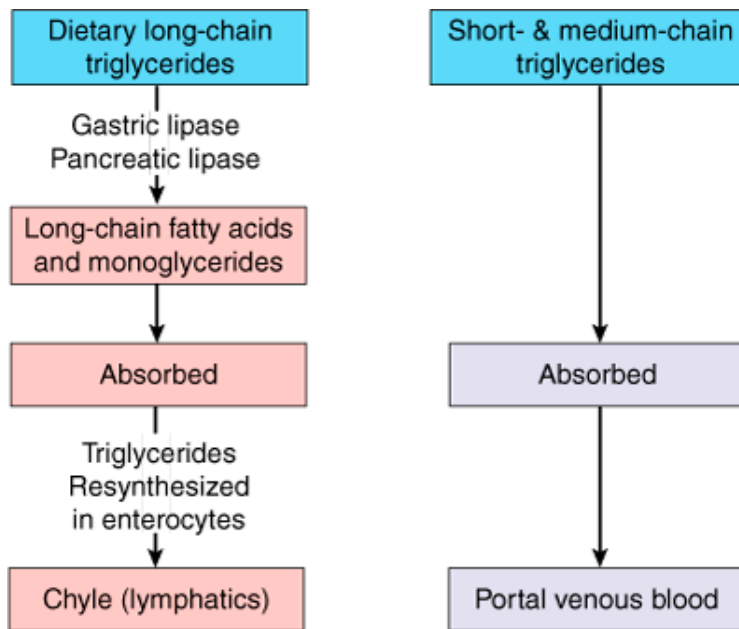

Of all amino acids, glutamine appears to be a unique, major source of energy for enterocytes. Active glutamine uptake into enterocytes occurs through both apical and basolateral transport mechanisms.

FAT DIGESTION AND ABSORPTION

Approximately 40% of the average Western diet consists of fat. Over 95% of dietary fat is in the form of long-chain triglycerides; the remainder includes phospholipids such as lecithin, fatty acids, cholesterol, and fat-soluble vitamins. Over 94% of the ingested fats are absorbed in the proximal jejunum.

Because fats are normally water insoluble, key to successful digestion of ingested fats is solubilization of them into an emulsion by the mechanical actions of mastication and antral peristalsis. Although lipolysis of triglycerides to form fatty acids and monoglycerides is initiated in the stomach by gastric lipase, its principal site is the proximal intestine, where pancreatic lipase is the catalyst (Fig. 28-9).

Fig. 28-9.

Fat digestion. Long-chain triglycerides, which constitute the majority of dietary fats, must undergo lipolysis into constituent long-chain fatty acids and monoglycerides before being absorbed by the intestinal epithelium. These reactions are catalyzed by gastric and pancreatic lipases. The products of lipolysis are transported in the form of mixed micelles to enterocytes, where they are resynthesized into triglycerides, which are then packaged in the form of chylomicrons that are secreted into the intestinal lymph (chyle). Triglycerides composed of short- and medium-chain fatty acids are absorbed by the intestinal epithelium directly, without undergoing lipolysis, and are secreted into the portal venous circulation.

Bile acids act as detergents that help in solubilization of the lipolysis by forming mixed micelles. These micelles are polymolecular aggregates with a hydrophobic core of fat, and a hydrophilic surface that act as shuttles, delivering the products of lipolysis to the enterocyte brush border membrane, where they are absorbed. The bile salts, however, remain in the bowel lumen and travel to the terminal ileum, where they are actively resorbed. They enter the portal circulation and are resecreted into bile, thus completing the enterohepatic circulation.

Dissociation of lipids from the micelles occurs in a thin layer of water (50 to 500 μm thick) with an acidic microenvironment immediately adjacent to the brush border called the *unstirred water layer*. Most lipids are absorbed in the proximal jejunum, whereas bile salts are absorbed in the distal ileum through an active process. Fatty acid binding proteins are a family of proteins located on the brush border membrane, facilitating diffusion of long-chain fatty acids across the brush border membrane. Cholesterol crosses the brush border membrane through an active process that is yet to be completely characterized. Within the enterocytes, triglycerides are resynthesized and incorporated into chylomicrons that are secreted into the intestinal lymphatics and ultimately enter the thoracic duct. In these chylomicrons, lipoproteins serve a detergent-like role similar to that served by bile salts in the mixed micelles.

The steps described above are required for the digestion and absorption of triglycerides containing long-chain fatty acids. However, triglycerides containing short- and medium-chain fatty acids are more hydrophilic and are absorbed without undergoing intraluminal hydrolysis, micellar solubilization, mucosal re-esterification, and chylomicron formation. Instead, they are directly absorbed and enter the portal venous circulation rather than the lymphatics. This information provides the rationale for administering nutritional supplements containing medium-chain triglycerides to patients with GI diseases associated with impaired digestion and/or malabsorption of long-chain triglycerides.

VITAMIN AND MINERAL ABSORPTION

Vitamin B12 (cobalamin) malabsorption can result from a variety of surgical manipulations. The vitamin is initially bound by saliva-

derived R protein. In the duodenum, R protein is hydrolyzed by pancreatic enzymes, allowing free cobalamin to bind to gastric parietal cell-derived intrinsic factor. The cobalamin-intrinsic factor complex is able to escape hydrolysis by pancreatic enzymes, allowing it to reach the terminal ileum, which expresses specific receptors for intrinsic factor. Subsequent events in cobalamin absorption are poorly characterized, but the intact complex probably enters enterocytes through translocation. Because each of these steps is necessary for cobalamin assimilation, gastric resection, gastric bypass, and ileal resection can each result in vitamin B₁₂ insufficiency.

Other water-soluble vitamins for which specific carrier-mediated transport processes have been characterized include ascorbic acid, folate, thiamine, riboflavin, pantothenic acid, and biotin. Fat-soluble vitamins A, D, and E appear to be absorbed through passive diffusion. Vitamin K appears to be absorbed through both passive diffusion and carrier-mediated uptake.

Calcium is absorbed through both transcellular transport and paracellular diffusion. The duodenum is the major site for transcellular transport; paracellular transport occurs throughout the small intestine. A key step in transcellular calcium transport is mediated by calbindin, a calcium-binding protein located in the cytoplasm of enterocytes. Regulation of calbindin synthesis is the principal mechanism by which vitamin D regulates intestinal calcium absorption. Abnormal calcium levels are increasingly seen in surgical patients who have undergone a gastric bypass. Although usual calcium supplementation is in the form of calcium carbonate, which is cheap, in such patients with low acid exposure, calcium citrate is a better formulation for replacement therapy.

Iron and magnesium are each absorbed through both transcellular and paracellular routes. A divalent metal transporter capable of transporting Fe²⁺, Zn²⁺, Mn²⁺, Co²⁺, Cd²⁺, Cu²⁺, Ni²⁺, and Pb²⁺ that has recently been localized to the intestinal brush border, may account for at least a portion of the transcellular absorption of these ions.⁸

Barrier and Immune Function

Although the intestinal epithelium allows for the efficient absorption of dietary nutrients, it must discriminate between pathogens and harmless antigens such as food proteins and commensal bacteria and it must resist invasion by pathogens. Factors contributing to epithelial defense include immunoglobulin A (IgA), mucins, and the relative impermeability of the brush border membrane and tight junctions to macromolecules and bacteria. Recently described factors likely to play important roles in intestinal mucosal defense include antimicrobial peptides such as the defensins.⁹ The intestinal component of the immune system, known as the *gut-associated lymphoid tissue* (GALT), contains over 70% of the body's immune cells.

The GALT is conceptually divided into inductive and effector sites.¹⁰ Inductive sites include Peyer's patches, mesenteric lymph nodes, and smaller isolated lymphoid follicles scattered throughout the small intestine (Fig. 28-10). Peyer's patches are macroscopic aggregates of B-cell follicles and intervening T-cell areas found in the lamina propria of the small intestine, primarily the distal ileum. Overlying Peyer's patches is a specialized epithelium containing M cells. These cells possess an apical membrane with microfolds rather than microvilli, which is characteristic of most intestinal epithelial cells. Using transepithelial vesicular transport, M cells transfer microbes to underlying professional antigen-presenting cells, such as dendritic cells. Dendritic cells, in addition, may sample luminal antigens directly through their dendrite-like processes that extend through epithelial tight junctions. Antigen-presenting cells interact with and prime naïve lymphocytes, which then exit through the draining lymphatics to enter the mesenteric lymph nodes, where they undergo differentiation. These lymphocytes then migrate into the systemic circulation via the thoracic duct and ultimately accumulate in the intestinal mucosa at effector sites. Alternative induction mechanisms, such as antigen presentation within mesenteric lymph nodes, are also likely to exist.

Fig. 28-10.

 Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Gut-associated lymphoid tissue. Select components of the gut-associated lymphoid tissue are schematically represented. Peyer's patches consist of a specialized follicle-associated epithelium (FAE) containing M cells, a subepithelial dome (SED) rich in dendritic cells (DC), and B-cell follicle containing germinal centers (GC). Plasma cells in the lamina propria produce immunoglobulin A (IgA), which is transported to the intestinal lumen where it serves as the first line of defense against pathogens. Other components of the gut-associated lymphoid tissue include isolated lymphoid follicles, mesenteric lymph nodes, and regulatory and effector lymphocytes. B = B cell; T = T cell.

Effector lymphocytes are distributed into distinct compartments. IgA-producing plasma cells are derived from B cells and are located in the lamina propria. CD4⁺ T cells are also located in the lamina propria. CD8⁺ T cells migrate preferentially to the epithelium, but are also found in the lamina propria. These T cells are central to immune regulation; in addition the CD8⁺ T cells have potent cytotoxic T lymphocyte activity. IgA is transported through the intestinal epithelial cells into the lumen, where it exists in the form of a dimer complexed with a secretory component. This configuration renders IgA resistant to proteolysis by digestive enzymes. IgA is believed to both help prevent the entry of microbes through the epithelium and to promote excretion of antigens or microbes that have already penetrated into the lamina propria.

Ineffective resistance to invasion by pathogens is hypothesized to play an etiologic role in sepsis by allowing translocation of bacteria and/or toxins into the systemic circulation. In contrast, overexuberant immune sensitivity or lack of tolerance to dietary antigens or commensal bacteria is believed to contribute to the pathogenesis of chronic inflammatory disorders such as celiac disease and Crohn's disease.¹⁰

Motility

Myocytes of the intestinal muscle layers are electrically and mechanically coordinated in the form of syncytia. Contractions of the muscularis propria are responsible for small intestinal peristalsis. Contraction of the outer longitudinal muscle layer results in bowel shortening; contraction of the inner circular layer results in luminal narrowing. Contractions of the muscularis mucosa contribute to mucosal or villus motility, but not to peristalsis.

Several distinctive patterns of muscularis propria activity have been observed to occur in the small intestine. These patterns include *ascending excitation* and *descending inhibition* in which muscular contraction occurs proximal to a stimulus, such as the presence of a

bolus of ingested food, and muscular relaxation occurs distal to the stimulus (Fig. 28-11). These two reflexes are present even in the absence of any extrinsic innervation to the small intestine and contribute to peristalsis when they are propagated in a coordinated fashion along the length of the intestine. The *fed* or *postprandial pattern* begins within 10 to 20 minutes of meal ingestion and abates 4 to 6 hours afterward. *Rhythmic segmentations* or pressure waves traveling only short distances also are observed. This segmenting pattern is hypothesized to assist in mixing intraluminal contents and in facilitating their contact with the absorptive mucosal surface. The *fasting pattern* or *interdigestive motor cycle* (IDMC) consists of three phases. Phase I is characterized by motor quiescence, phase II by seemingly disorganized pressure waves occurring at submaximal rates, and phase III by sustained pressure waves occurring at maximal rates. This pattern is hypothesized to expel residual debris and bacteria from the small intestine. The median duration of the IDMC ranges from 90 to 120 minutes. At any given time, different portions of the small intestine can be in different phases of the IDMC.

Fig. 28-11.

Ascending excitation and descending inhibition. The presence of a food bolus within the intestinal lumen is sensed by a sensory neuron (SN) that relays signals to (a) excitatory motor neurons (EMN) that have projections to intestinal muscle cells located proximal to the food bolus and (b) inhibitory motor neurons (IMN) that have projections to intestinal muscle cells located distal to the food bolus. This stereotypical motor reflex is controlled by the enteric nervous system and occurs in the absence of extraintestinal innervations. It contributes to peristalsis.

The regulatory mechanisms driving small intestinal motility consist of both pacemakers intrinsic to the small intestine and external neurohumoral modulatory signals. The interstitial cells of Cajal are pleomorphic mesenchymal cells located within the muscularis propria of the intestine that generate the electrical slow wave (basic electrical rhythm or pacesetter potential) that plays a pacemaker role in setting the fundamental rhythmicity of small intestinal contractions. The frequency of the slow wave varies along the longitudinal axis of the intestine: It ranges from 12 waves per minute in the duodenum to 7 waves per minute in the distal ileum. Smooth muscle contraction occurs only when an electrical action potential (spike burst) is superimposed on the slow wave. Thus, the slow wave determines the maximum frequency of contractions; however, not every slow wave is associated with a contraction.

This intrinsic contractile mechanism is subject to neural and hormonal regulation. The enteric motor system (ENS) provides both inhibitory and excitatory stimuli. The predominant excitatory transmitters are acetylcholine and substance P, and the inhibitory transmitters include nitric oxide, vasoactive intestinal peptide, and adenosine triphosphate. In general, the sympathetic motor supply is inhibitory to the ENS; therefore, increased sympathetic input into the intestine leads to decreased intestinal smooth muscle activity. The parasympathetic motor supply is more complex, with projections to both inhibitory and excitatory ENS motor neurons. Correspondingly, the effects of parasympathetic inputs into intestinal motility are more difficult to predict.

Endocrine Function

Endocrinology as a discipline was born with the discovery of secretin, an intestinal regulatory peptide that was the first hormone to be

identified. The small intestine is now recognized to be the largest hormone-producing organ in the body, both with respect to the number of hormone-producing cells and the number of individual hormones produced.¹¹ Over 30 peptide hormone genes have been identified as being expressed in the GI tract. Because of differential posttranscriptional and posttranslational processing, over 100 distinct regulatory peptides are produced. In addition, monoamines, such as histamine and dopamine, and eicosanoids with hormone-like activities are produced in the intestine.

"Gut hormones" were previously conceptualized as peptides produced by the enteroendocrine cells of the intestinal mucosa that are released into the systemic circulation to reach receptors in target sites in the GI tract. Now it is clear that "gut hormone" genes are widely expressed throughout the body, not only in endocrine cells, but also in central and peripheral neurons.¹² The products of these genes are general intercellular messengers that can act as endocrine, paracrine, autocrine, or neurocrine mediators. Thus, they may act as true blood-borne hormones as well as through local effects.

There are notable homology patterns among individual regulatory peptides found in the GI tract. Based on these homologies, approximately one half of the known regulatory peptides can be classified into families.¹² For example, the secretin family includes secretin, glucagon, and glucagon-like peptides, glucose-dependent insulinotropic peptide, vasoactive intestinal polypeptide, peptide histidine isoleucine, growth hormone releasing hormone, and pituitary adenylyl cyclase-activating peptide. Other peptide families include those named for insulin, epidermal growth factor, gastrin, pancreatic polypeptide, tachykinin, and somatostatin.

Receptor subtype multiplicity and cell-specific expression patterns for these receptor subtypes that are characteristic of these regulatory mediators make definition of their actions complex. Detailed description of these actions is beyond the scope of this chapter; however, examples of regulatory peptides produced by enteroendocrine cells of the small intestinal epithelium and their most commonly ascribed functions are summarized in Table 28-2. Some of these peptides or their analogues are used in routine clinical practice. For example, therapeutic applications of octreotide, a long-acting analogue of somatostatin, include the amelioration of symptoms associated with neuroendocrine tumors (e.g., carcinoid syndrome), postgastrectomy dumping syndrome, enterocutaneous fistulas, and the initial treatment of acute hemorrhage due to esophageal varices. The gastrin secretory response to secretin administration forms the basis for the standard test used to establish the diagnosis of Zollinger-Ellison syndrome. Cholecystokinin is used in evaluations of gallbladder ejection fraction, a parameter that may have use in patients who have symptoms of biliary colic but are not found to have gallstones. Of the peptides listed in Table 28-2, glucagon-like peptide 2 (GLP-2) has been identified as a specific and potent intestinotrophic hormone. GLP-2 both stimulates cellular proliferation and inhibits apoptosis in the intestinal epithelium. It has been demonstrated to induce intestinal regeneration and promote healing in numerous experimental models of intestinal disease. It is currently under clinical evaluation as an intestinotrophic agent in patients suffering from the short bowel syndrome, as discussed in the Short Bowel Syndrome section below.

Table 28-2 Representative Regulatory Peptides Produced in the Small Intestine		
Hormone	Source ^a	Actions
Somatostatin	D cell	Inhibits GI secretion, motility, and splanchnic perfusion
Secretin	S cell	Stimulates exocrine pancreatic secretion
		Stimulates intestinal secretion
Cholecystokinin	I cell	Stimulates pancreatic exocrine secretion
		Stimulates gallbladder emptying
		Inhibits sphincter of Oddi contraction
Motilin	M cell	Simulates intestinal motility
Peptide YY	L cell	Inhibits intestinal motility and secretion
Glucagon-like peptide 2	L cell	Stimulates intestinal epithelial proliferation

Neurotensin	N cell	Stimulates pancreatic and biliary secretion
		Inhibits small bowel motility
		Stimulates intestinal mucosal growth

^a This table indicates which enteroendocrine cell types located in the intestinal epithelium produce these peptides. These peptides are also widely expressed in nonintestinal tissues.

Intestinal Adaptation

The small intestine has the capacity to adapt in response to varying demands imposed by physiologic and pathologic conditions. Of particular relevance to many of the diseases discussed in this chapter is the adaptation that occurs in the remnant intestine following surgical resection of a large portion of the small intestine (massive small bowel resection). Postresection intestinal adaptation has been studied extensively using animal models. Within a few hours after bowel resection, the remnant small intestine displays evidence of epithelial cellular hyperplasia. With additional time, villi lengthen, intestinal absorptive surface area increases, and digestive and absorptive functions improve. Postresection intestinal adaptation in human patients is less well studied, but seems to follow similar steps as that seen in experimental models, and takes 1 to 2 years to complete.¹³

The mechanisms responsible for inducing postresection intestinal adaptation are under active investigation. Several classes of effectors that stimulate intestinal growth include specific nutrients, peptide hormones and growth factors, pancreatic secretions, and some cytokines.¹⁴ Nutritional components with intestinal growth-stimulating effects include fiber, fatty acids, triglycerides, glutamine, polyamines, and lectins. Peptide growth factors reported to induce growth include epidermal growth factor, transforming growth factor alpha, insulin-like growth factors I and II, keratinocyte growth factor, hepatocyte growth factor, gastrin, peptide YY, neurotensin, and bombesin. Cytokines that stimulate growth include interleukin (IL)-11, IL-3, and IL-15. The most recently characterized stimulator of enterocyte proliferation is GLP-2, which has potent trophic activity that is specific for the intestinal epithelium.¹⁵ As serum concentrations of GLP-2 rise following massive small bowel resection and GLP-2 immunoneutralization inhibits postresection intestinal adaptation, GLP-2 is a promising candidate mediator of this response.

Postresection adaptation serves to compensate for the function of intestine that has been resected. Jejunal resection generally is better tolerated, as ileum shows better capacity to compensate. However, the magnitude of this response is limited. If enough small intestine is resected, a devastating condition known as the *short bowel syndrome* results. This condition is discussed in the Short Bowel Syndrome section at the end of this chapter.

SMALL BOWEL OBSTRUCTION

Epidemiology

Mechanical small bowel obstruction is the most frequently encountered surgical disorder of the small intestine. Although a wide range of etiologies for this condition exist, the obstructing lesion can be conceptualized according to its anatomic relationship to the intestinal wall as:

1. Intraluminal (e.g., foreign bodies, gallstones, or meconium)
2. Intramural (e.g., tumors, Crohn's disease–associated inflammatory strictures)
3. Extrinsic (e.g., adhesions, hernias, or carcinomatosis)

Intra-abdominal adhesions related to prior abdominal surgery account for up to 75% of the cases of small bowel obstruction. Over 300,000 patients are estimated to undergo surgery annually to treat adhesion-induced small bowel obstruction in the United States.¹⁶

Less prevalent etiologies for small bowel obstruction include hernias, malignant bowel obstruction, and Crohn's disease. The frequency with which obstruction related to these conditions is encountered varies according to the patient population and practice setting. Cancer-related small bowel obstructions are commonly due to extrinsic compression or invasion by advanced malignancies arising in

organs other than the small bowel; few are due to primary small bowel tumors. The most commonly encountered etiologies of small bowel obstruction are summarized in Table 28-3. Although congenital abnormalities capable of causing small bowel obstruction usually become evident during childhood, they sometimes elude detection and are diagnosed for the first time in adult patients presenting with abdominal symptoms. For example, intestinal malrotation and midgut volvulus should not be forgotten when considering the differential diagnosis of adult patients with acute or chronic symptoms of small bowel obstruction, especially those without a history of prior abdominal surgery. A rare etiology of obstruction is the superior mesenteric artery syndrome, characterized by compression of the third portion of the duodenum by the superior mesenteric artery as it crosses over this portion of the duodenum. This condition should be considered in young asthenic individuals who have chronic symptoms suggestive of proximal small bowel obstruction.

Table 28-3 Small Bowel Obstruction: Common Etiologies
Adhesions
Neoplasms
Primary small bowel neoplasms
Secondary small bowel cancer (e.g., melanoma-derived metastasis)
Local invasion by intra-abdominal malignancy (e.g., desmoid tumors)
Carcinomatosis
Hernias
External (e.g., inguinal and femoral)
Internal (e.g., following Roux-en-Y gastric bypass surgery)
Crohn's disease
Volvulus
Intussusception
Radiation-induced stricture
Postischemic stricture
Foreign body
Gallstone ileus
Diverticulitis
Meckel's diverticulum
Hematoma
Congenital abnormalities (e.g., webs, duplications, and malrotation)

Pathophysiology

With onset of obstruction, gas and fluid accumulate within the intestinal lumen proximal to the site of obstruction. The intestinal activity increases in an effort to overcome the obstruction, accounting for the colicky pain and the diarrhea that some experience even in the presence of complete bowel obstruction. Most of the gas that accumulates originates from swallowed air, although some is produced within the intestine. The fluid consists of swallowed liquids and GI secretions (obstruction stimulates intestinal epithelial water secretion). With ongoing gas and fluid accumulation, the bowel distends and intraluminal and intramural pressures rise. The intestinal motility is eventually reduced with fewer contractions. With obstruction, the luminal flora of the small bowel, which is usually sterile, changes and a variety of organisms have been cultured from the contents. Translocation of these bacteria to regional lymph nodes has been demonstrated, although the significance of this process is not well understood. If the intramural pressure becomes high enough, intestinal microvascular perfusion is impaired, leading to intestinal ischemia, and, ultimately, necrosis. This condition is termed *strangulated bowel obstruction*.

With *partial small bowel obstruction*, only a portion of the intestinal lumen is occluded, allowing passage of some gas and fluid. The

progression of pathophysiologic events described above tends to occur more slowly than with *complete small bowel obstruction*, and development of strangulation is less likely.

A particularly dangerous form of bowel obstruction is *closed loop obstruction*, in which a segment of intestine is obstructed both proximally and distally (e.g., with volvulus). In such cases, the accumulating gas and fluid cannot escape either proximally or distally from the obstructed segment, leading to a rapid rise in luminal pressure, and a rapid progression to strangulation.

Clinical Presentation

The symptoms of small bowel obstruction are colicky abdominal pain, nausea, vomiting, and obstipation. Vomiting is a more prominent symptom with proximal obstructions than distal. Character of vomitus is important as with bacterial overgrowth, the vomitus is more feculent, suggesting a more established obstruction (Fig. 28-12). Continued passage of flatus and/or stool beyond 6 to 12 hours after onset of symptoms is characteristic of partial rather than complete obstruction. The signs of small bowel obstruction include abdominal distention that is most pronounced if the site of obstruction is in the distal ileum, and may be absent if the site of obstruction is in the proximal small intestine. Bowel sounds may be hyperactive initially, but in late stages of bowel obstruction, minimal bowel sounds may be heard. Laboratory findings reflect intravascular volume depletion and consist of hemoconcentration and electrolyte abnormalities. Mild leukocytosis is common.

Chronic partial small bowel obstruction. This patient presented with a several months' history of chronic abdominal pain, and intermittent vomiting. The coronal computed tomographic image shows grossly dilated loops of proximal small bowel on the left side (*wide arrow*), with decompressed loops of small bowel on the right side (*narrow arrow*). The dilated segment shows evidence of fecalization of bowel contents, consistent with the chronic nature of the obstruction. Patient's vomitus had characteristic feculent smell and quality. At exploratory laparotomy, adhesive bands were identified and divided.

Features of strangulated obstruction include abdominal pain often disproportionate to the degree of abdominal findings, suggestive of intestinal ischemia. Patients often have tachycardia, localized abdominal tenderness, fever, marked leukocytosis, and acidosis. Any of these findings should alert the clinician to the possibility of strangulation, and the need for early surgical intervention.

Diagnosis

The diagnostic evaluation should focus on the following goals: (a) distinguish mechanical obstruction from ileus, (b) determine the

etiology of the obstruction, (c) discriminate partial from complete obstruction, and (d) discriminate simple from strangulating obstruction.

Important elements to obtain on history include prior abdominal operations (suggesting the presence of adhesions) and the presence of abdominal disorders (e.g., intra-abdominal cancer or inflammatory bowel disease) that may provide insights into the etiology of obstruction. Upon examination, a meticulous search for hernias (particularly in the inguinal and femoral regions) should be conducted. The stool should be checked for gross or occult blood, the presence of which is suggestive of intestinal strangulation.

The diagnosis of small bowel obstruction is usually confirmed with radiographic examination. The *abdominal series* consists of (a) a radiograph of the abdomen with the patient in a supine position, (b) a radiograph of the abdomen with the patient in an upright position, and (c) a radiograph of the chest with the patient in an upright position. The finding most specific for small bowel obstruction is the triad of dilated small bowel loops (>3 cm in diameter), air-fluid levels seen on upright films, and a paucity of air in the colon. The sensitivity of abdominal radiographs in the detection of small bowel obstruction ranges from 70 to 80%.¹⁷ Specificity is low because ileus and colonic obstruction can be associated with findings that mimic those observed with small bowel obstruction. False-negative findings on radiographs can result when the site of obstruction is located in the proximal small bowel and when the bowel lumen is filled with fluid but no gas, thereby preventing visualization of air-fluid levels or bowel distention. The latter situation is associated with closed-loop obstruction. Despite these limitations, abdominal radiographs remain an important study in patients with suspected small bowel obstruction because of their widespread availability and low cost.

Computed tomographic (CT) scanning is 80 to 90% sensitive and 70 to 90% specific in the detection of small bowel obstruction.¹⁷ The findings of small bowel obstruction include a discrete transition zone with dilation of bowel proximally, decompression of bowel distally, intraluminal contrast that does not pass beyond the transition zone, and a colon containing little gas or fluid (Fig. 28-13). CT scanning may also provide evidence for the presence of closed-loop obstruction and strangulation. Closed-loop obstruction is suggested by the presence of a U-shaped or C-shaped dilated bowel loop associated with a radial distribution of mesenteric vessels converging toward a torsion point. Strangulation is suggested by thickening of the bowel wall, pneumatosis intestinalis (air in the bowel wall), portal venous gas, mesenteric haziness, and poor uptake of IV contrast into the wall of the affected bowel (Fig. 28-14). CT scanning also offers a global evaluation of the abdomen and may therefore reveal the etiology of obstruction. This feature is important in the acute setting when intestinal obstruction represents only one of many diagnoses in patients presenting with acute abdominal conditions.

Intestinal pneumatosis. This computed tomographic scan shows intestinal pneumatosis (arrow). The cause of this radiologic finding was intestinal ischemia. Patient was taken emergently to the operating room and underwent resection of an infarcted segment of small bowel.

The CT scan usually is performed after administration of oral water soluble contrast, or diluted barium. The water soluble contrast has been shown to have prognostic and therapeutic values too. Several studies and a subsequent meta-analysis have shown that

appearance of the contrast in the colon within 24 hours is predictive of nonsurgical resolution of bowel obstruction.¹⁸ Although use of oral contrast did not alter the rate of surgical intervention, it did reduce the overall length of hospital stay in those presenting with small bowel obstruction.

A limitation of CT scanning is its low sensitivity (<50%) in the detection of low-grade or partial small bowel obstruction. A subtle transition zone may be difficult to identify in the axial images obtained during CT scanning. In such cases, contrast examinations of the small bowel, either *small bowel series* (small bowel follow-through) or *enteroclysis*, can be helpful. For standard small bowel series, contrast is swallowed or instilled into the stomach through a nasogastric (NG) tube. Abdominal radiographs are then taken serially as the contrast travels distally in the intestine. Although barium can be used, water-soluble contrast agents, such as Gastrografin, should be used if the possibility of intestinal perforation exists. These examinations are more labor-intensive and less rapidly performed than CT scanning but may offer greater sensitivity in the detection of luminal and mural etiologies of obstruction, such as primary intestinal tumors. For enteroclysis, 200 to 250 mL of barium followed by 1 to 2 L of a solution of methylcellulose in water is instilled into the proximal jejunum via a long nasoenteric catheter. The double-contrast technique used in enteroclysis permits a better assessment of mucosal surface and detection of relatively small lesions, even through overlapping small bowel loops. Enteroclysis is rarely performed in the acute setting but offers greater sensitivity than small bowel series in the detection of lesions that may be causing partial small bowel obstruction. Recently, CT enteroclysis has been used, and reported to be superior to plain x-ray small bowel contrast studies.

Therapy

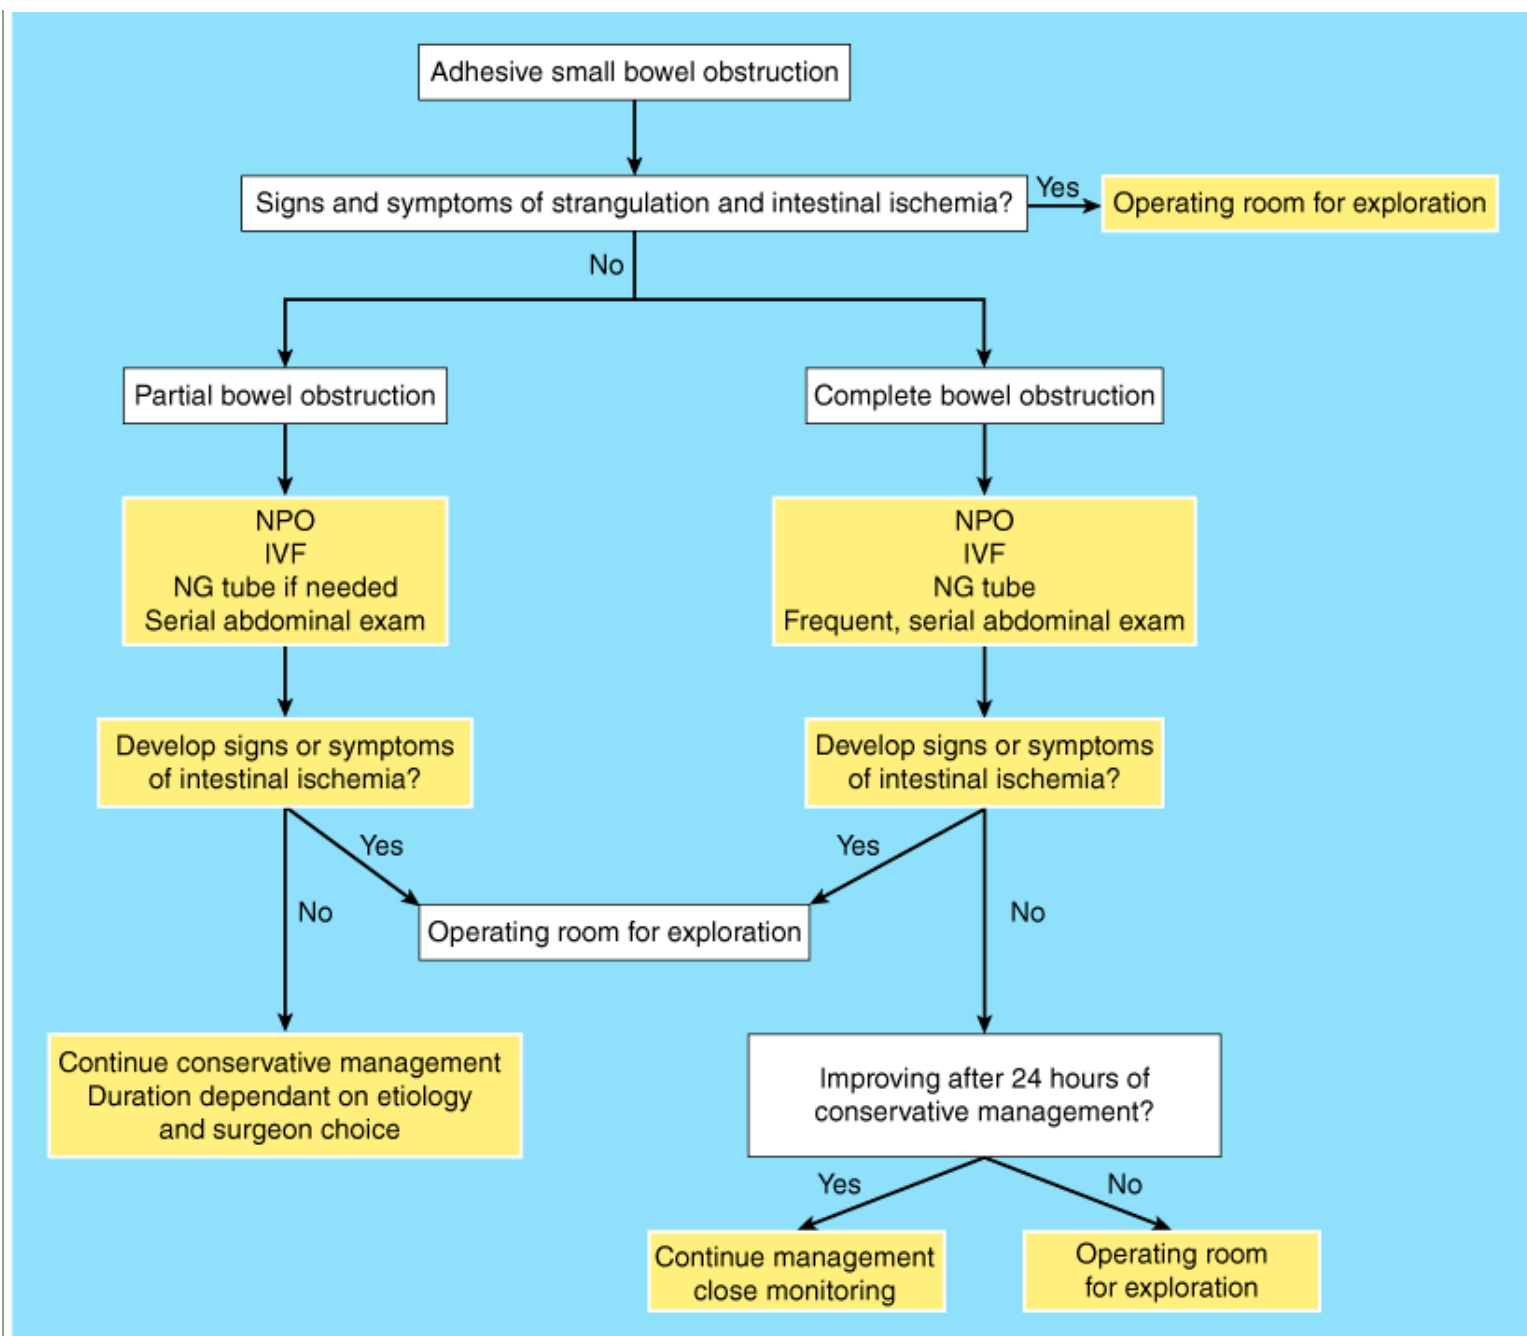

Small bowel obstruction is usually associated with a marked depletion of intravascular volume due to decreased oral intake, vomiting, and sequestration of fluid in bowel lumen and wall. Therefore, fluid resuscitation is integral to treatment. Isotonic fluid should be given intravenously and an indwelling bladder catheter placed to monitor urine output. Central-venous or pulmonary-artery catheter monitoring may be necessary to assist with fluid management, particularly in patients with underlying cardiac disease. Broad-spectrum antibiotics are given by some because of concerns that bacterial translocation may occur in the setting of small bowel obstruction; however, there are no controlled data to support this approach.

The stomach should be continuously evacuated of air and fluid using a NG tube. Effective gastric decompression decreases nausea, distention, and the risk of vomiting and aspiration. Longer nasoenteric tubes, with tips placed into the jejunum or ileum, were favored in the past but are rarely used today, as they are associated with higher complication rates than NG tubes, with no proven greater efficacy in several studies.

The standard therapy for *complete small bowel obstruction* generally has been expeditious surgery, although recently, some have advocated nonoperative approaches in management of these patients, providing closed loop obstruction is ruled out, and there is no evidence of intestinal ischemia. Such patients need to be observed closely and undergo serial exams. The rationale for those favoring early surgical intervention is to minimize the risk for bowel strangulation, which is associated with an increased risk for morbidity and mortality. Clinical signs and currently available laboratory tests and imaging studies do not reliably permit the distinction between patients with simple obstruction and those with strangulated obstruction before the onset of irreversible ischemia. Therefore, the goal is to operate before the onset of irreversible ischemia. Others note, however, that a period of observation and NG decompression, providing no tachycardia, tenderness, or an increase in white cell count is noted, is appropriate (see Fig. 28-15 for a proposed management algorithm).

Fig. 28-15.

Management algorithm of small bowel obstruction. IVF = intravenous fluid; NG = nasogastric; NPO = nothing by mouth.

Conservative therapy, in the form of NG decompression and fluid resuscitation is the initial recommendation for:

1. Partial small bowel obstruction
2. Obstruction occurring in the early postoperative period
3. Intestinal obstruction due to Crohn's disease
4. Carcinomatosis

In *partial obstruction*, progression to strangulation is unlikely to occur and an attempt at nonoperative resolution is warranted. Nonoperative management has been documented to be successful in 65 to 81% of patients with partial small bowel obstruction. Of those successfully treated nonoperatively, only 5 to 15% have been reported to have symptoms that were not substantially improved within 48 hours after initiation of therapy.¹⁹ Therefore, most patients with partial small obstruction whose symptoms do not improve

within 48 hours after initiation of nonoperative therapy should undergo surgery. Patients undergoing nonoperative therapy should be closely monitored for signs suggestive of peritonitis, the development of which would mandate urgent surgery. As stated before in the Diagnosis section above, the administration of hypertonic water-soluble contrast agents, such as Gastrografin used in upper GI and small bowel follow-through examinations, causes a shift of fluid into the intestinal lumen, thereby increasing the pressure gradient across the site of obstruction. This effect may accelerate resolution of partial small bowel obstruction; however, there is less evidence that administration of water-soluble contrast agents increases the probability of an episode of bowel obstruction being successfully managed nonoperatively.¹⁸

Obstruction presenting in *the early postoperative period* has been reported to occur in 0.7% patients undergoing laparotomy.²⁰ Patients undergoing pelvic surgery, especially colorectal procedures, have the greatest risk for developing early postoperative small bowel obstruction. The presence of obstruction should be considered if symptoms of intestinal obstruction occur after the initial return of bowel function or if bowel function fails to return within the expected 3 to 5 days after abdominal surgery. Plain radiographs may demonstrate dilated loops of small intestine with air-fluid levels but are interpreted as normal or nonspecific in up to one third of patients with early postoperative obstruction. CT scanning or small bowel series is often required to make the diagnosis. Obstruction that occurs in the early postoperative period is usually partial and only rarely is associated with strangulation. Therefore, a period of extended nonoperative therapy (2 to 3 weeks) consisting of bowel rest, hydration, and total parenteral nutrition (TPN) administration is usually warranted. However, if complete obstruction is demonstrated or if signs suggestive of peritonitis are detected, expeditious reoperation should be undertaken without delay.

Crohn's disease as a cause of small bowel obstruction is discussed in more detail below in the Crohn's Disease section.

Twenty-five to 33 percent of patients with a history of cancer who present with small bowel obstruction have adhesions as the etiology of their obstruction and therefore should not be denied appropriate therapy.²¹ Even in cases in which the obstruction is related to recurrent malignancy, palliative resection or bypass can be performed. Patients with obvious carcinomatosis pose a difficult challenge, given their limited prognosis. Management must be tailored to an individual patient's prognosis and desires, and relief of the obstruction may be best achieved by a bypass procedure, avoiding a potentially difficult bowel resection.

The operative procedure performed for small bowel obstruction varies according to the etiology of the obstruction. For example, adhesions are lysed, tumors are resected, and hernias are reduced and repaired. Regardless of the etiology, the affected intestine should be examined, and nonviable bowel resected. Criteria suggesting viability are normal color, peristalsis, and marginal arterial pulsations. Usually, visual inspection alone is adequate in judging viability. In borderline cases, a Doppler probe may be used to check for pulsatile flow to the bowel, and arterial perfusion can be verified by visualizing intravenously administered fluorescein dye in the bowel wall under ultraviolet illumination. Neither technique, however, has been found to be superior to clinical judgment. In general, if the patient is hemodynamically stable, short lengths of bowel of questionable viability should be resected and primary anastomosis of the remaining intestine performed. However, if the viability of a large proportion of the intestine is in question, a concerted effort to preserve intestinal tissue should be made. In such situations, the bowel of uncertain viability should be left intact and the patient re-explored in 24 to 48 hours in a "second-look" operation. At that time, definitive resection of nonviable bowel is completed.

Successful laparoscopic surgery for bowel obstruction is being reported with greater frequency.²² Those that undergo successful laparoscopic procedure have a quicker recovery and less postoperative discomfort. Because distended loops of bowel can interfere with adequate visualization, early cases of proximal small bowel obstruction that are likely due to a single adhesive band are best suited for this approach. Presence of bowel distention and multiple adhesions can cause these procedures to be difficult and potentially hazardous. Conversion rate to open surgery can be as high as 33%.²²

Outcomes

Prognosis is related to the etiology of obstruction. The majority of patients who are treated conservatively for adhesive small bowel obstruction do not require future readmissions; less than 20% of such patients will have a readmission over the subsequent 5 years

with another episode of bowel obstruction.²³

The perioperative mortality rate associated with surgery for nonstrangulating small bowel obstruction is less than 5%, with most deaths occurring in elderly patients with significant comorbidities. Mortality rates associated with surgery for strangulating obstruction range from 8 to 25%.

Prevention

With adhesive small bowel obstruction representing a large therapeutic burden, prevention of postoperative adhesions has become an area of great interest. Good surgical technique, careful handling of tissue, and minimal use and exposure of peritoneum to foreign bodies, form the cornerstone of adhesion prevention. These measures alone are often inadequate. In patients undergoing colorectal or pelvic surgery, hospital readmission rates of greater than 30% over the subsequent 10 years have been reported for adhesive small bowel obstruction.²⁴ Use of laparoscopic surgery, when possible, has been strongly promoted. In those undergoing open surgery, several strategies for adhesion prevention have been tried; however, the only therapy that has shown some success has been the use of hyaluronan-based agents, such as Seprafilm. The use of this barrier has been clearly shown to reduce the incidence of postoperative bowel adhesions; however, its effect in actually reducing the incidence of small bowel obstruction remains less well defined.²⁵

ILEUS AND OTHER DISORDERS OF INTESTINAL MOTILITY

Ileus and intestinal pseudo-obstruction designate clinical syndromes caused by impaired intestinal motility and are characterized by symptoms and signs of intestinal obstruction in the absence of a lesion-causing mechanical obstruction. Ileus is a major cause of morbidity in hospitalized patients. Postoperative ileus is the most frequently implicated cause of delayed discharge following abdominal operations; its economic impact has been estimated to be between \$750 million and \$1 billion annually in the United States.²⁶

Ileus is a temporary motility disorder that is reversed with time as the inciting factor is corrected. In contrast, chronic intestinal pseudo-obstruction comprises a spectrum of specific disorders associated with irreversible intestinal dysmotility.

Pathophysiology

Numerous factors capable of impairing intestinal motility, and thus inciting ileus, have been described (Table 28-4). The most frequently encountered factors are abdominal operations, infection and inflammation, electrolyte abnormalities, and drugs.

Table 28-4 Ileus: Common Etiologies
Abdominal surgery
Infection
Sepsis
Intra-abdominal abscess
Peritonitis
Pneumonia
Electrolyte abnormalities
Hypokalemia
Hypomagnesemia
Hypermagnesemia
Hyponatremia
Medications
Anticholinergics
Opiates

Phenothiazines
Calcium channel blockers
Tricyclic antidepressants
Hypothyroidism
Ureteral colic
Retroperitoneal hemorrhage
Spinal cord injury
Myocardial infarction
Mesenteric ischemia

Following most abdominal operations or injuries, the motility of the GI tract is transiently impaired. Among the proposed mechanisms responsible for this dysmotility are surgical stress-induced sympathetic reflexes, inflammatory response mediator release, and anesthetic/analgesic effects; each of which can inhibit intestinal motility. The return of normal motility generally follows a characteristic temporal sequence, with small intestinal motility returning to normal within the first 24 hours after laparotomy and gastric and colonic motility returning to normal by 48 hours and 3 to 5 days, respectively. Because small bowel motility is returned before colonic and gastric motility, listening for bowel sounds is not a reliable indicator that ileus has fully resolved. Functional evidence of coordinated GI motility in the form of passing flatus or bowel movement is a more useful indicator. Resolution of ileus may be delayed in the presence of other factors capable of inciting ileus such as the presence of intra-abdominal abscesses or electrolyte abnormalities.

Chronic intestinal pseudo-obstruction can be caused by a large number of specific abnormalities affecting intestinal smooth muscle, the myenteric plexus, or the extraintestinal nervous system (Table 28-5). Visceral myopathies constitute a group of diseases characterized by degeneration and fibrosis of the intestinal muscularis propria. Visceral neuropathies encompass a variety of degenerative disorders of the myenteric and submucosal plexuses. Both sporadic and familial forms of visceral myopathies and neuropathies exist. Systemic disorders involving the smooth muscle, such as progressive systemic sclerosis and progressive muscular dystrophy, and neurologic diseases such as Parkinson's disease also can be complicated by chronic intestinal pseudo-obstruction. In addition, viral infections such as those associated with cytomegalovirus (CMV) and Epstein-Barr virus can cause intestinal pseudo-obstruction.

Table 28-5 Chronic Intestinal Pseudo-Obstruction: Etiologies
Primary causes
Familial types
Familial visceral myopathies (types I, II, and III)
Familial visceral neuropathies (types I and II)
Childhood visceral myopathies (types I and II)
Sporadic types
Visceral myopathies
Visceral neuropathies
Secondary causes
Smooth muscle disorders
Collagen vascular diseases (e.g., scleroderma)
Muscular dystrophies (e.g., myotonic dystrophy)
Amyloidosis
Neurologic disorders

Chagas' disease, Parkinson's disease, spinal cord injury
Endocrine disorders
Diabetes, hypothyroidism, hypoparathyroidism
Miscellaneous disorders
Radiation enteritis
Pharmacologic causes
(e.g., phenothiazines and tricyclic antidepressants)
Viral infections

Clinical Presentation

The clinical presentation of ileus resembles that of small bowel obstruction. Inability to tolerate liquids and solids by mouth, nausea, and lack of flatus or bowel movements are the most common symptoms. Vomiting and abdominal distention may occur. Bowel sounds are characteristically diminished or absent, in contrast to the hyperactive bowel sounds that usually accompany mechanical small bowel obstruction. The clinical manifestations of chronic intestinal pseudo-obstruction include variable degrees of nausea and vomiting and abdominal pain and distention.

Diagnosis

Routine postoperative ileus should be expected and requires no diagnostic evaluation. If ileus persists beyond 3 to 5 days postoperatively or occurs in the absence of abdominal surgery, diagnostic evaluation to detect specific underlying factors capable of inciting ileus and to rule out the presence of mechanical obstruction is warranted.

Patient medication lists should be reviewed for the presence of drugs, especially opiates, known to be associated with impaired intestinal motility. Measurement of serum electrolytes may demonstrate hypokalemia, hypocalcemia, hypomagnesemia, hypermagnesemia, or other electrolyte abnormalities commonly associated with ileus. Abdominal radiographs often are obtained, but the distinction between ileus and mechanical obstruction may be difficult based on this test alone. In the postoperative setting, CT scanning is the test of choice as it can demonstrate the presence of an intra-abdominal abscess or other evidence of peritoneal sepsis that may be causing ileus and can exclude the presence of complete mechanical obstruction.

The diagnosis of chronic pseudo-obstruction is suggested by clinical features and confirmed by radiographic and manometric studies. Diagnostic laparotomy or laparoscopy with full-thickness biopsy of the small intestine may be required to establish the specific underlying cause.

Therapy

The management of ileus consists of limiting oral intake and correcting the underlying inciting factor. If vomiting or abdominal distention are prominent, the stomach should be decompressed using a NG tube. Fluid and electrolytes should be administered intravenously until ileus resolves. If the duration of ileus is prolonged, TPN may be required.

Given the frequency of postoperative ileus and its financial impact, a large number of investigations have been conducted to define strategies to reduce its duration. Although often recommended, the use of early ambulation and routine NG intubation has not been demonstrated to be associated with earlier resolution of postoperative ileus. There is some evidence that early postoperative feeding protocols are generally well tolerated, reduce postoperative ileus, and can result in a shorter hospital stay.²⁷ The administration of NSAIDs such as ketorolac and concomitant reductions in opioid dosing have been shown to reduce the duration of ileus in most studies. Similarly, the use of perioperative thoracic epidural anesthesia/analgesia with regimens containing local anesthetics combined with limitation or elimination of systemically administered opioids have been shown to reduce duration of postoperative ileus, although they have not reduced the overall length of hospital stay.²⁸ Interestingly, recent data have suggested that limiting intra and

postoperative fluid administration can also result in reduction of postoperative ileus, and shortened hospital stay. Table 28-6 summarizes some of the measures used to minimize postoperative ileus.

Table 28-6 Measures to Reduce Postoperative Ileus
Intraoperative measures
Minimize handling of the bowel
Laparoscopic approach, if possible
Avoid excessive intraoperative fluid administration
Postoperative measures
Early enteral feeding
Epidural anesthesia, if indicated
Avoid excessive IV fluid administration
Correct electrolyte abnormalities
Consider μ -opioid antagonists

Most other pharmacologic agents, including prokinetic agents, are associated with efficacy-toxicity profiles that are too unfavorable to warrant routine use. Recently, administration of alvimopan, a novel peripherally active μ -opioid receptor antagonist with limited oral absorption, has been shown to reduce duration of postoperative ileus, hospital stay, and rate of readmissions in several prospective, randomized, placebo-controlled trials, and the subsequent meta-analysis.³⁰

The therapy for patients with chronic intestinal pseudo-obstruction focuses on palliation of symptoms as well as fluid, electrolyte, and nutritional management. Surgery should be avoided, if at all possible. No standard therapies are curative or delay the natural history of any of the specific disorders causing intestinal pseudo-obstruction. Prokinetic agents, such as metoclopramide and erythromycin, are associated with poor efficacy. Cisapride has been associated with palliation of symptoms; however, because of cardiac toxicity and reported deaths, this agent is restricted to compassionate use.

Patients with refractory disease may require strict limitation of oral intake and long-term TPN administration. Despite these measures, some patients will continue to have severe abdominal pain or such copious intestinal secretions that vomiting and fluid and electrolyte losses remain substantial. These patients may require a decompressive gastrostomy or an extended small bowel resection to remove abnormal intestine. Small intestinal transplantation has been applied in these patients with increasing frequency; the ultimate role of this modality remains to be defined.

CROHN'S DISEASE

Crohn's disease is a chronic, idiopathic transmural inflammatory disease with a propensity to affect the distal ileum, although any part of the alimentary tract can be involved. Estimates of the incidence of Crohn's disease in the United States have ranged from 3.6 to 8.8 per 100,000, with recent studies suggesting a prevalence of about 200 cases per 100,000.³¹ A dramatic increase in incidence in the United States was observed to occur from the mid-1950s through the early 1970s. Incidence rates have been stable since the 1980s. Substantial regional variations in incidence have been observed, with the highest incidences reported to exist in northern latitudes. The incidence of Crohn's disease varies among ethnic groups within the same geographic region. For example, members of the Eastern European Ashkenazi Jewish population are at two- to fourfold higher risk of developing Crohn's disease than members of other populations living in the same location.

Most studies suggest that Crohn's disease is slightly more prevalent in females than in males. The mean age at which patients are diagnosed with Crohn's disease falls in the third decade of life years, with a second smaller peak in the sixth decade of life, giving it a bimodal distribution. The age at diagnosis can, however, range from early childhood through the entire life span.

Both genetic and environmental factors appear to influence the risk for developing Crohn's disease. The relative risk among first-degree relatives of patients with Crohn's disease is 14 to 15 times higher than that of the general population. Approximately one in five patients with Crohn's disease will report having at least one affected relative. The concordance rate among monozygotic twins is as high as 67%; however, Crohn's disease is not associated with simple mendelian inheritance patterns. Although there is a tendency within families for either ulcerative colitis or Crohn's disease to be present exclusively, mixed kindreds also occur, suggesting the presence of some shared genetic traits as a basis for both diseases.

Higher socioeconomic status is associated with an increased risk of Crohn's disease. Most studies have found breastfeeding to be protective against the development of Crohn's disease. Crohn's disease is more prevalent among smokers. Furthermore, smoking is associated with the increased risk for both the need for surgery and the risk of relapse after surgery for Crohn's disease.

Pathophysiology

Crohn's disease is characterized by sustained inflammation. Whether this inflammation represents an appropriate response to a yet unrecognized pathogen or an inappropriate response to a normally innocuous stimulus is unknown. Various hypotheses on the roles of environmental and genetic factors in the pathogenesis of Crohn's disease have been proposed. Many infectious agents have been suggested to be the causative organism of Crohn's disease. Candidate organisms have included chlamydia, *Listeria monocytogenes*, *Pseudomonas* species, reovirus, *Mycobacterium paratuberculosis*, and many others. There is no conclusive evidence that any of these organisms is the causative agent. Studies using animal models suggest that in a genetically susceptible host, nonpathogenic, commensal enteric flora are sufficient to induce a chronic inflammatory response resembling that associated with Crohn's disease. In these models, the sustained intestinal inflammation is the result of either abnormal epithelial barrier function or immune dysregulation. Poor barrier function is hypothesized to permit inappropriate exposure of lamina propria lymphocytes to antigenic stimuli derived from the intestinal lumen. In addition, a variety of defects in immune regulatory mechanisms, (e.g., over-responsiveness of mucosal T cells to enteric flora-derived antigens) can lead to defective immune tolerance and sustained inflammation.

Specific genetic defects associated with Crohn's disease in human patients are beginning to be defined. For example, the presence of a locus on chromosome 16 (the so-called *IBD1 locus*) has been linked to Crohn's disease. The IBD1 locus has been identified as the *NOD2* gene.^{32,33} Persons with allelic variants on both chromosomes have a 40-fold relative risk of Crohn's disease compared to those without variant *NOD2* genes. The relevance of this gene to the pathogenesis of Crohn's disease is biologically plausible, as the protein product of the *NOD2* gene mediates the innate immune response to microbial pathogens. Other putative IBD loci have been identified on other chromosomes (IBD2 on chromosome 12q, and IBD3 on chromosome 6), and are under investigation.

Pathology

Although the pathologic hallmark of Crohn's disease is focal, transmural inflammation of the intestine, a spectrum of pathologic lesions can be present. The earliest lesion characteristic of Crohn's disease is the aphthous ulcer. These superficial ulcers are up to 3 mm in diameter and are surrounded by a halo of erythema. In the small intestine, aphthous ulcers typically arise over lymphoid aggregates. Granulomas are highly characteristic of Crohn's disease and are reported to be present in up to 70% of intestinal specimens obtained during surgical resection. These granulomas are noncaseating and can be found in both areas of active disease and apparently normal intestine, in any layer of the bowel wall, and in mesenteric lymph nodes.

As disease progresses, aphthae coalesce into larger, stellate-shaped ulcers. Linear or serpiginous ulcers may form when multiple ulcers fuse in a direction parallel to the longitudinal axis of the intestine. With transverse coalescence of ulcers, a cobblestoned appearance of the mucosa may arise.

With advanced disease, inflammation can be transmural. Serosal involvement results in adhesion of the inflamed bowel to other loops of bowel or other adjacent organs. Transmural inflammation also can result in fibrosis with stricture formation, intra-abdominal

abscesses, fistulas, and, rarely, free perforation. Inflammation in Crohn's disease can affect discontinuous portions of intestine: so-called *skip lesions* that are separated by intervening normal appearing intestine.

A feature of Crohn's disease that is grossly evident and helpful in identifying affected segments of intestine during surgery is the presence of *fat wrapping*, which represents encroachment of mesenteric fat onto the serosal surface of the bowel (Fig. 28-16). This finding is virtually pathognomonic of Crohn's disease. The presence of fat wrapping correlates well with the presence of underlying acute and chronic inflammation.

Crohn's disease. This intraoperative photograph demonstrates encroachment of mesenteric fat onto the serosal surface of the intestine ("fat wrapping") that is characteristic of intestinal segments affected by active Crohn's disease.

Features that allow for differentiation between Crohn's disease of the colon and ulcerative colitis include the layers of the bowel wall affected (inflammation in ulcerative colitis is limited to the mucosa and submucosa but may involve the full thickness of the bowel wall in Crohn's disease) and the longitudinal extent of inflammation (inflammation is continuous and characteristically affects the rectum in ulcerative colitis but may be discontinuous and spare the rectum in Crohn's disease). In the absence of full expression of features of advanced disease, Crohn's colitis can sometimes be difficult to distinguish from ulcerative colitis. It is also important to remember that, although ulcerative colitis is a disease of the colon, it can be associated with inflammatory changes in the distal ileum (backwash ileitis).

Clinical Presentation

The most common symptoms of Crohn's disease are abdominal pain, diarrhea, and weight loss. However, the clinical features are highly variable among individual patients and depend on which segment(s) of the GI tract is (are) predominantly affected, the intensity of inflammation, and the presence or absence of specific complications. Patients with Crohn's disease can be classified by their predominant clinical manifestation as having primarily (a) fibrostenotic disease, (b) fistulizing disease, and (c) aggressive inflammatory disease. There is substantial overlap among these disease patterns in individual patients, however. The onset of symptoms is insidious, and, once present, their severity follows a waxing and waning course. Constitutional symptoms, particularly weight loss and fever, or growth retardation in children, may also be prominent and are occasionally the sole presenting features of Crohn's disease.

The disease affects the small bowel in 80% of cases, and colon alone in 20%. In those with small bowel disease, the majority have ileocecal disease. The small bowel alone is affected in 15 to 30% of patients. Isolated perineal and anorectal disease occurs in 5 to 10% of affected patients. Uncommon sites of involvement include the esophagus, stomach, and duodenum.

An estimated one fourth of all patients with Crohn's disease will have an extraintestinal manifestation of their disease. One fourth of those affected will have more than one manifestation. Many of these complications are common to both Crohn's disease and ulcerative colitis, although as a whole, they are more prevalent among patients with Crohn's disease than those with ulcerative colitis. The most common extraintestinal manifestations are listed in Table 28-7. The clinical severity of some of these manifestations, such as erythema nodosum and peripheral arthritis, is correlated with the severity of intestinal inflammation. The severity of other manifestations, such as pyoderma gangrenosum and ankylosing spondylitis, bears no apparent relationship to the severity of intestinal inflammation.

Diagnosis

The diagnosis usually is established with endoscopic findings in a patient with a compatible clinical history. The diagnosis should be

considered in those presenting with acute or chronic abdominal pain, especially when localized to the right lower quadrant, chronic diarrhea, evidence of intestinal inflammation on radiography or endoscopy, the discovery of a bowel stricture or fistula arising from the bowel, and evidence of inflammation or granulomas on intestinal histology. Disorders associated with clinical presentations that resemble those of Crohn's disease include ulcerative colitis, functional bowel disorders such as irritable bowel syndrome, mesenteric ischemia, collagen vascular diseases, carcinoma and lymphoma, diverticular disease, and infectious enteritidis. These infectious enteritides are most frequently diagnosed in immunocompromised patients but can also occur in patients with normal immune function. Acute ileitis caused by *Campylobacter* and *Yersinia* species can be difficult to distinguish from that caused by an acute presentation of Crohn's disease. Typhoid enteritis caused by *Salmonella typhosa* can lead to overt intestinal bleeding and perforation, most often affecting the terminal ileum. The distal ileum and cecum are the most common sites of intestinal involvement by infection due to *Mycobacterium tuberculosis*. This condition can result in intestinal inflammation, strictures, and fistula formation, similar to those seen in Crohn's disease. CMV can cause intestinal ulcers, bleeding, and perforation.

No single symptom, sign, or diagnostic test establishes the diagnosis of Crohn's disease. Instead, the diagnosis is based on a complete assessment of the clinical presentation with confirmatory findings derived from radiographic, endoscopic, and, in most cases, pathologic tests. Colonoscopy with intubation of terminal ileum is the main diagnostic tool and can reveal focal ulcerations adjacent to areas of normal appearing mucosa along with polypoid mucosal changes that give a "cobblestone appearance." Skip areas of involvement are typical with segments of normal appearing bowel interrupted by large areas of obvious disease; this pattern is different from the continuous involvement in ulcerative colitis. Pseudopolyps, as seen in ulcerative colitis, are also often present. Contrast examinations of the small bowel and colon may reveal strictures or networks of ulcers and fissures. CT scanning may reveal intra-abdominal abscesses and is useful in acute presentations to rule out the presence of other intra-abdominal disorders. Esophagogastroduodenoscopy (EGD) is done for disease of the proximal alimentary tract. Because Crohn's disease often affects the small bowel, which is difficult to image, capsule endoscopy has been increasingly used to make this diagnosis (Fig. 28-17).³⁴

Crohn's disease. This image was captured by a wireless capsule endoscope as it was traveling through the small intestine. It demonstrates a superficial ulceration in the small bowel consistent with Crohn's disease.

(Courtesy of Dr. Anne C. Travis, Division of Gastroenterology, Brigham and Women's Hospital.)

Several antibodies also have been identified in patients with inflammatory bowel disease, which may have diagnostic value. The most commonly tested antibodies are perinuclear antineutrophil cytoplasmic antibody (pANCA) and anti-*Saccharomyces cerevisiae* antibody (ASCA). ASCA+/pANCA- is associated with a diagnosis of Crohn's disease, while ASCA-/pANCA+ is correlated with ulcerative colitis. Although these antibody tests are commercially available, their widespread use has been hampered by low test sensitivities.

Because of the insidious, and often, nonspecific presentation, the diagnosis of Crohn's disease typically is made only after symptoms have been present for several years. However, in acute presentations, the diagnosis is sometimes made intraoperatively or during surgical evaluation. The initial manifestation of Crohn's disease can consist of right lower quadrant abdominal mimicking the presentation of acute appendicitis. In patients with this presentation, Crohn's disease can be discovered for the first time during laparotomy or laparoscopy performed for presumed appendicitis. In some patients, the initial manifestation of Crohn's disease is an acute abdomen related to small bowel obstruction, intra-abdominal abscess, or free intestinal perforation. In other patients, perianal abscesses and fistulas requiring surgical therapy may be the first manifestation of Crohn's disease.

Therapy

Because no curative therapies are available for Crohn's disease, the goal of treatment is to palliate symptoms rather than to achieve cure. Medical therapy is used to induce and maintain disease remission. Surgery is reserved for specific indications described below in the Surgical Therapy section. In addition, nutritional support in the form of aggressive enteral regimens or, if necessary, parenteral nutrition, is used to manage the malnutrition that is common in patient's with Crohn's disease.

Medical Therapy

Pharmacologic agents used to treat Crohn's disease include antibiotics, aminosalicylates, corticosteroids, and immunomodulators. Antibiotics have an adjunctive role in the treatment of infectious complications associated with Crohn's disease. They also are used to treat patients with perianal disease, enterocutaneous fistulas, and active colonic disease.

Most studies have shown oral 5-aminosalicylic acid (5-ASA) drugs (e.g., mesalamine) to be superior to placebo in inducing disease remission. Its efficacy in the maintenance of remission is less clear. Aminosalicylates are associated with minimal toxicity and are available in a variety of formulations that allow for their delivery to specific regions of the alimentary tract. In Crohn's disease, sulfasalazine, the parent compound of 5-ASA and widely used in ulcerative colitis, has been shown to be less effective than 5-ASA.

Orally administered glucocorticoids are used to treat patients with mildly to moderately severe disease that does not respond to aminosalicylates. Patients with severe active disease usually require IV administration of glucocorticoids. Although glucocorticoids are effective in inducing remission, they are ineffective in preventing relapse and their adverse side-effect profile makes long-term use hazardous. Therefore, they should be tapered once remission is achieved. Some patients are unable to undergo glucocorticoid tapering without suffering recurrence of symptoms. Such patients are said to have *steroid dependence*. For these patients, along with those who do not respond to steroids at all (steroid resistant), use of immune modulators should be considered.

The thiopurine antimetabolites azathioprine and its active metabolite, 6-mercaptopurine, have demonstrated efficacy in inducing remission, in maintaining remission, and in allowing for glucocorticoid tapering in glucocorticoid-dependent patients. A response to the medications is usually observed in 3 to 6 months. There is also some evidence that they decrease the risk of relapse after intestinal resection for Crohn's disease. These agents are relatively safe but can induce bone marrow suppression and promote infectious complications. For patients who do not respond to the thiopurines, methotrexate is an alternative that usually is given intramuscularly before switching to oral form after achieving symptomatic control. There is little role for cyclosporine in Crohn's disease; its efficacy/toxicity profile in this disease is poor.

Infliximab is a chimeric monoclonal anti-tumor necrosis factor alpha antibody that has been shown to have efficacy in inducing remission and in promoting closure of enterocutaneous fistulas.³⁵ It generally is used for patients resistant to standard therapy to help taper steroid dosage. Infliximab generally is well tolerated but should not be used in patients with ongoing septic processes, such as undrained intra-abdominal abscesses.

For patients with perianal disease, antibiotic therapy with metronidazole or ciprofloxacin is the primary step. Two to 4 weeks of therapy is needed before improvements are seen, and often long-term therapy is required to prevent relapse. In cases of relapse, azathioprine can be considered. In patients with fistulas, infliximab and azathioprine are drugs of choice.

Surgical Therapy

Fifty to 70% of patients with Crohn's disease will ultimately require at least one surgical intervention for their disease.^{36,37} Surgery generally is reserved for patients whose disease is unresponsive to aggressive medical therapy or who develop complications of their disease (Table 28-8). Failure of medical management may be the indication for surgery if symptoms persist despite aggressive therapy for several months or if symptoms recur whenever aggressive therapy is tapered. Surgery should be considered if medication-induced complications arise, specifically corticosteroid-related complications, such as cushingoid features, cataracts, glaucoma, systemic hypertension, compression fractures, or aseptic necrosis of the femoral head. Growth retardation constitutes an indication for surgery in 30% of children with Crohn's disease.

Table 28-8 Indications for Surgical Intervention in Crohn's Disease

Recurrence of symptoms when high-dose steroids are tapered
Drug induced complications (Cushing's disease, hypertension)
Development of disease complications
Obstruction
Perforation
Complicated fistulas
Hemorrhage
Malignancy risk

One of the most common indications for surgical intervention is intestinal obstruction. Abscesses and fistulas frequently are encountered during operations performed for intestinal obstruction in these patients, but are rarely the only indication for surgery. Most abscesses are amenable to percutaneous drainage and fistulas unless associated with symptoms or metabolic derangements do not require surgical intervention. Less common complications that require surgical intervention are acute GI hemorrhage, perforations, and development of cancer.

Although most commonly, surgery for Crohn's disease is planned, an uncommon, but not rare, scenario is the intraoperative discovery of inflammation limited to the terminal ileum during operations performed for presumed appendicitis. This scenario can result from an acute presentation of Crohn's disease or from acute ileitis caused by bacteria such as *Yersinia* or *Campylobacter*. Both conditions should be treated medically; ileal resection is generally not indicated. However, the appendix, even if normal appearing, should be removed (unless the cecum is inflamed, increasing the potential morbidity of this procedure) to eliminate appendicitis from the differential diagnosis of abdominal pain in these patients, particularly those with Crohn's disease who may be destined to have recurring symptoms.

When the diagnosis of Crohn's disease is known and surgery planned, thorough examination of the entire intestine should be performed. The presence of active disease is suggested by thickening of the bowel wall, narrowing of the lumen, serosal inflammation and coverage by creeping fat, and thickening of the mesentery. Skip lesions are present in approximately 20% of cases and should be sought. The length of uninvolved small intestine should be noted.

Segmental intestinal resection of grossly evident disease followed by primary anastomosis is the usual procedure of choice. Microscopic evidence of Crohn's disease at the resection margins does not compromise a safe anastomosis, and frozen-section analysis of resection margins is unnecessary. In a randomized prospective trial, the effects of achieving 2-cm resection margins beyond grossly evident disease were compared with achieving 12-cm resection margins.³⁸ There were no evident differences with respect to clinical recurrence rates or anastomotic recurrences. Recurrence rates were similar whether margins were histologically free of or involved with Crohn's disease.

An alternative to segmental resection for obstructing lesions is stricturoplasty (Fig. 28-18). This technique allows for preservation of intestinal surface area and is especially well suited to patients with extensive disease and fibrotic strictures who may have undergone previous resection and are at risk for developing short bowel syndrome. In this technique, the bowel is opened longitudinally to expose the lumen. Any intraluminal ulcerations should be biopsied to rule out the presence of neoplasia. Depending on the length of the stricture, the reconstruction can be fashioned in a manner similar to the Heinecke-Mikulicz pyloroplasty (for strictures less than 12 cm in length) or the Finney pyloroplasty (for longer strictures as much as 25 cm in length). For longer strictures, variations on the standard stricturoplasty, namely the side-to-side isoperistaltic enteroenterostomy, have been advocated, and used for strictures with mean lengths of 50 cm.³⁹ Stricturoplasty sites should be marked with metallic clips to facilitate their identification on radiographs and during subsequent operations. Stricturoplasty is associated with recurrence rates that are no different from those associated with segmental resection. Because the affected bowel is left in situ rather than resected, there is the potential for cancer developing at the stricturoplasty site. However, as data on this complication are limited to anecdotes, this risk remains a theoretical one. Stricturoplasty

is contraindicated in patients with intra-abdominal abscesses or intestinal fistulas. The presence of a solitary stricture relatively close to a segment for which resection is planned is a relative contraindication. In general, stricturoplasty is performed in cases where single or multiple strictures are identified in diffusely involved segments of bowel, or where previous resections have been performed, and maintenance of intestinal length is of great importance.

Fig. 28-18.

Stricturoplasty. The wall of the strictured bowel is incised longitudinally. Reconstruction is performed by closing the defect transversely in a manner similar to the Heinecke-Mikulicz pyloroplasty for short strictures (**A**), or the Finney pyloroplasty for longer strictures (**B**).

Intestinal bypass procedures are sometimes required in the presence of intramesenteric abscesses or if the diseased bowel is coalesced in the form of a dense inflammatory mass, making its mobilization unsafe. Bypass procedures (gastrojejunostomy) also are used in the presence of duodenal strictures, for which stricturoplasty and segmental resection can be technically difficult.

Since the 1990s, laparoscopic surgical techniques have been applied to patients with Crohn's disease. The inflammatory changes associated with Crohn's disease, such as thickened and foreshortened mesentery, obliterated tissue planes, and friable tissues with engorged vasculature, can make a laparoscopic approach challenging. Theoretical advantages of laparoscopic surgery include less postoperative pain, earlier return of normal intestinal function that allows for shorter hospital stay, and superior cosmesis. In a prospective randomized trial comparing laparoscopic and open surgery for Crohn's disease conducted at a single institution, laparoscopic surgery was associated with faster recovery of pulmonary function, fewer complications, and shorter length of hospital stay.⁴⁰ A meta-analysis of subsequent studies has confirmed that laparoscopic surgery for Crohn's disease is associated with less postoperative pain, shorter duration of ileus, and a shorter hospital stay. The rates of disease recurrence were similar between the two groups.⁴¹

Outcomes

Overall complication rates following surgery for Crohn's disease range from 15 to 30%. Wound infections, postoperative intra-abdominal abscesses, and anastomotic leaks account for most of these complications.

Most patients whose disease is resected eventually develop recurrence. If recurrence is defined endoscopically, 70% recur within 1 year of a bowel resection and 85% by 3 years.⁴² Clinical recurrence, defined as the return of symptoms confirmed as being due to Crohn's disease, affects 60% of patients by 5 years and 94% by 15 years after intestinal resection. Reoperation becomes necessary in approximately one third of patients by 5 years after the initial operation, with a median time to reoperation of 7 to 10 years.⁴³

INTESTINAL FISTULAS

A *fistula* is defined as an abnormal communication between two epithelialized surfaces. The communication occurs between two parts of the GI tract or adjacent organs in an *internal fistula* (e.g., enterocolonic fistula or colovesicular fistula). An *external fistula* (e.g., enterocutaneous fistula or rectovaginal fistula) involves the skin or another external surface epithelium. Enterocutaneous fistulas that drain less than 200 mL of fluid per day are known as *low-output fistulas*, whereas those that drain more than 500 mL of fluid per day are known as *high-output fistulas*.

More than 80% of enterocutaneous fistulas represent iatrogenic complications that occur as the result of enterotomies or intestinal anastomotic dehiscences. Fistulas that arise spontaneously without antecedent iatrogenic injury are usually manifestations of progression of underlying Crohn's disease or cancer.

Pathophysiology

The manifestations of fistulas depend on which structures are involved. Low-resistance enteroenteric fistulas, which allow luminal contents to bypass a significant proportion of the small intestine, may result in clinically significant malabsorption. Enterovesicular fistulas often cause recurrent urinary tract infections. The drainage emanating from enterocutaneous fistulas are irritating to the skin and cause excoriation. The loss of enteric luminal contents, particularly from high-output fistulas originating from the proximal small intestine, results in dehydration, electrolyte abnormalities, and malnutrition.

Fistulas have the potential to close spontaneously. Factors inhibiting spontaneous closure, however, include malnutrition, sepsis, inflammatory bowel disease, cancer, radiation, obstruction of the intestine distal to the origin of the fistula, foreign bodies, high output, short fistulous tract (<2 cm), and epithelialization of the fistula tract (Table 28-9).

Presence of a foreign body (e.g., meshes or sutures)

Epithelialization of fistula tract
Fistula tract <2 cm
Distal obstruction to the fistula site

Clinical Presentation

Iatrogenic enterocutaneous fistulas usually become clinically evident between the fifth and tenth postoperative days. Fever, leukocytosis, prolonged ileus, abdominal tenderness, and wound infection are the initial signs. The diagnosis becomes obvious when drainage of enteric material through the abdominal wound or through existing drains occurs. These fistulas are often associated with intra-abdominal abscesses.

Diagnosis

CT scanning following the administration of enteral contrast is the most useful initial test. Leakage of contrast material from the intestinal lumen can be observed. Intra-abdominal abscesses should be sought and drained percutaneously. If the anatomy of the fistula is not clear on CT scanning, a small bowel series or enteroclysis examination can be obtained to demonstrate the fistula's site of origin in the bowel. This study also is useful to rule out the presence of intestinal obstruction distal to the site of origin. Occasionally, contrast administered into the intestine does not demonstrate the fistula tract. A *fistulogram*, in which contrast is injected under pressure through a catheter placed percutaneously into the fistula tract, may offer greater sensitivity in localizing the fistula origin.

Therapy

The treatment of enterocutaneous fistulas should proceed through an orderly sequence of steps.⁴⁴

1. Stabilization. Fluid and electrolyte resuscitation is begun. Nutrition is provided, usually through the parenteral route initially. Sepsis is controlled with antibiotics and drainage of abscesses. The skin is protected from the fistula effluent with ostomy appliances or fistula drains.
2. Investigation. The anatomy of the fistula is defined using the studies described above in the Diagnosis section.
3. Decision. The available treatment options are considered, and a timeline for conservative measures determined.
4. Definitive management. This entails the surgical procedure, and requires appropriate preoperative planning and surgical experience.
5. Rehabilitation.

The overall objectives are to increase the probability of spontaneous closure. Nutrition and time are the key components of this approach. Most patients will require TPN; however, a trial of oral or enteral nutrition should be attempted in patients with low-output fistulas originating from the distal intestine. The somatostatin analogue octreotide is a useful adjunct, particularly in patients with high-output fistulas; its administration reduces the volume of fistula output, thereby facilitating fluid and electrolyte management. Further, octreotide may accelerate the rate at which fistulas close; however, its administration has not clearly been demonstrated to increase the probability of spontaneous closure.

TIMING OF SURGICAL INTERVENTION

Most surgeons would pursue 2 to 3 months of conservative therapy before considering surgical intervention. This approach is based on evidence that 90% of fistulas that are going to close, close within a 5-week interval, and also that surgical interventions after this time period are associated with better outcomes and lower morbidity.⁴⁵

If the fistula fails to resolve during this period, surgery may be required during which the fistula tract, together with the segment of intestine from which it originates, should be resected. Simple closure of the opening in the intestine from which the fistula originates is associated with high recurrence rates. Patients with intestinal fistulas typically have extensive and dense intra-abdominal adhesions.

As a result, operations performed for nonhealing fistulas can present formidable challenges. Successful applications of alternative therapies to close intestinal fistulas, such as the use of biologic sealants, have been reported. The indications for their use remain to be defined.

Outcomes

Enterocutaneous fistulas are associated with a 10 to 15% mortality rate, mostly related to sepsis or underlying disease. Overall, 50% of intestinal fistulas close spontaneously. A useful mnemonic designates factors that inhibit spontaneous closure of intestinal fistulas: "FRIEND" (*F*oreign body within the fistula tract, *R*adiation enteritis, *I*nfection/Inflammation at the fistula origin, *E*pithelialization of the fistula tract, *N*eoplasm at the fistula origin, *D*istal obstruction of the intestine) (Table 28-10). Surgery for fistulas is associated with a greater than 50% morbidity rate, including a 10% recurrence rate.

Table 28-10 Features of Small Intestinal Malignancies			
Tumor Type	Cell of Origin	Frequency ^a	Predominant Site
Adenocarcinoma	Epithelial cell	35–50%	Duodenum
Carcinoid	Enterochromaffin cell	20–40%	Ileum
Lymphoma	Lymphocyte	10–15%	Ileum
GIST	?Interstitial cell of Cajal	10–15%	—

^a Frequencies given as percentages of small intestinal malignancies comprised by each of the tumor types. GI stromal tumors (GISTs) display no regional variation in prevalence within the small intestine.

SMALL BOWEL NEOPLASMS

Adenomas are the most common benign neoplasm of the small intestine. Other benign tumors include fibromas, lipomas, hemangiomas, lymphangiomas, and neurofibromas. The prevalence of small bowel tumors identified at autopsy is 0.2 to 0.3%, which is significantly higher than the rate of operation for small bowel tumors. This suggests that the majority of small bowel tumors are asymptomatic. These lesions are most frequently encountered in the duodenum as incidental findings during EGD examinations (Fig. 28-19). Their reported prevalence of duodenal polyps, as detected during EGD performed for other reasons, ranges from 0.3 to 4.6%.⁴⁶

Duodenal polyp. This polyp was incidentally encountered during esophagogastroduodenoscopy. It was biopsied and found to be an adenoma.

Benign neoplasms account for 30 to 50% of small bowel tumors and include adenomas, lipomas, hemartomas, and hemangiomas. Primary small bowel cancers are rare, with an estimated incidence of 5300 cases per year in the United States.⁴⁷ Among small bowel cancers, adenocarcinomas comprise 35 to 50% of all cases, carcinoid tumors comprise 20 to 40%, and lymphomas comprise approximately 10 to 15 percent. Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors arising in the small intestine and comprise up to 15% of small bowel malignancies. GISTs comprise the vast majority of tumors that were formerly classified as leiomyomas, leiomyosarcomas, and smooth muscle tumors of the intestine. The small intestine is frequently affected by metastases from or local invasion by cancers originating at other sites. Melanoma, in particular, is associated with a propensity for metastasis to the small intestine.

Most patients with small intestinal cancers are in their fifth or sixth decade of life. Reported risk factors for developing small intestinal cancers include consumption of red meat, ingestion of smoked or cured foods, Crohn's disease, celiac sprue, hereditary nonpolyposis colorectal cancer, familial adenomatous polyposis (FAP), and Peutz-Jeghers syndrome.

Pathophysiology

The small intestine contains more than 90% of the mucosal surface area of the GI tract, but only 1.1 to 2.4% of all GI malignancies. Proposed explanations for the low frequency of small intestinal neoplasms include (a) dilution of environmental carcinogens in the liquid chyme present in the small intestinal lumen, (b) rapid transit of chyme, limiting the contact time between carcinogens and the intestinal mucosa, (c) a relatively low concentration of bacteria in small intestinal chyme and, therefore, a relatively low concentration of carcinogenic products of bacterial metabolism, (d) mucosal protection by secretory IgA and hydrolases such as benzpyrene hydroxylase that may render carcinogens less active, and (e) efficient epithelial cellular apoptotic mechanisms that serve to eliminate clones harboring genetic mutations.

Recent advances have begun to clarify the molecular pathogenesis of small intestinal adenocarcinomas and GISTs; there has been less progress with respect to the pathogenesis of the other small intestinal malignancies (see Table 28-10). Small intestinal adenocarcinomas are believed to arise from pre-existing adenomas through a sequential accumulation of genetic abnormalities in a model similar to that described for the pathogenesis of colorectal cancer. Adenomas are histologically classified as tubular, villous, and tubulovillous. Tubular adenomas have the least aggressive features. Villous adenomas have the most aggressive features and tend to be large, sessile, and located in the second portion of the duodenum. Malignant degeneration has been reported to be present in up to 45% of villous adenomas by the time of diagnosis. Patients with FAP have a nearly 100% cumulative lifetime risk of developing duodenal adenomas that have the potential to undergo malignant transformation. The risk of duodenal cancer in these patients is over 100-fold that in the general population. Indeed, duodenal cancer is the leading cause of cancer-related death among patients with FAP who have undergone colectomy. Patients with Peutz-Jeghers syndrome develop hamartomatous polyps; however, these polyps can contain adenomatous foci that can undergo malignant transformation (Fig. 28-20).

A defining feature of GISTs is their gain of function mutation of protooncogene KIT, a receptor tyrosine kinase. Pathologic KIT signal transduction is believed to be a central event in GIST pathogenesis.⁴⁸ The majority of GISTs have activating mutations in the *c-kit* protooncogene, which cause KIT to become constitutively activated, presumably leading to persistence of cellular growth or survival signals. Because the interstitial cells of Cajal normally express KIT, these cells have been implicated as the cell of origin for GISTs. KIT expression is assessed by staining the tissues for CD117 antigen, which is part of the KIT receptor, and present in 95% of GISTs.

Clinical Presentation

Most small intestinal neoplasms are asymptomatic until they become large. Partial small bowel obstruction, with associated symptoms of crampy abdominal pain and distention, nausea, and vomiting, is the most common mode of presentation. Obstruction can be the result of either luminal narrowing by the tumor itself or intussusception, with the tumor serving as the lead point. Hemorrhage, usually indolent, is the second most common mode of presentation.

Physical examination may be unrevealing. Up to 25% of patients with small intestinal malignancies are reported to have a palpable abdominal mass. Findings of intestinal obstruction are reported to be present in 25% of patients. Fecal occult blood test may be positive. Jaundice secondary to biliary obstruction or hepatic metastasis may be present. Cachexia, hepatomegaly, and ascites may be present with advanced disease.

Although the clinical presentation usually is not specific for tumor type, some general comments are appropriate. Adenocarcinomas, as well as adenomas (from which most are believed to arise), are most commonly found in the duodenum, except in patients with Crohn's disease, in whom most are found in the ileum. Lesions in the periampullary location can cause obstructive jaundice or pancreatitis. Adenocarcinomas located in the duodenum tend to be diagnosed earlier in their progression than those located in the jejunum or ileum, which are rarely diagnosed before the onset of locally advanced or metastatic disease.

Carcinoid tumors of the small intestine also are usually diagnosed after the development of metastatic disease. These tumors are associated with a more aggressive behavior than the more common appendiceal carcinoid tumors. Approximately 25 to 50% of patients with carcinoid tumor-derived liver metastases will develop manifestations of the carcinoid syndrome. These manifestations include diarrhea, flushing, hypotension, tachycardia, and fibrosis of the endocardium and valves of the right heart. Candidate tumor-derived mediators of the carcinoid syndrome such as serotonin, bradykinin, and substance P undergo nearly complete metabolism during first passage through the liver. As a result, symptoms of carcinoid syndrome are rare in the absence of liver metastases.

Lymphoma may involve the small intestine primarily or as a manifestation of disseminated systemic disease. Primary small intestinal lymphomas are most commonly located in the ileum, which contains the highest concentration of lymphoid tissue in the intestine. Although partial small bowel obstruction is the most common mode of presentation, 10% of patients with small intestinal lymphoma present with bowel perforation.

Sixty to 70% of GISTs are located in the stomach. The small intestine is the second most common site, containing 25 to 35% of GISTs. There appears to be no regional variation in the prevalence of GISTs within the small intestine. GISTs have a greater propensity to be associated with overt hemorrhage than the other small intestinal malignancies (Fig. 28-21).

Fig. 28-21.

Jejunal GI stromal tumor. This patient presented with overt obscure GI bleeding and was found to have a 7-cm jejunal GI stromal tumor. The picture represents the laparoscopic view of the mass (*black arrow*), arising from the antimesenteric side of the small bowel (*). He underwent a successful laparoscopic resection.

Metastatic tumors involving the small intestine can induce intestinal obstruction and bleeding.

Diagnosis

Because of the absent or nonspecific symptoms associated with most small intestinal neoplasms, these lesions rarely are diagnosed preoperatively. Laboratory tests are nonspecific, with the exception of elevated serum 5-hydroxyindole acetic acid levels in patients with the carcinoid syndrome. Elevated carcinoembryonic antigen levels are associated with small intestinal adenocarcinomas, but only in the presence of liver metastases.

Contrast radiography of the small intestine may demonstrate benign and malignant lesions. Enteroclysis is reported to have a sensitivity of over 90% in the detection of small bowel tumors and is the test of choice, particularly for tumors located in the distal small bowel. Upper GI with small bowel follow-through examinations have reported sensitivities ranging from only 30 to 44%.⁴⁹ CT scanning has low sensitivity for detecting mucosal or intramural lesions, but can demonstrate large tumors and is useful in the staging of intestinal malignancies. Tumors associated with significant bleeding can be localized with angiography or radioisotope-tagged red blood cell scans.

Tumors located in the duodenum can be visualized and biopsied on EGD. In addition, endoscopic ultrasonography can offer additional information such as the layers of the intestinal wall involved by the lesion. Occasionally, the distal ileum can successfully be visualized during colonoscopy. Intraoperative enteroscopy can be used to directly visualize small intestinal tumors beyond the reach of standard endoscopic techniques. Recently, capsule endoscopy and double-balloon endoscopy have been used to evaluate small bowel.

Therapy

Benign neoplasms of the small intestine that are symptomatic should be surgically resected or removed endoscopically, if feasible. Tumors located in the duodenum, including asymptomatic lesions incidentally found during EGD, can pose the greatest therapeutic challenges. These lesions should be biopsied; symptomatic tumors and adenomas, because of their malignant potential, should be removed. In general, duodenal tumors less than 1 cm in diameter are amenable to endoscopic polypectomy. Lesions greater than 2 cm in diameter are technically difficult to remove endoscopically and should therefore be removed surgically. Surgical options include transduodenal polypectomy and segmental duodenal resection. Tumors located in the second portion of the duodenum near the ampulla of Vater may require pancreaticoduodenectomy. Endoscopic ultrasonography may offer utility for duodenal tumors ranging in size between 1 and 2 cm in diameter, with those limited to the mucosa being amenable to endoscopic polypectomy.⁵⁰ Adenomas can recur; therefore, surveillance endoscopy is required after these procedures.

Duodenal adenomas occurring in the setting of FAP require an especially aggressive approach to management. Patients with FAP should undergo screening EGD starting sometime during their second or third decade of life. Adenomas detected should be removed endoscopically, if possible, followed by surveillance endoscopy in 6 months and yearly thereafter, in the absence of recurrence. If surgery is required, pancreaticoduodenectomy generally is necessary because adenomas in patients with FAP tend to be multiple and sessile, with a predilection for the periampullary region. Further, localized resections are complicated by high recurrence rates. Given the potential for recurrences in the duodenal remnant following pylorus preserving pancreaticoduodenectomy, there is a rationale for recommending the application of standard pancreaticoduodenectomy in these patients. However, recurrences have been reported even following this procedure; therefore, continuing surveillance is necessary. For most adenocarcinomas of the duodenum, except those in the distal duodenum, pancreaticoduodenectomy is required.

The surgical therapy of jejunal and ileal malignancies usually consists of wide local resection of the intestine harboring the lesion. For adenocarcinomas, a wide excision of corresponding mesentery is done to achieve regional lymphadenectomy, as is done for

adenocarcinomas of the colon. In the presence of locally advanced or metastatic disease, palliative intestinal resection or bypass is performed. Chemotherapy has no proven efficacy in the adjuvant or palliative treatment of small intestinal adenocarcinomas.

The goal of surgical therapy for carcinoids is resection of all visible disease. Localized small intestinal carcinoid tumors should be treated with segmental intestinal resection and regional lymphadenectomy. Nodal metastases are unusual with tumors less than 1 cm in diameter but are present with 75 to 90% of tumors larger than 3 cm in diameter. In approximately 30% of cases, multiple small intestinal carcinoid tumors are present. Therefore, the entire small intestine should be examined before planning extent of resection. In the presence of metastatic disease, tumor debulking should be conducted as it can be associated with long-term survival and amelioration of symptoms of the carcinoid syndrome. Response rates of 30 to 50% have been reported to chemotherapy regimens based on agents such as doxorubicin, 5-fluorouracil, and streptozocin. However, none of these regimens is associated with a clearly demonstrable impact on the natural history of disease. Octreotide is the most effective pharmacologic agent for management of symptoms of carcinoid syndrome.

Localized small intestinal lymphoma should be treated with segmental resection of the involved intestine and adjacent mesentery. If the small intestine is diffusely affected by lymphoma, chemotherapy rather than surgical resection should be the primary therapy. The value to adjuvant chemotherapy after resection of localized lymphoma is controversial.

Small intestinal GISTs should be treated with segmental intestinal resection. If the diagnosis is known before resection, wide lymphadenectomy can be avoided as GISTs are rarely associated with lymph node metastases. GISTs are resistant to conventional chemotherapy agents. Imatinib (Gleevec) is a tyrosine kinase inhibitor with potent activity against tyrosine kinase KIT, and is used in those with metastatic disease. Recent clinical trials have shown that 80% of patients with unresectable or metastatic GISTs derive clinical benefit from the administration of imatinib, with 50 to 60% having objective evidence of reduction in tumor volume.⁴⁹ Imatinib has shown great promise as a neoadjuvant and adjuvant therapy of GISTs. Recent reports have emphasized the potential for development of tumor resistance to this agent. In this setting, an alternative tyrosine kinase inhibitor, sunitinib, has been used with good results.⁵¹

Metastatic cancers affecting the small intestine that are symptomatic should be treated with palliative resection or bypass except in the most advanced cases. Systemic therapy may be offered if effective chemotherapy exists for the primary cancer.

Outcomes

Complete resection of duodenal adenocarcinomas is associated with postoperative 5-year survival rates ranging from 50 to 60%. Complete resection of adenocarcinomas located in the jejunum or ileum is associated with 5-year survival rates of only 5 to 30%.⁵² Five-year survival rates of 75 to 95% following resection of localized small intestinal carcinoid tumors have been reported. In the presence of carcinoid tumor-derived liver metastases, 5-year survival rates of 19 to 54% have been reported. The overall 5-year survival rate for patients diagnosed with intestinal lymphoma ranges from 20 to 40%. For patients with localized lymphoma amenable to surgical resection, the 5-year survival rate is 60%.

The recurrence rate following resection of GISTs averages 35%. The 5-year survival rate following surgical resection has been reported to range from 35 to 60%. Both tumor size and mitotic index are independently correlated with prognosis. Low-grade tumors (mitotic index <10 per high-power field) measuring less than 5 cm in diameter are associated with excellent prognosis.

RADIATION ENTERITIS

Radiation therapy is a component of multimodality therapy for many intra-abdominal and pelvic cancers such as those of the cervix, endometrium, ovary, bladder, prostate, and rectum. An undesired side effect of radiation therapy is radiation-induced injury to the small intestine, which can present clinically as two distinct syndromes: acute and chronic radiation enteritis. Acute radiation enteritis is a transient condition that occurs in approximately 75% of patients undergoing radiation therapy for abdominal and pelvic cancers. Chronic radiation enteritis is inexorable and develops in approximately 5 to 15% of these patients.

Pathophysiology

Radiation induces cellular injury directly and through the generation of free radicals. The principal mechanism of radiation-induced cell death is believed to be apoptosis resulting from free-radical–induced breaks in double-stranded DNA. Because radiation has its greatest impact on rapidly proliferating cells, the small intestinal epithelium is acutely susceptible to radiation-induced injury. Pathologic correlates of this acute injury include villus blunting and a dense infiltrate of leukocytes and plasma cells within the crypts. With severe cases, mucosal sloughing, ulceration, and hemorrhage are observed. The intensity of injury is related to the dose of radiation administered, with most cases occurring in patients who have received at least 4500 cGy. Risk factors for acute radiation enteritis include conditions that may limit splanchnic perfusion, such as hypertension, diabetes mellitus, coronary artery disease, and restricted mobility of the small intestine due to adhesions. Injury is potentiated by concomitant administration of chemotherapeutic agents such as doxorubicin, 5-fluorouracil, actinomycin D, and methotrexate that act as radiation-sensitizers. Because of the intestinal epithelium's capacity for regeneration, the mucosal injury that is characteristic of acute radiation enteritis resolves after the cessation of radiation therapy.

In contrast, chronic radiation enteritis is characterized by a progressive occlusive vasculitis that leads to chronic ischemia and fibrosis that affects all layers of the intestinal wall, rather than the mucosa alone. These changes can lead to strictures, abscesses, and fistulas, which are responsible for the clinical manifestations of chronic radiation enteritis.

Clinical Presentation

The most common manifestations of acute radiation enteritis are nausea, vomiting, diarrhea, and crampy abdominal pain. Symptoms generally are transient and subside after the discontinuation of radiation therapy. Because the diagnosis usually is obvious, given the clinical context, no specific diagnostic tests are required. However, if patients develop signs suggestive of peritonitis, CT scanning should be performed to rule out the presence of other conditions capable of causing acute abdominal syndromes.

The clinical manifestations of chronic radiation enteritis usually become evident within 2 years of radiation administration, although they can begin as early as several months or as late as decades afterward. The most common clinical presentation is one of partial small bowel obstruction with nausea, vomiting, intermittent abdominal distention, crampy abdominal pain, and weight loss being the most common symptoms. The terminal ileum is the most frequently affected segment. Other manifestations of chronic radiation enteritis include complete bowel obstruction, acute or chronic intestinal hemorrhage, and abscess or fistula formation.

Diagnosis

Evaluation of patients suspected of having chronic radiation enteritis should include review of the records of their radiation treatments for information on total radiation dose administered, fractionation, and volume of treatment. Areas that received high doses should be noted, as lesions subsequently found in imaging studies usually localize to areas that had received high radiation doses. Enteroclysis is the most accurate imaging test for diagnosing chronic radiation enteritis, with reported sensitivities and specificities of over 90% (Fig. 28-22). CT scan findings are neither very sensitive nor specific for chronic radiation enteritis. However, CT scanning should be obtained to rule out the presence of recurrent cancer because its clinical manifestations may overlap with those of chronic radiation enteritis.

Fig. 28-22.

Radiation enteritis. This contrast radiograph reveals widely separated loops of small bowel with luminal narrowing, loss of mucosal folds, and ulceration. This patient had received radiation therapy for a pelvic malignancy 8 years before this examination.

Therapy

Most cases of acute radiation enteritis are self limited. Supportive therapy, including the administration of antiemetics, usually is sufficient. Patients with diarrhea-induced dehydration may require hospital admission and parenteral fluid administration. Rarely are symptoms severe enough to necessitate reduction in or cessation of radiation therapy.

In contrast, the treatment of radiation enteritis represents a formidable challenge. Surgery for this condition is difficult, is associated with high morbidity rates, and should be avoided in the absence of specific indications such as high-grade obstruction, perforation, hemorrhage, intra-abdominal abscesses, and fistulas. The goal of surgery is limited resection of diseased intestine with primary anastomosis between healthy bowel segments. However, the characteristically diffuse nature of fibrosis and dense adhesions among bowel segments can make limited resection difficult to achieve. Further, it is difficult to distinguish between normal and irradiated intestine intraoperatively by either gross inspection or even frozen section analysis. This distinction is important as anastomoses between irradiated segments of intestine have been associated with leak rates as high as 50%.⁵³ If limited resection is not achievable, an intestinal bypass procedure may be an option, except in cases for which hemorrhage is the surgical indication. There remain cases in which resections extensive enough to cause short bowel syndrome are unavoidable. This condition is discussed in detail below in the Short Bowel Syndrome section.

Outcomes

Acute radiation injury to the intestine is self limited; its severity is not correlated with the probability of chronic radiation enteritis developing. Surgery for chronic radiation enteritis is associated with high morbidity rates and reported mortality rates averaging 10%.

Prevention

In view of significant morbidity associated with radiation enteritis, groups have studied possible measures to reduce or prevent such side effects. Keeping radiation exposure to below 5000 cGy is associated with minimal long-term side effects and recommended, where clinically possible.

Uses of multibeam radiation techniques to minimize the area of maximal radiation exposure, as well as tilt tables to move the bowel out of the pelvis during radiation are increasingly used. A few small studies have suggested that oral sulfasalazine may help reduce the incidence of acute radiation-induced enteritis.⁵⁴

In patients undergoing pelvic surgery who are likely to require postoperative radiation therapy, surgical techniques that keep the small bowel out of the pelvis have been recommended. These measures include use of an absorbable mesh sling to separate the pelvis from the true abdominal cavity and prevent the small bowel from being exposed to pelvic radiation.⁵⁵

MECKEL'S DIVERTICULUM

Meckel's diverticulum is the most prevalent congenital anomaly of the GI tract, affecting approximately 2% of the general population.⁵⁶ A 3:2 male-to-female prevalence ratio has been reported. Meckel's diverticula are designated *true diverticula* because their walls contain all of the layers found in normal small intestine. Their location varies among individual patients, but they are usually found in the ileum within 100 cm of the ileocecal valve (Fig. 28-23). Approximately 60% of Meckel's diverticula contain heterotopic mucosa, of which over 60% consist of gastric mucosa. Pancreatic acini are the next most common; others include Brunner's glands, pancreatic islets, colonic mucosa, endometriosis, and hepatobiliary tissues. A useful, although crude, mnemonic describing Meckel's diverticula is the "rule of twos": 2% prevalence, 2:1 female predominance, location 2 ft proximal to the ileocecal valve in adults, and one half of those who are symptomatic are under 2 years of age.

Fig. 28-23.

Meckel's diverticulum. This intraoperative photograph shows Meckel's diverticulum in ileum that has been eviscerated.

Pathophysiology

During the eighth week of gestation, the omphalomesenteric (vitelline) duct normally undergoes obliteration. Failure or incomplete

vitelline duct obliteration results in a spectrum of abnormalities, the most common of which is Meckel's diverticulum. Other abnormalities include omphalomesenteric fistula, enterocyst, and a fibrous band connecting the intestine to the umbilicus. A remnant of the left vitelline artery can persist to form a mesodiverticular band tethering a Meckel's diverticulum to the ileal mesentery.

Bleeding associated with Meckel's diverticulum is usually the result of ileal mucosal ulceration that occurs adjacent to acid-producing, heterotopic gastric mucosa located within the diverticulum. Intestinal obstruction associated with Meckel's diverticulum can result from several mechanisms:

1. Volvulus of the intestine around the fibrous band attaching the diverticulum to the umbilicus
2. Entrapment of intestine by a mesodiverticular band (Fig. 28-24)
3. Intussusception with the diverticulum acting as a lead point
4. Stricture secondary to chronic diverticulitis

Fig. 28-24.

A. Meckel's diverticulum with mesodiverticular band. **B.** One mechanism by which Meckel's diverticula can cause small bowel obstruction is entrapment of the intestine by a mesodiverticular band.

Meckel's diverticula can be found in inguinal or femoral hernia sacs (known as *Littre's hernia*). These hernias, when incarcerated, can cause intestinal obstruction.

Clinical Presentation

Meckel's diverticula are asymptomatic unless associated complications arise. The lifetime incidence rate of complications arising in patients with Meckel's diverticula has been estimated to be approximately 4 to 6%.^{56,57} Although initial data had suggested that the risk of developing a complication related to Meckel's diverticulum decreases with age, this has been now been questioned. In population-based reviews at Olmsted County, Minnesota, Cullen and colleagues showed that the risk of developing Meckel's-related complications does not change with age.⁵⁷

The most common presentations associated with symptomatic Meckel's diverticula are bleeding, intestinal obstruction, and diverticulitis. Bleeding is the most common presentation in children with Meckel's diverticula, representing over 50% of Meckel's diverticulum-related complications among patients younger than 18 years of age. Bleeding associated with Meckel's diverticula is rare among patients older than 30 years of age.

Intestinal obstruction is the most common presentation in adults with Meckel's diverticula. Diverticulitis, present in 20% of patients with symptomatic Meckel's diverticula, is associated with a clinical syndrome that is indistinguishable from acute appendicitis.

Neoplasms, most commonly carcinoid tumors, are present in 0.5 to 3.2% of symptomatic Meckel's diverticula that are resected.⁵⁶

Diagnosis

Most Meckel's diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. In the absence of bleeding, Meckel's diverticula rarely are diagnosed before the time of surgical intervention. For those presenting with symptoms suggestive of a Meckel's diverticulum, confirmatory imaging can be challenging. The sensitivity of CT scanning for the detection of Meckel's diverticula is too low to be clinically useful. Enteroclysis is associated with an accuracy of 75%, but usually is not applicable during acute presentations of complications related to Meckel's diverticula. Radionuclide scans (^{99m}Tc -pertechnetate) can be helpful in the diagnosis of Meckel's diverticulum; this test is, however, positive only when the diverticulum contains associated ectopic gastric mucosa that is capable of uptake of the tracer (Fig. 28-25). The accuracy of radionuclide scanning is reported to be 90% in pediatric patients but less than 50% in adults. Angiography can localize the site of bleeding during acute hemorrhage related to Meckel's diverticula.

Fig. 28-25.

Meckel's diverticulum with ectopic gastric tissue. The diagnosis was made in this patient using ^{99m}Tc -pertechnetate scintigraphy. The study revealed an abnormal focus of radiotracer accumulation in the right lower quadrant (arrow).

Therapy

The surgical treatment of symptomatic Meckel's diverticula should consist of diverticulectomy with removal of associated bands connecting the diverticulum to the abdominal wall or intestinal mesentery. If the indication for diverticulectomy is bleeding, segmental resection of ileum that includes both the diverticulum and the adjacent ileal peptic ulcer should be performed. Segmental ileal resection may also be necessary if the diverticulum contains a tumor or if the base of the diverticulum is inflamed or perforated.

The management of incidentally found (asymptomatic) Meckel's diverticula is controversial. Until recently, most authors recommended against prophylactic removal of asymptomatic Meckel's diverticula, given the low lifetime incidence of complications. More recently, greater enthusiasm for prophylactic diverticulectomy has appeared in the literature.⁵⁷ Proponents of this approach cite the minimal morbidity associated with removing Meckel's diverticula and the possibility that previous estimates of the lifetime incidence of complications related to Meckel's diverticula may be erroneously low. Other authors have advocated a selective approach, with a recommendation to remove diverticula attached by bands and those with narrow bases, on the assumption that these diverticula are more likely to develop complications. No controlled data supporting or refuting these recommendations exist.

ACQUIRED DIVERTICULA

Acquired diverticula are designated *false diverticula* because their walls consist of mucosa and submucosa but lack a complete muscularis. Acquired diverticula are more common in the duodenum, and tend to be located near the ampulla; such diverticula are known as *perampullary*, *juxtapapillary*, or *peri-Vaterian diverticula*. Approximately 75% of juxtapapillary diverticula arise on the medial wall of the duodenum. Acquired diverticula in the jejunum or ileum are known as *jejunoileal diverticula*. Eighty percent of jejunoileal diverticula are localized to the jejunum, 15% to the ileum, and 5% to both jejunum and ileum. Diverticula in the jejunum tend to be large and accompanied by multiple other diverticula, whereas those in the ileum tend to be small and solitary.

The prevalence of duodenal diverticula, as detected on upper GI examinations (Fig. 28-26), has been reported to range from 0.16 to 6%.⁵⁸ Their prevalence, as detected during endoscopic retrograde cholangiography (ERCP) examinations, has been reported to range from 5 to 27%. A 23% prevalence rate has been reported in an autopsy series. The prevalence of duodenal diverticula increases with age; they are rare in patients under the age of 40 years. The mean age of diagnosis ranges from 56 to 76 years.

Fig. 28-26.

Duodenal diverticulum. This contrast radiograph demonstrates a duodenal diverticulum (*arrows*) that extends medially into the substance of the head of the pancreas.

The prevalence of jejunoileal diverticula (Fig. 28-27) has been estimated to range from 1 to 5%.⁵⁹ Their prevalence increases with age; most patients diagnosed with these diverticula are in the sixth and seventh decades of life.

Fig. 28-27.

Jejunoileal diverticula. This picture demonstrates incidental jejunal diverticula identified during a laparoscopic cholecystectomy. The diverticula are typically located on the mesenteric aspect of the jejunum. Resection was not indicated as the diverticula were asymptomatic.

Pathophysiology

The pathogenesis of acquired diverticula is hypothesized to be related to acquired abnormalities of intestinal smooth muscle or dysregulated motility, leading to herniation of mucosa and submucosa through weakened areas of muscularis.

Acquired diverticula can be associated with bacterial overgrowth, leading to vitamin B12 deficiency, megaloblastic anemia, malabsorption, and steatorrhea. Periapillary duodenal diverticula have been described to become distended with intraluminal debris and to compress the common bile duct or pancreatic duct, thus causing obstructive jaundice or pancreatitis, respectively. Jejunoileal diverticula also can cause intestinal obstruction through intussusception or compression of adjacent bowel.

Clinical Presentation

Acquired diverticula are asymptomatic unless associated complications arise. Such complications are estimated to occur in 6 to 10% of patients with acquired diverticula and include intestinal obstruction, diverticulitis, hemorrhage, perforation, and malabsorption. Periapillary duodenal diverticula may be associated with choledocholithiasis, cholangitis, recurrent pancreatitis, and sphincter of Oddi dysfunction. However, a clear link between the presence of the diverticula and the development of these conditions has not been demonstrated. Symptoms such as intermittent abdominal pain, flatulence, diarrhea, and constipation are reported to be present in 10 to 30% of patients with jejunoileal diverticula. The relationship between these symptoms and the presence of the diverticula is similarly unclear.

Diagnosis

Most acquired diverticula are discovered incidentally on radiographic imaging, during endoscopy, or at the time of surgery. On ultrasound and CT scanning, duodenal diverticula may be mistaken for pancreatic pseudocysts and fluid collections, biliary cysts, and periapillary neoplasms. These lesions can be missed on endoscopy, particularly with forward-viewing endoscopes, and are best diagnosed on upper GI radiographs. Enteroclysis is the most sensitive test for detecting jejunoileal diverticula.

Therapy

Asymptomatic acquired diverticula should be left alone. Bacterial overgrowth associated with acquired diverticula is treated with antibiotics. Other complications, such as bleeding and diverticulitis, are treated with segmental intestinal resection for diverticula located in the jejunum or ileum.

Bleeding and obstruction related to lateral duodenal diverticula generally are treated with diverticulectomy alone. These procedures can be technically difficult for medial duodenal diverticula that penetrate into the substance of the pancreas. Complications related to these medial duodenal diverticula should be managed nonoperatively if possible, using endoscopy. In emergent situations, bleeding related to medial duodenal diverticula can be controlled using a lateral duodenotomy and oversewing of the bleeding vessel. Similarly, perforation can be managed with wide drainage rather than complex surgery. Whether diverticulectomy should be done in patients with biliary or pancreatic symptoms is controversial and is not routinely recommended.⁵⁸

MESENTERIC ISCHEMIA

Mesenteric ischemia can present as one of two distinct clinical syndromes: acute mesenteric ischemia and chronic mesenteric ischemia.

Four distinct pathophysiologic mechanisms can lead to acute mesenteric ischemia:

1. Arterial embolus
2. Arterial thrombosis
3. Vasospasm (also known as nonocclusive mesenteric ischemia)
4. Venous thrombosis

Embolus is the most common cause of acute mesenteric ischemia, and is responsible for more than 50% of cases. The embolic source is usually in the heart; most often the left atrial or ventricular thrombi or valvular lesions. Indeed, up to 95% of patients with acute mesenteric ischemia due to emboli will have a documented history of cardiac disease. Embolism to the superior mesenteric artery accounts for 50% of cases; most of these emboli become wedged and cause occlusion at branch points in the mid- to distal superior mesenteric artery, usually distal to the origin of the middle colic artery. In contrast, acute occlusions due to thrombosis tend to occur in the proximal mesenteric arteries, near their origins. Acute thrombosis is usually superimposed on pre-existing atherosclerotic lesions at these sites. Nonocclusive mesenteric ischemia is the result of vasospasm and usually is diagnosed in critically ill patients receiving vasopressor agents.

Mesenteric venous thrombosis accounts for 5 to 15% of cases of acute mesenteric ischemia and involves the superior mesenteric vein in 95% of cases.⁶⁰ The inferior mesenteric vein is only rarely involved. Mesenteric venous thrombosis is classified as primary if no etiologic factor is identifiable, or as secondary if an etiologic factor, such as heritable or acquired coagulation disorders, is identified.

Regardless of the pathophysiologic mechanism, acute mesenteric ischemia can lead to intestinal mucosal sloughing within 3 hours of onset and full-thickness intestinal infarction by 6 hours.

In contrast, *chronic mesenteric ischemia* develops insidiously, allowing for development of collateral circulation, and, therefore, rarely leads to intestinal infarction. Chronic mesenteric arterial ischemia results from atherosclerotic lesions in the main splanchnic arteries (celiac, superior mesenteric, and inferior mesenteric arteries). In most patients with symptoms attributable to chronic mesenteric ischemia, at least two of these arteries are either occluded or severely stenosed. A chronic form of mesenteric venous thrombosis can involve the portal or splenic veins and may lead to portal hypertension, with resulting esophagogastric varices, splenomegaly, and hypersplenism.

Severe abdominal pain, out of proportion to the degree of tenderness on examination, is the hallmark of acute mesenteric ischemia, regardless of the pathophysiologic mechanism. The pain typically is perceived to be colicky and most severe in the midabdomen. Associated symptoms can include nausea, vomiting, and diarrhea. Physical findings are characteristically absent early in the course of ischemia. With the onset of bowel infarction, abdominal distention, peritonitis, and passage of bloody stools occur.

Chronic mesenteric ischemia presents insidiously. Postprandial abdominal pain is the most prevalent symptom, producing a characteristic aversion to food ("food-fear") and weight loss. These patients are often thought to have a malignancy and suffer a prolonged period of symptoms before the correct diagnosis is made.

Most patients with chronic mesenteric venous thrombosis are asymptomatic because of the presence of extensive collateral venous drainage routes; this condition is usually discovered as an incidental finding on imaging studies. However, some patients with chronic mesenteric venous thrombosis present with bleeding from esophagogastric varices.

The diagnosis and management of these disorders that are of primary vascular origin are discussed in the section on Mesenteric Artery Disease in Chap. 23.

MISCELLANEOUS CONDITIONS

Obscure Gastrointestinal Bleeding

Up to 90% of lesions responsible for GI bleeding are within the reach of EGD and colonoscopy. *Obscure GI bleeding* refers to GI bleeding for which no source has been identified by routine endoscopic studies (EGD and colonoscopy). *Overt GI bleeding* refers to the presence of hematemesis, melena, or hematochezia. In contrast, *occult GI bleeding* occurs in the absence of overt bleeding and is identified on laboratory tests (e.g., iron-deficiency anemia) or examination of the stool (e.g., positive guaiac test). Obscure GI bleeding is occult in 20% of cases.⁶¹

Obscure bleeding can be frustrating for both the patient and the clinician, and particularly true for obscure-overt bleeding that cannot be localized despite aggressive diagnostic measures. One study from a tertiary referral center reported that the typical patient with obscure-overt bleeding had suffered intermittent episodes of hemorrhage for 26 months, had undergone up to 20 diagnostic tests, and had received an average of 20 units of blood before reaching a diagnosis.⁶² Most of the small bowel is beyond the reach of these examinations and, hence, contains most lesions responsible for obscure GI bleeding. Small intestinal angiodysplasias account for approximately 75% of cases in adults, and neoplasms for approximately 10%. Meckel's diverticulum is the most common etiology of obscure GI bleeding in children. Other etiologies of obscure GI bleeding include Crohn's disease, infectious enteritides, NSAID-induced ulcers and erosions, vasculitis, ischemia, varices, diverticula, and intussusception.

The diagnostic evaluation of patients with obscure GI bleeding should be tailored to the severity to bleeding and to the availability of technology and expertise. Enteroscopy is playing an increasingly important role. Several endoscopic techniques for visualizing the small intestine are available: push enteroscopy, Sonde enteroscopy, intraoperative enteroscopy, double-balloon enteroscopy, and wireless capsule enteroscopy.

Push enteroscopy entails advancing a long endoscope (such as a pediatric or adult colonoscope or a specialized instrument) beyond the ligament of Treitz into the proximal jejunum. This procedure can allow for visualization of approximately 60 cm of the proximal jejunum. Reported diagnostic yield rates in patients with obscure GI bleeding range from 3 to 65%. In addition to diagnosis, push enteroscopy allows for cauterization of bleeding sites.

In Sonde enteroscopy, a long, thin fiber-optic instrument is propelled through the intestine by peristalsis following inflation of a balloon at the instrument's tip. Visualization is done during instrument withdrawal; approximately 50 to 75% of the small intestinal mucosa can be examined. However, this instrument lacks biopsy or therapeutic capability. Further, it lacks tip deflection capability, limiting complete mucosal visualization, and therefore has been abandoned in favor of capsule endoscopy.

Wireless capsule enteroscopy relies on a radiotelemetry capsule enteroscope that is small enough to swallow and has no external wires, fiber-optic bundles, or cables. While the capsule is being propelled through the intestine by peristalsis, video images are transmitted using radiotelemetry to an array of detectors attached to the patient's body. These detectors capture the images and permit continuous triangulation of the capsule location in the abdomen, facilitating the localization of lesions detected. The entire

system is portable, allowing the patient to be ambulatory during the entire examination. Capsule endoscopy is an excellent tool in the patient who is hemodynamically stable but continues to bleed. This technique has reported success rates as high as 90% in identifying a small bowel pathology.⁶¹

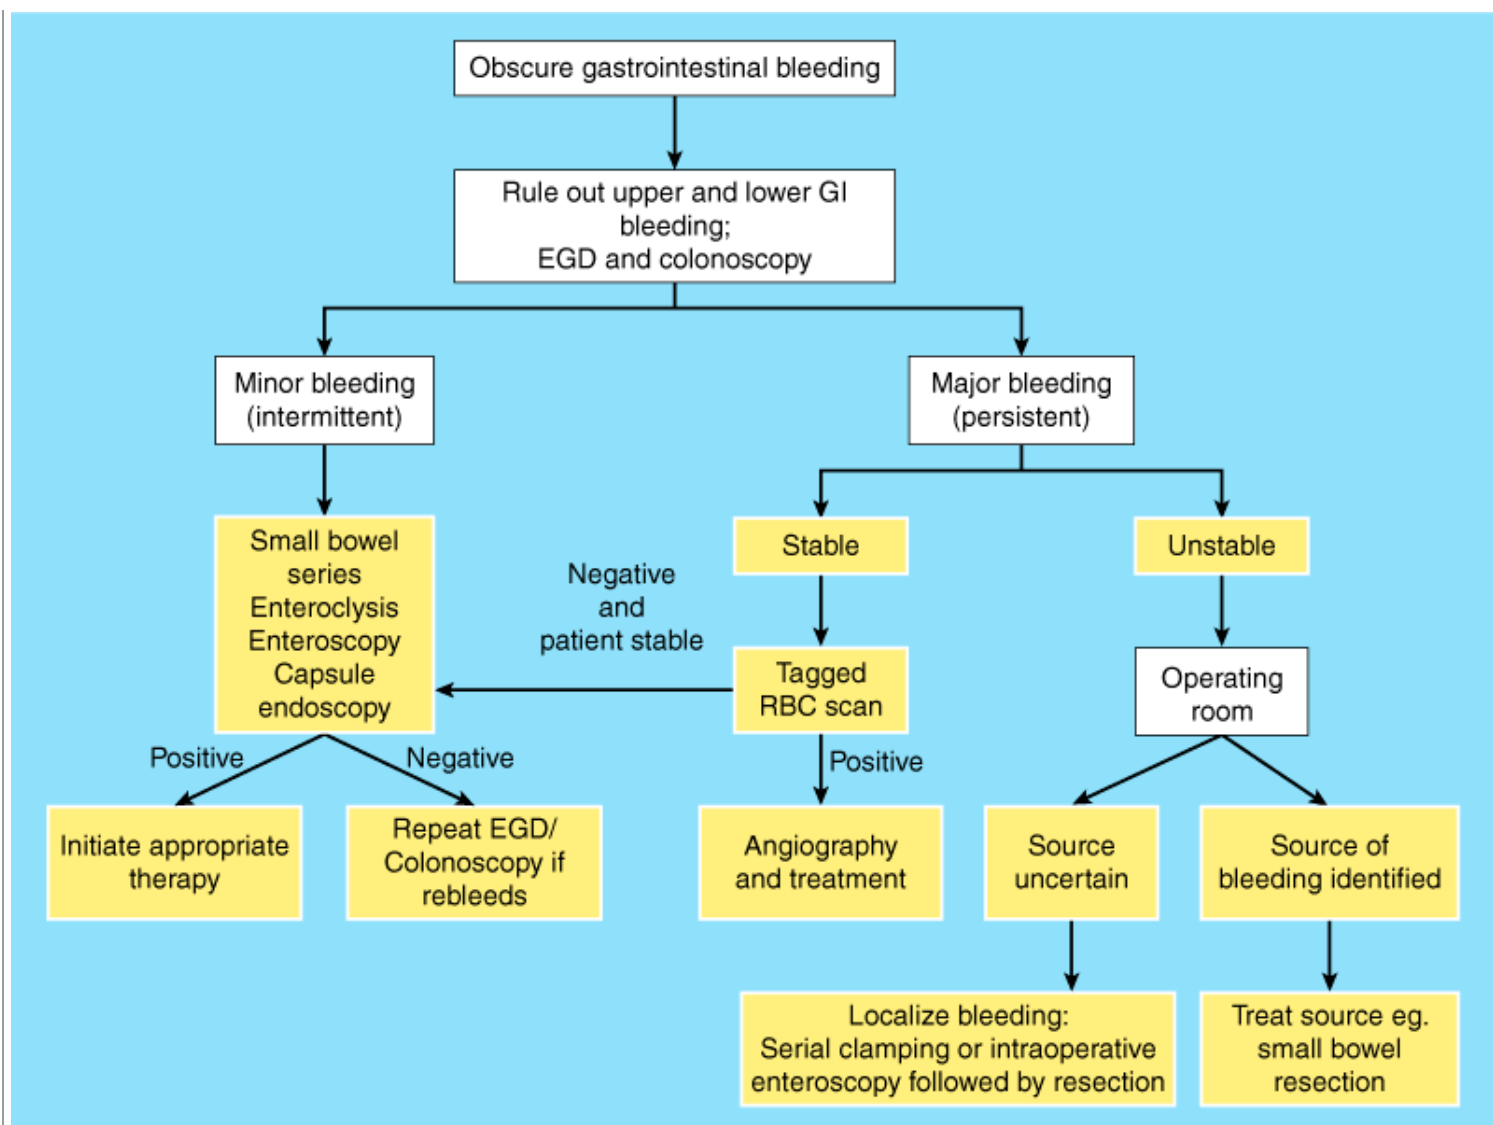

For patients in whom bleeding from an obscure GI source has apparently stopped, push enteroscopy or capsule enteroscopy is a reasonable initial study. If these examinations do not reveal a potential source of bleeding, then enteroclysis should be performed. Standard small bowel follow-through examinations are associated with a low diagnostic yield in this setting and should be avoided. If still no diagnosis has been made, a "watch-and-wait" approach is reasonable, although angiography should be considered if the prior episode of bleeding was overt. Angiography can reveal angiodysplasia and vascular tumors in the small intestine even in the absence of ongoing bleeding.

For persistent mild bleeding from an obscure GI source, push and capsule enteroscopy can be used. If these examinations are nondiagnostic, then ^{99m}Tc-labeled red blood cell scanning should be performed and, if positive, followed by angiography to localize the source of bleeding. ^{99m}Tc-pertechnetate scintigraphy to diagnose Meckel's diverticulum should be considered, although its yield in patients older than 40 years of age is extremely low. Patients who remain undiagnosed but continue to bleed and those with recurrent episodic bleeding significant enough to require blood transfusions should then undergo exploration with intraoperative enteroscopy.

Patients with persistent severe bleeding from an obscure source should undergo angiography to help localize the bleeding source. Therapy can be tailored based on the source. Push enteroscopy also can be attempted, but capsule enteroscopy is too slow to be applicable in this setting. If these examinations fail to localize the source of bleeding, exploratory laparoscopy or laparotomy with intraoperative enteroscopy is indicated. Intraoperative enteroscopy can be done during either laparotomy or laparoscopy. An endoscope (usually a colonoscope) is inserted into the small bowel through peroral intubation or through an enterotomy made in the small bowel or cecum. The endoscope is advanced by successively telescoping short segments of intestine onto the end of the instrument. In addition to the endoscopic image, the transilluminated bowel should be examined externally with the operating room lights dimmed, as this maneuver may facilitate the identification of angiodysplasias. Identified lesions should be marked with a suture placed on the serosal surface of the bowel; these lesions can be resected after completion of endoscopy. Examination should be performed during instrument insertion rather than withdrawal because instrument-induced mucosal trauma can be confused with angiodysplasias. Reported diagnostic rates, when applied to patients with obscure GI bleeding, range from 83 to 100%.

Figure 28-28 provides a diagnostic and management algorithm for patients with obscure GI bleeding.

Small Bowel Perforation

Before the 1980s, duodenal perforation due to peptic ulcer disease was the most common form of small bowel perforation. Today, iatrogenic injury incurred during GI endoscopy is the most common cause of small bowel perforation. Other etiologies of small bowel perforation include infections (especially tuberculosis, typhoid, and CMV), Crohn's disease, ischemia, drugs (e.g., potassium- and NSAID-induced ulcers), radiation-induced injury, Meckel's and acquired diverticula, neoplasms (especially lymphoma, adenocarcinoma, and melanoma), and foreign bodies.

Among iatrogenic injuries, duodenal perforation during ERCP with endoscopic sphincterotomy is the most common. This complication occurs in 0.3 to 2% of cases. Patients who have undergone Billroth II gastrectomy are at increased risk of duodenal perforations as well as free jejunal perforations during ERCP. Although ERCP-related duodenal perforations can result in a free perforation, most are retroperitoneal. Manifestations of such a contained duodenal perforation following ERCP can resemble those of ERCP-induced pancreatitis, including hyperamylasemia.

CT scanning is the most sensitive test for diagnosing duodenal perforations; positive findings include pneumoperitoneum for free perforations, but more commonly retroperitoneal air, contrast extravasation, and paraduodenal fluid collections. If all patients

undergoing a therapeutic ERCP are imaged with a CT scan following the procedure, up to 30% will have evidence of air in the retroperitoneum, but the majority are asymptomatic. These patients do not require any specific therapy.⁶³

True cases of retroperitoneal perforations of the duodenum can be managed nonoperatively, in the absence of progression and sepsis. However, intraperitoneal duodenal perforations require surgical repair with pyloric exclusion and gastrojejunostomy or tube duodenostomy. Iatrogenic small bowel perforation incurred during endoscopy, if immediately recognized, can sometimes be repaired using endoscopic techniques.

Perforation of the jejunum and ileum occurs into the peritoneal cavity and usually causes overt symptoms and signs, such as abdominal pain, tenderness, and distention accompanied by fever and tachycardia. Plain abdominal radiographs may reveal free intraperitoneal air if intraperitoneal perforation has occurred. If perforation is suspected, but not clinically obvious, CT scanning should be performed. Jejunal and ileal perforations require surgical repair or segmental resection.

Chylous Ascites

Chylous ascites refers to the accumulation of triglyceride-rich peritoneal fluid with a milky or creamy appearance, caused by the presence of intestinal lymph in the peritoneal cavity. Chylomicrons, produced by the intestine and secreted into lymph during the absorption of long-chain fatty acids, account for the characteristic appearance and triglyceride content of chyle.

The most common etiologies of chylous ascites in Western countries are abdominal malignancies and cirrhosis. In Eastern and developing countries, infectious etiologies such as tuberculosis and filariasis account for most cases. Chylous ascites also can develop as a complication of abdominal and thoracic operations and trauma. Operations particularly associated with this complication include abdominal aortic aneurysm repair, retroperitoneal lymph node dissection, inferior vena cava resection, and liver transplantation. Other etiologies of chylous ascites include congenital lymphatic abnormalities (e.g., primary lymphatic hypoplasia), radiation, pancreatitis, and right-sided heart failure.

Three mechanisms have been postulated to cause chylous ascites: (a) exudation of chyle from dilated lymphatics on the wall of the bowel and in the mesentery caused by obstruction of lymphatic vessels at the base of the mesentery or the cisterna chيلي (e.g., by malignancies), (b) direct leakage of chyle through a lymphoperitoneal fistula (e.g., those that develop as a result of trauma or surgery), and (c) exudation of chyle through the wall of dilated retroperitoneal lymphatic vessels (e.g., in congenital lymphangiectasia or thoracic duct obstruction).

Patients with chylous ascites develop abdominal distention over a period of weeks to months. Postoperative chylous ascites can present acutely during the first postoperative week. Delayed presentations following surgery can occur if the mechanism of ascites formation is adhesion-induced lymphatic obstruction rather than lymphatic vessel disruption. Dyspnea may result if abdominal distention is severe enough.

Paracentesis is the most important diagnostic test. Chyle typically has a cloudy and turbid appearance; however, it may be clear in fasting patients (such as those in the immediate postoperative period). Fluid triglyceride concentrations above 110 mg/dL are diagnostic. CT scanning may be useful in identifying pathologic intra-abdominal lymph nodes and masses and in identifying the extent and localization of fluid. Lymphangiography and lymphoscintigraphy may help localize lymph leaks and obstruction; this information is particularly useful for surgical planning.

There are little data on optimal management of patients with chylous ascites. The general approach is to focus on evaluating and treating the underlying causes, especially for patients with infectious, inflammatory, or hemodynamic etiologies for this condition.

Most patients respond to administration of a high-protein and low-fat diet supplemented with medium-chain triglycerides. This regimen is designed to minimize chyle production and flow. Medium-chain triglycerides are absorbed by the intestinal epithelium and are transported to liver through the portal vein; they do not contribute to chylomicron formation.

Patients who do not respond to this approach should fast and be placed on TPN. Octreotide can further decrease lymph flow.

Paracentesis is indicated for respiratory difficulties related to abdominal distention. Overall, 60% of patients will respond to conservative therapy. However, 30% of patients will require surgical therapy for chylous ascites. In general, postoperative and trauma-related cases that fail to respond to initial nonoperative therapy are best managed by surgical repair. Lymphatic leaks are localized and repaired with fine nonabsorbable sutures. If extravasation of chyle is localized to the periphery of the small bowel mesentery, then a limited small bowel resection can be performed instead. For patients who are poor surgical candidates and do not respond to prolonged conservative therapy, peritoneovenous shunting may be an option. However, these shunts are associated with high rates of complications, including sepsis and disseminated intravascular coagulation. Because of the viscosity of chyle, these shunts are associated with a high occlusion rate.

Intussusception

Intussusception refers to a condition where one segment of the intestine becomes drawn in to the lumen of the proximal segment of the bowel. It usually is seen in the pediatric population, where the cecum intussuscepts in to the ileum (ileocolic intussusception). In children, it is often an idiopathic condition and treated nonsurgically by radiologic reduction.

Adult intussusceptions are far less common, and usually have a distinct pathologic lead point, which can be malignant in up to one half of cases.⁶⁴ They commonly present with a history of intermittent abdominal pain and signs and symptoms of bowel obstruction. CT scan is the investigation of choice, where a "target sign" may be seen (Fig. 28-29). Treatment is surgical resection of the involved segment and the lead point, which needs to undergo pathologic evaluation to rule out an underlying malignancy.

Fig. 28-29.

Small bowel intussusception. Panel **A** demonstrates the target sign seen on computed tomographic scans in patients with small bowel intussusception (*arrow*). Panel **B** demonstrates the distal bowel clearly within the lumen of the proximal bowel (*arrow*).

With increasing use of CT imaging, target signs are sometimes seen on CT scans of patients who do not have a clinical presentation indicative of bowel obstruction. In such cases, the finding is of little clinical significance and is probably related to normal peristalsis.

In patients who have undergone a Roux-en-Y gastric bypass surgery, an atypical form of intussusception has been increasingly described. In these cases, the proximal bowel is drawn in to the lumen of the distal bowel (retrograde intussusception). These intussusceptions usually are not associated with a lead point, and may represent a motility disorder of the bowel following the Roux-en-Y reconstruction.⁶⁵ Surgical reductions without resection have been successfully reported in these patients.

Pneumatosis Intestinalis

Pneumatosis intestinalis indicates the presence of gas within the bowel wall. It may affect any region of the GI tract but is most commonly seen in the jejunum. Pneumatosis intestinalis is not a disease but merely a sign that can be idiopathic, or associated with many intestinal or nonintestinal disorders such as obstructive pulmonary disease and asthma. Most cases of pneumatosis intestinalis are secondary to an identifiable cause, and 15% are idiopathic. The pathogenesis of pneumatosis intestinalis is not fully understood.

The surgical interest in this finding is the association of it with bowel ischemia and infarction, both of which necessitate emergent surgical intervention (see Fig. 28-15). Thus, patients with this radiologic finding need to be fully evaluated and monitored closely to rule out such intra-abdominal catastrophes.

SHORT BOWEL SYNDROME

Intestinal resection is performed for many of the diseases discussed in this chapter and generally is associated with minimal morbidity. However, when the extent of resection is great enough, a devastating condition known as the *short bowel syndrome* may result. Short bowel syndrome has been arbitrarily defined as the presence of less than 200 cm of residual small bowel in adult patients.⁶⁶ A functional definition, in which insufficient intestinal absorptive capacity results in the clinical manifestations of diarrhea, dehydration, and malnutrition, is more broadly applicable.

In adults, the most common etiologies of short bowel syndrome are acute mesenteric ischemia, malignancy, and Crohn's disease. Seventy-five percent of cases result from resection of a large amount of small bowel at a single operation. Twenty-five percent of

cases result from the cumulative effects of multiple operations during which small intestine is resected. This latter pattern is typical of patients with Crohn's disease who develop short bowel syndrome; the former is typical of patients with acute mesenteric ischemia who develop intestinal infarction. In pediatric patients, intestinal atresias, volvulus, and necrotizing enterocolitis are the most common etiologies of short bowel syndrome.

The prevalence of short bowel syndrome has been estimated to be as high as 2 million patients in the United States.⁶⁶ The most recent available data on chronic home TPN administration were obtained in 1992. At that time, approximately 40,000 patients were receiving TPN chronically at home. The most prevalent indication for TPN among these patients was short bowel syndrome; however, this estimate does not include patients with short bowel syndrome not receiving TPN at home. It also fails to include those who have been weaned off of TPN.

Pathophysiology

Resection of less than 50% of the small intestine is generally well tolerated. However, clinically significant malabsorption occurs when greater than 50 to 80% of the small intestine has been resected. Among adult patients who lack a functional colon, lifelong TPN dependence is likely to persist if there is less than 100 cm of residual small intestine. Among adult patients who have an intact and functional colon, lifelong TPN dependence is likely to persist if there is less than 60 cm of residual small intestine. Among infants with short bowel syndrome, weaning from TPN-dependence has been achieved with as little as 10 cm of residual small intestine.

Residual bowel length is not the only factor predictive of achieving independence from TPN (enteral autonomy), however. Other determinants of the severity of malabsorption include the presence or absence of an intact colon, as indicated in the paragraph above. The colon has the capacity to absorb large fluid and electrolyte loads. In addition, the colon can play an important, albeit small, role in nutrient assimilation by absorbing short-chain fatty acids. Second, an intact ileocecal valve is believed to be associated with decreased malabsorption. The ileocecal valve delays transit of chyme from the small intestine into the colon, thereby prolonging the contact time between nutrients and the small intestinal absorptive mucosa. Third, healthy, rather than diseased, residual small intestine is associated with decreased severity of malabsorption. Fourth, resection of jejunum is better tolerated than resection of ileum, as the capacity for bile salt and vitamin B12 absorption is specific to the ileum (Table 28-11).

Table 28-11 Risk Factors for Development of Short Bowel Syndrome after Massive Small Bowel Resection
Small bowel length <200 cm
Absence of ileocecal valve
Absence of colon
Diseased remaining bowel (e.g., Crohn's disease)
Ileal resection

During the first 1 to 2 years following massive small bowel resection, the remaining intestine undergoes compensatory adaptation, as discussed in the section on Intestinal Adaptation. Clinically, the period of adaptation is associated with reductions in volume and frequency of bowel movements, increases in the capacity for enteral nutrient assimilation, and reductions in TPN requirements. As this process completes, some patients are successfully weaned off TPN. Understanding the mechanisms mediating intestinal adaptation may suggest strategies for enhancing adaptation in patients with short bowel syndrome who are unable to achieve independence from TPN. To date, the phenomenon of intestinal adaptation in human patients remains poorly understood.¹³

Malabsorption in patients who have undergone massive small bowel resection is exacerbated by a characteristic hypergastrinemia-associated gastric acid hypersecretion that persists for 1 to 2 years postoperatively. The increased acid load delivered to the duodenum inhibits absorption by a variety of mechanisms, including the inhibition of digestive enzymes, most of which function optimally under alkaline conditions.

Therapy

MEDICAL THERAPY

For patients having undergone massive small bowel resection, the initial treatment priorities include management of the primary condition precipitating the intestinal resection and the repletion of fluid and electrolytes lost in the severe diarrhea that characteristically occurs. Most patients will require TPN, at least initially. Enteral nutrition should be gradually introduced, once ileus has resolved. High-dose histamine-2 receptor antagonists or proton pump inhibitors should be administered to reduce gastric acid secretion. Antimotility agents such as loperamide hydrochloride or diphenoxylate may be administered to delay small intestinal transit. Octreotide can be administered to reduce the volume of GI secretions, although, in animal models, its use is associated with an inhibition of intestinal adaptation.

During the period of adaptation, generally lasting 1 to 2 years postoperatively, TPN and enteral nutrition are titrated in an attempt to allow for independence from TPN. Patients who remain dependent on TPN face substantial TPN-associated morbidities including catheter sepsis, venous thrombosis, liver and kidney failure, and osteoporosis. Liver failure is a significant source of morbidity, and often leads to liver transplantation (always in combination with small bowel transplantation). Due to these complications, patients with short bowel syndrome on TPN have a reduced life expectancy with 5-year survival rates of 50 to 75%. Costs associated with chronic TPN administration are estimated to be as high as \$150,000 per patient annually. Because of these problems, alternative therapies for short bowel syndrome are under investigation.

NONTRANSPLANT SURGICAL THERAPY

Among patients with stomas, restoration of intestinal continuity should be performed whenever possible, to capitalize on the absorptive capacity of all residual intestine. Other forms of nontransplant surgery designed to improve intestinal absorption are associated with unclear efficacy and/or substantial morbidities and therefore should not be applied routinely.

The goal of these operations is to increase nutrient and fluid absorption by either slowing intestinal transit or increasing intestinal length. Operations designed to slow intestinal transit include segmental reversal of the small bowel, interposition of a segment of colon between segments of small bowel, construction of small intestinal valves, and electrical pacing of the small intestine.⁶⁷ Reported experience with these procedures is limited to case reports or series of a few cases. Objective evidence of increased absorption is lacking; further, these procedures are frequently associated with intestinal obstruction.

The intestinal lengthening operation for which there is the greatest experience is the longitudinal intestinal lengthening and tailoring procedure, first described by Bianchi in 1980.⁶⁸ Approximately 100 of these procedures have been reported in the literature. The procedure entails separation of the dual vasculature of the small intestine, followed by longitudinal division of the bowel with subsequent isoperistaltic end-to-end anastomosis. This procedure has the potential to double the length of small intestine to which it is applied. This procedure has generally been used for pediatric patients with *dilated* residual small bowel.

In 2003, the serial transverse enteroplasty procedure was described.⁶⁹ This procedure is designed to accomplish lengthening of dilated small intestine without the need for separating its dual vasculature (Fig. 28-30). Initial experimental studies and recent data from an international registry based in Boston have been promising.⁷⁰

INTESTINAL TRANSPLANTATION

This complex procedure is being increasingly performed to treat patients with short bowel syndrome. Approximately 1000 patients worldwide had undergone this procedure by 2003.⁷¹ The currently accepted indication for intestinal transplantation is the presence of life-threatening complications attributable to intestinal failure and/or long-term TPN therapy. Specific complications for which intestinal transplantation is indicated include (a) impending or overt liver failure, (b) thrombosis of major central veins, (c) frequent episodes of catheter-related sepsis, and (d) frequent episodes of severe dehydration.

Currently, approximately 45% of transplants involving the small intestine are performed as isolated intestinal transplants, 40% as combined intestine/liver transplants, and 15% as multivisceral transplants.

Isolated intestinal transplantation is used for patients with intestinal failure who have no significant liver disease or failure of other organs. Combined intestine/liver transplantation is used for patients with both intestinal and liver failure. Multivisceral transplantation has been used for patients with giant desmoid tumors involving the vascular supply of the liver and pancreas as well as that of the intestine, for diffuse GI motility disturbances, and for diffuse splanchnic thrombosis.

Nearly 80% of survivors have full intestinal graft function with no need for TPN. However, morbidities associated with intestinal transplantation are substantial and include acute and chronic rejection, CMV infection, and posttransplant lymphoproliferative disease.

ALTERNATIVE THERAPIES

Pharmacologic and biologic therapies designed to expand intestinal mucosal surface area or to enhance the efficiency of intestinal absorption are beginning to undergo clinical evaluation. Promising regimens include GLP-2 and the combination of glutamine and growth hormone with a modified, high-carbohydrate diet.¹³

Outcomes

Approximately 50 to 70% of patients with short bowel syndrome who initially require TPN are ultimately able to achieve independence from TPN.⁶⁶ Prognosis for achieving enteral autonomy is better among pediatric patients than among adults.

Information on survival among patients with short bowel syndrome is limited. In a study of 124 adults with short bowel syndrome due

to nonmalignant etiologies, the survival rates at 2 and 5 years of follow-up were 86 and 45%, respectively.⁷² Patients with end-enterostomies and those having less than 50 cm of residual small intestine had significantly worse survivals than those without these features.

No randomized trials comparing intestinal transplantation to chronic TPN administration among patients with short bowel syndrome have been reported. In the most recent United Network for Organ Sharing cohort evaluated, the 1-year patient and graft survival rates for isolated intestine recipients were 77 and 65%, respectively, and 50 and 49 percent, respectively, for intestine/liver recipients.⁶⁶ Five-year patient and graft survival rates for isolated intestine recipients were 50 and 38%, respectively, and for intestine/liver recipients, 37 and 36%, respectively.

Schwartz's Principles of Surgery > Part II. Specific Considerations > Chapter 29. Colon, Rectum, and Anus >

KEY POINTS

1. Resection principles: The mesenteric clearance technique dictates the extent of resection and is determined by the nature of the primary pathology, the intent of resection, the location of the lesion, and the condition of the mesentery.
2. Minimally invasive resection: Laparoscopic and/or hand-assisted laparoscopy has been shown to be both safe and efficacious for colorectal resection.
3. Function after resection: Bowel function is often compromised after colorectal resection, especially after low anterior resection. For this reason, it is important to obtain a history of prior anorectal trauma and/or incontinence before considering a low anastomosis.
4. Ostomies: Preoperative marking for a planned stoma is critical for a patient's quality of life. Ideally, a stoma should be located within the rectus muscle, in a location where the patient can easily see and manipulate the appliance, and away from previous scars, bony prominences, or abdominal creases.
5. Inflammatory bowel disease: Both Crohn's disease and ulcerative colitis are associated with an increased risk of colorectal carcinoma. Risk depends upon the amount of colon involved and the duration of disease.
6. Pathogenesis of colorectal cancer: A variety of mutations have been identified in colorectal cancer. Mutations may cause activation of oncogenes (K-ras) and/or inactivation of tumor-suppressor genes [adenomatous polyposis coli (APC) < DCC (deleted in colorectal carcinoma), p53].
7. Early rectal cancer: Optimal treatment of very early rectal cancer (T1NXMX) is controversial. Transanal excision alone has been associated with a very high rate of local recurrence. In patients who will tolerate and accept radical surgery, this approach is probably appropriate. Chemoradiation either before or after transanal excision can also be considered, but has not been prospectively studied.
8. Anal epidermoid carcinoma: Unlike rectal adenocarcinoma, anal epidermoid carcinoma is treated primarily with chemoradiation. Surgery is reserved for patients with persistent or recurrent disease.
9. Rectal prolapse: Rectal prolapse occurs most commonly in elderly women. Transabdominal repair (rectopexy with or without resection) offers more durability than perineal proctosigmoidectomy, but carries greater operative risk.
10. Hemorrhoids: Hemorrhoids are cushions of submucosal tissue containing venules, arterioles, and smooth muscle fiber. They are thought to play a role in maintaining continence. Resection is only indicated for refractory symptoms.
11. Fistula in ano: Treatment of fistula in ano depends upon the location of the fistula, amount of anal sphincter involved in the fistula, and the underlying disease process.

EMBRYOLOGY AND ANATOMY

Embryology

The embryonic GI tract begins developing during the fourth week of gestation. The primitive gut is derived from the endoderm and divided into three segments: *foregut*, *midgut*, and *hindgut*. Both *midgut* and *hindgut* contribute to the colon, rectum, and anus.

The *midgut* develops into the small intestine, ascending colon, and proximal transverse colon, and receives blood supply from the superior mesenteric artery. During the sixth week of gestation, the *midgut* herniates out of the abdominal cavity, and then rotates 270° counterclockwise around the superior mesenteric artery to return to its final position inside the abdominal cavity during the tenth week of gestation.

The *hindgut* develops into the distal transverse colon, descending colon, rectum, and proximal anus, all of which receive their blood supply from the inferior mesenteric artery. During the sixth week of gestation, the distal-most end of the *hindgut*, the *cloaca*, is divided by the urorectal septum into the urogenital sinus and the rectum.

The distal anal canal is derived from ectoderm and receives its blood supply from the internal pudendal artery. The dentate line divides the endodermal *hindgut* from the ectodermal distal anal canal.

Anatomy

The large intestine extends from the ileocecal valve to the anus. It is divided anatomically and functionally into the *colon*, *rectum*, and *anal canal*. The wall of the colon and rectum comprise five distinct layers: mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa. In the colon, the outer longitudinal muscle is separated into three *teniae coli*, which converge proximally at the appendix and distally at the rectum, where the outer longitudinal muscle layer is

circumferential. In the distal rectum, the inner smooth muscle layer coalesces to form the internal anal sphincter. The intraperitoneal colon and proximal one third of the rectum are covered by serosa; the mid and lower rectum lack serosa.

COLON LANDMARKS

The colon begins at the junction of the terminal ileum and cecum and extends 3 to 5 ft to the rectum. The rectosigmoid junction is found at approximately the level of the sacral promontory and is arbitrarily described as the point at which the three *teniae coli* coalesce to form the outer longitudinal smooth muscle layer of the rectum. The *cecum* is the widest diameter portion of the colon (normally 7.5 to 8.5 cm) and has the thinnest muscular wall. As a result, the cecum is most vulnerable to perforation and least vulnerable to obstruction. The ascending colon usually is fixed to the retroperitoneum. The hepatic flexure marks the transition to the transverse colon. The intraperitoneal transverse colon is relatively mobile, but is tethered by the gastrocolic ligament and colonic mesentery. The greater omentum is attached to the anterior/superior edge of the transverse colon. These attachments explain the characteristic triangular appearance of the transverse colon observed during colonoscopy. The splenic flexure marks the transition from the transverse colon to the descending colon. The attachments between the splenic flexure and the spleen (the lienocolic ligament) can be short and dense, making mobilization of this flexure during colectomy challenging. The descending colon is relatively fixed to the retroperitoneum. The sigmoid colon is the narrowest part of the large intestine and is extremely mobile. Although the sigmoid colon usually is located in the left lower quadrant, redundancy and mobility can result in a portion of the sigmoid colon residing in the right lower quadrant. This mobility explains why volvulus is most common in the sigmoid colon and why diseases affecting the sigmoid colon, such as diverticulitis, may occasionally present as right-sided abdominal pain. The narrow caliber of the sigmoid colon makes this segment of the large intestine the most vulnerable to obstruction.

COLON VASCULAR SUPPLY

The arterial supply to the colon is highly variable (Fig. 29-1). In general, the *superior mesenteric artery* branches into the *ileocolic artery* (absent in up to 20% of people), which supplies blood flow to the terminal ileum and proximal ascending colon, the *right colic artery*, which supplies the ascending colon, and the *middle colic artery*, which supplies the transverse colon. The *inferior mesenteric artery* branches into the *left colic artery*, which supplies the descending colon, several *sigmoidal branches*, which supply the sigmoid colon, and the *superior rectal artery*, which supplies the proximal rectum. The terminal branches of each artery form anastomoses with the terminal branches of the adjacent artery and communicate via the *marginal artery of Drummond*. This arcade is complete in only 15 to 20% of people.

Arterial blood supply to the colon. a. = artery.

Except for the *inferior mesenteric vein*, the veins of the colon parallel their corresponding arteries and bear the same terminology (Fig. 29-2). The inferior mesenteric vein ascends in the retroperitoneal plane over the psoas muscle and continues posterior to the pancreas to join the splenic vein. During a colectomy, this vein often is

mobilized independently and ligated at the inferior edge of the pancreas.

COLON LYMPHATIC DRAINAGE

The lymphatic drainage of the colon originates in a network of lymphatics in the muscularis mucosa. Lymphatic vessels and lymph nodes follow the regional arteries. Lymph nodes are found on the bowel wall (epicolic), along the inner margin of the bowel adjacent to the arterial arcades (paracolic), around the named mesenteric vessels (intermediate), and at the origin of the superior and inferior mesenteric arteries (main). The *sentinel lymph nodes* are the first one to four lymph nodes to drain a specific segment of the colon, and are thought to be the first site of metastasis in colon cancer. The use of sentinel lymph node dissection and analysis in colon cancer remains controversial.

COLON NERVE SUPPLY

The colon is innervated by both *sympathetic* (inhibitory) and *parasympathetic* (stimulatory) nerves, which parallel the course of the arteries. Sympathetic nerves arise from T6–T12 and L1–L3. The parasympathetic innervation to the right and transverse colon is from the vagus nerve; the parasympathetic nerves to the left colon arise from sacral nerves S2–S4 to form the nervi erigentes.

ANORECTAL LANDMARKS

The rectum is approximately 12 to 15 cm in length. Three distinct submucosal folds, the *valves of Houston*, extend into the rectal lumen. Posteriorly, the *presacral fascia* separates the rectum from the presacral venous plexus and the pelvic nerves. At S4, the rectosacral fascia (*Waldeyer's fascia*) extends forward and downward and attaches to the fascia propria at the anorectal junction. Anteriorly, *Denonvilliers' fascia* separates the rectum from the prostate and seminal vesicles in men and from the vagina in women. The *lateral ligaments* support the lower rectum. The surgical anal canal measures 2 to 4 cm in length and generally is longer in men than in women. It begins at the anorectal junction and terminates at the anal verge. The *dentate or pectinate line* marks the transition point between columnar rectal mucosa and squamous anoderm. The 1 to 2 cm of mucosa just proximal to the dentate line shares histologic characteristics of columnar, cuboidal, and squamous epithelium and is referred to as the *anal transition zone*. The dentate line is surrounded by longitudinal mucosal folds, known as the *columns of Morgagni*, into which the anal crypts empty. These crypts are the source of cryptoglandular abscesses (Fig. 29-3).

Fig. 29-3.

The lining of the anal canal.

[From Goldberg SM, Gordon PH, Nivatvongs S (eds): *Essentials of Anorectal Surgery*. Philadelphia: J.B. Lippincott Company, 1980, p 4. Reproduced with permission from Stanley M. Goldberg, MD.]

In the distal rectum, the inner smooth muscle is thickened and comprises the *internal anal sphincter* that is surrounded by the *subcutaneous*, *superficial*, and *deep external sphincter*. The *deep external anal sphincter* is an extension of the *puborectalis* muscle. The *puborectalis*, *iliococcygeus*, and *pubococcygeus* muscles form the *levator ani* muscle of the pelvic floor (Fig. 29-4).

Fig. 29-4.

The distal rectum and anal canal. m. = muscle.

ANORECTAL VASCULAR SUPPLY

The *superior rectal artery* arises from the terminal branch of the inferior mesenteric artery and supplies the upper rectum. The *middle rectal artery* arises from the internal iliac; the presence and size of these arteries are highly variable. The *inferior rectal artery* arises from the internal pudendal artery, which is a branch of the

internal iliac artery. A rich network of collaterals connects the terminal arterioles of each of these arteries, thus making the rectum relatively resistant to ischemia (Fig. 29-5).

Fig. 29-5.

Source: Brunicaudi FC, Andersen DK, Billiar TR, Dunn DL, Hunter JG, Matthews JB, Pollock RE: *Schwartz's Principles of Surgery, 9th Edition*: <http://www.accessmedicine.com>
Copyright © The McGraw-Hill Companies, Inc. All rights reserved.

Arterial supply to the rectum and anal canal.

The venous drainage of the rectum parallels the arterial supply. The *superior rectal vein* drains into the portal system via the inferior mesenteric vein. The *middle rectal vein* drains into the internal iliac vein. The *inferior rectal vein* drains into the internal pudendal vein, and subsequently into the internal iliac vein. A submucosal plexus deep to the columns of Morgagni forms the *hemorrhoidal plexus* and drains into all three veins.

ANORECTAL LYMPHATIC DRAINAGE

Lymphatic drainage of the rectum parallels the vascular supply. Lymphatic channels in the upper and middle rectum drain superiorly into the inferior mesenteric lymph nodes. Lymphatic channels in the lower rectum drain both superiorly into the inferior mesenteric lymph nodes and laterally into the internal iliac lymph nodes. The anal canal has a more complex pattern of lymphatic drainage. Proximal to the dentate line, lymph drains into both the inferior mesenteric lymph nodes and the internal iliac lymph nodes. Distal to the dentate line, lymph primarily drains into the inguinal lymph nodes, but also can drain into the inferior mesenteric lymph nodes and internal iliac lymph nodes.

ANORECTAL NERVE SUPPLY

Both sympathetic and parasympathetic nerves innervate the anorectum. Sympathetic nerve fibers are derived from L1–L3 and join the preaortic plexus. The preaortic nerve fibers then extend below the aorta to form the *hypogastric plexus*, which subsequently joins the parasympathetic fibers to form the pelvic plexus. Parasympathetic nerve fibers are known as the *nervi erigentes* and originate from S2–S4. These fibers join the sympathetic fibers to form the pelvic plexus. Sympathetic and parasympathetic fibers then supply the anorectum and adjacent urogenital organs.

The internal anal sphincter is innervated by sympathetic and parasympathetic nerve fibers; both types of fibers inhibit sphincter contraction. The external anal sphincter and puborectalis muscles are innervated by the *inferior rectal branch* of the *internal pudendal nerve*. The levator ani receives innervation from both the *internal pudendal nerve* and direct branches of S3 to S5. Sensory innervation to the anal canal is provided by the *inferior rectal branch* of the *pudendal nerve*.

Although the rectum is relatively insensate, the anal canal below the dentate line is sensate.

Congenital Anomalies

Perturbation of the embryologic development of the midgut and hindgut may result in anatomic abnormalities of the colon, rectum, and anus. Failure of the midgut to rotate and return to the abdominal cavity during the tenth week of gestation results in varying degrees of intestinal malrotation and colonic nonfixation. Failure of canalization of the primitive gut can result in colonic duplication. Incomplete descent of the urogenital septum may result in imperforate anus and associated fistulas to the genitourinary tract. Many infants with congenital anomalies of the hindgut have associated abnormalities in the genitourinary tract.

NORMAL PHYSIOLOGY

Fluid and Electrolyte Exchanges

The colon is a major site for water absorption and electrolyte exchange. Approximately 90% of the water contained in ileal fluid is absorbed in the colon (1000 to 2000 mL/d), and up to 5000 mL of fluid can be absorbed daily. Sodium is absorbed actively via a Na-K ATPase. The colon can absorb up to 400 mEq of sodium per

day. Water accompanies the transported sodium and is absorbed passively along an osmotic gradient. Potassium is actively secreted into the colonic lumen and absorbed by passive diffusion. Chloride is absorbed actively via a chloride–bicarbonate exchange.

Bacterial degradation of protein and urea produces ammonia. Ammonia is subsequently absorbed and transported to the liver. Absorption of ammonia depends, in part, upon intraluminal pH. A decrease in colonic bacteria (e.g., broad-spectrum antibiotic usage) and/or a decrease in intraluminal pH (e.g., lactulose administration) will decrease ammonia absorption.

Short-Chain Fatty Acids

Short-chain fatty acids (acetate, butyrate, and propionate) are produced by bacterial fermentation of dietary carbohydrates. Short-chain fatty acids are an important source of energy for the colonic mucosa, and metabolism by colonocytes provides energy for processes such as active transport of sodium. Lack of a dietary source for production of short-chain fatty acids, or diversion of the fecal stream by an ileostomy or colostomy, may result in mucosal atrophy and "diversion colitis."

Colonic Microflora and Intestinal Gas

Approximately 30% of fecal dry weight is composed of bacteria (10^{11} to 10^{12} bacteria/g of feces). Anaerobes are the predominant class of microorganism, and *Bacteroides* species are the most common (10^{11} to 10^{12} organisms/mL). *Escherichia coli* are the most numerous aerobes (10^8 to 10^{10} organisms/mL). Endogenous microflora are crucial for the breakdown of carbohydrates and proteins in the colon and participate in the metabolism of bilirubin, bile acids, estrogen, and cholesterol. Colonic bacteria also are necessary for production of vitamin K. Endogenous bacteria also are thought to suppress the emergence of pathogenic microorganisms, such as *Clostridium difficile*. However, the high bacterial load of the large intestine may contribute to sepsis in critically ill patients and may contribute to intra-abdominal sepsis, abscess, and wound infection following colectomy.

Intestinal gas arises from swallowed air, diffusion from the blood, and intraluminal production. Nitrogen, oxygen, carbon dioxide, hydrogen, and methane are the major components of intestinal gas. Nitrogen and oxygen are largely derived from swallowed air. Carbon dioxide is produced by the reaction of bicarbonate and hydrogen ions, and by the digestion of triglycerides to fatty acids. Hydrogen and methane are produced by colonic bacteria. The production of methane is highly variable. The GI tract usually contains between 100 and 200 mL of gas and 400 to 1200 mL per day are released as flatus, depending upon the type of food ingested.

Motility, Defecation, and Continence

MOTILITY

Unlike the small intestine, the large intestine does not demonstrate cyclic motor activity characteristic of the migratory motor complex. Instead, the colon displays intermittent contractions of either low or high amplitude. Low-amplitude, short-duration contractions occur in bursts and appear to move the colonic contents both antegrade and retrograde. It is thought that these bursts of motor activity delay colonic transit and thus increase the time available for absorption of water and exchange of electrolytes. High-amplitude contractions occur in a more coordinated fashion and create "mass movements." Bursts of "rectal motor complexes" also have been described. In general, cholinergic activation increases colonic motility.

DEFECATION

Defecation is a complex, coordinated mechanism involving colonic mass movement, increased intra-abdominal and rectal pressure, and relaxation of the pelvic floor. Distention of the rectum causes a reflex relaxation of the internal anal sphincter (the rectoanal inhibitory reflex) that allows the contents to make contact with the anal canal. This "sampling reflex" allows the sensory epithelium to distinguish solid stool from liquid stool and gas. If defecation does not occur, the rectum relaxes and the urge to defecate passes (the *accommodation response*). Defecation proceeds by coordination of increasing intra-abdominal pressure via the Valsalva maneuver, increased rectal contraction, relaxation of the puborectalis muscle, and opening of the anal canal.

CONTINENCE

The maintenance of fecal continence is at least as complex as the mechanism of defecation. Continence requires adequate rectal wall compliance to accommodate the fecal bolus, appropriate neurogenic control of the pelvic floor and sphincter mechanism, and functional internal and external sphincter muscles. At rest, the puborectalis muscle creates a "sling" around the distal rectum, forming a relatively acute angle that distributes intra-abdominal forces onto the pelvic floor. With defecation, this angle straightens, allowing downward force to be applied along the axis of the rectum and anal canal. The internal and external sphincters are tonically active at rest. The internal sphincter is responsible for most of the resting, involuntary sphincter tone (resting pressure). The external sphincter is responsible for most of the voluntary sphincter tone (squeeze pressure). Branches of the pudendal nerve innervate both the internal and external sphincter. Finally, the hemorrhoidal cushions may contribute to continence by mechanically blocking the anal canal. Thus, impaired continence may result from poor rectal compliance, injury to the internal and/or external sphincter or puborectalis, or nerve damage or neuropathy.

CLINICAL EVALUATION

Clinical Assessment

A complete history and physical examination is the starting point for evaluating any patient with suspected disease of the colon and rectum. Special attention should be paid to the patient's past medical and surgical history to detect underlying conditions that might contribute to a GI problem. If patients have had prior intestinal

surgery, it is essential that one understand the resultant GI anatomy. A history of anorectal surgery may be critical for patients with either abdominal or anorectal complaints. Obstetric history in women is essential to suspect occult pelvic floor and/or anal sphincter damage. A family history of colorectal disease, especially inflammatory bowel disease, polyps, and colorectal cancer, is crucial. In addition to family history of colorectal disease, history of other malignancies may suggest the presence of a genetic syndrome. Medication use must be detailed as many drugs cause GI symptoms. Before recommending operative intervention, the adequacy of medical treatment must be ascertained. In addition to examining the abdomen, visual inspection of the anus and perineum and careful digital rectal exam are essential.

Endoscopy

ANOSCOPY

The anoscope is a useful instrument for examination of the anal canal. Anoscopes are made in a variety of sizes and measure approximately 8 cm in length. A larger anoscope provides better exposure for anal procedures such as rubber band ligation or sclerotherapy of hemorrhoids. The anoscope, with obturator in place, should be adequately lubricated and gently inserted into the anal canal. The obturator is withdrawn, inspection of the visualized anal canal is done, and the anoscope should then be withdrawn. It is rotated 90° and reinserted to allow visualization of all four quadrants of the canal. If the patient complains of severe perianal pain and cannot tolerate a digital rectal examination, anoscopy should not be attempted without anesthesia.

PROCTOSCOPY

The rigid proctoscope is useful for examination of the rectum and distal sigmoid colon and occasionally is used therapeutically. The standard proctoscope is 25 cm in length and available in various diameters. Most often, a 15- or 19-mm diameter proctoscope is used for diagnostic examinations. The large (25-mm diameter) proctoscope is useful for procedures such as polypectomy, electrocoagulation, or detorsion of a sigmoid volvulus. A smaller "pediatric" proctoscope (11-mm diameter) is better tolerated by patients with anal stricture. Suction is necessary for an adequate proctoscopic examination.

FLEXIBLE SIGMOIDOSCOPY AND COLONOSCOPY

Video or fiber-optic flexible sigmoidoscopy and colonoscopy provide excellent visualization of the colon and rectum. Sigmoidoscopes measure 60 cm in length. Full depth of insertion may allow visualization as high as the splenic flexure, although the mobility and redundancy of the sigmoid colon often limit the extent of the examination. Partial preparation with enemas usually is adequate for sigmoidoscopy and most patients can tolerate this procedure without sedation. Colonoscopes measure 100 to 160 cm in length and are capable of examining the entire colon and terminal ileum. A complete oral bowel preparation usually is necessary for colonoscopy and the duration and discomfort of the procedure usually require conscious sedation. Both sigmoidoscopy and colonoscopy can be used diagnostically and therapeutically. Electrocautery generally should not be used in the absence of a complete bowel preparation because of the risk of explosion of intestinal methane or hydrogen gases. Diagnostic colonoscopes possess a single channel through which instruments such as snares, biopsy forceps, or electrocautery can be passed; this channel also provides suction and irrigation capability. Therapeutic colonoscopes possess two channels to allow simultaneous suction/irrigation and the use of snares, biopsy forceps, or electrocautery.

CAPSULE ENDOSCOPY

Capsule endoscopy is an emerging technology that uses a small ingestible camera. After swallowing the camera, images of the mucosa of the GI tract are captured, transmitted by radiofrequency to a belt-held receiver, then downloaded to a computer for viewing and analysis. At present, capsule endoscopy largely has been used to detect small bowel lesions. However, it has been suggested that this technique might also be useful for diagnosing colorectal disease.^{1–3} At present, the use of capsule endoscopy in the evaluation of colorectal disease remains unproven.

Imaging

PLAIN X-RAYS AND CONTRAST STUDIES

Despite advanced radiologic techniques, plain x-rays and contrast studies continue to play an important role in the evaluation of patients with suspected colon and rectal diseases. Plain x-rays of the abdomen (supine, upright, and diaphragmatic views) are useful for detecting free intra-abdominal air, bowel gas patterns suggestive of small or large bowel obstruction, and volvulus. Contrast studies are useful for evaluating obstructive symptoms, delineating fistulous tracts, and diagnosing small perforations or anastomotic leaks. While Gastrografin cannot provide the mucosal detail provided by barium, this water-soluble contrast agent is recommended if perforation or leak is suspected. Double-contrast barium enema has been reported to be 70 to 90% sensitive for the detection of mass lesions greater than 1 cm in diameter.⁴ Detection of small lesions can be extremely difficult, especially in a patient with extensive diverticulosis. For this reason, a colonoscopy is preferred for evaluating nonobstructing mass lesions in the colon. Double-contrast barium enema has been used as a back-up examination if colonoscopy is incomplete.

COMPUTED TOMOGRAPHY

Computed tomography (CT) is commonly used in the evaluation of patients with abdominal complaints. Its utility is primarily in the detection of extraluminal disease, such as intra-abdominal abscesses and pericolic inflammation, and in staging colorectal carcinoma, because of its sensitivity in detection of hepatic metastases. Extravasation of oral or rectal contrast also may confirm the diagnosis of perforation or anastomotic leak. Nonspecific findings such as bowel wall thickening or mesenteric stranding may suggest inflammatory bowel disease, enteritis/colitis, or ischemia. A standard CT scan is relatively insensitive for the detection of

intraluminal lesions.

VIRTUAL COLONOSCOPY/COMPUTED TOMOGRAPHY COLOGRAPHY

Virtual colonoscopy (CT colography) is a new radiologic technique that is designed to overcome some of the limitations of traditional CT scanning. This technology uses helical CT and three-dimensional reconstruction to detect intraluminal colonic lesions. Oral bowel preparation, oral and rectal contrast, and colon insufflation are used to maximize sensitivity. Early evaluation of virtual colonoscopy suggests that accuracy may approach that of colonoscopy for detection of lesions 1 cm in diameter or greater.

MAGNETIC RESONANCE IMAGING

The main use of magnetic resonance imaging (MRI) in colorectal disorders is in evaluation of pelvic lesions. MRI is more sensitive than CT for detecting bony involvement or pelvic sidewall extension of rectal tumors. MRI accurately determines the extent of spread of rectal cancer into the adjacent mesorectum and can reliably predict difficulty achieving radial margin clearance of a rectal cancer by surgery alone. When the radial margin is threatened, neoadjuvant chemoradiation generally is indicated. MRI also can be helpful in the detection and delineation of complex fistulas in ano. The use of an endorectal coil may increase sensitivity.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) is used for imaging tissues with high levels of anaerobic glycolysis, such as malignant tumors.¹⁸ F-fluorodeoxyglucose is injected as a tracer; metabolism of this molecule then results in positron emission. PET has been used as an adjunct to CT in the staging of colorectal cancer and may prove useful in discriminating recurrent cancer from fibrosis. The combination of PET and CT technology recently has been introduced. By combining these modalities, anatomic correlation between regions of high isotope accumulation ("hot spots") on PET and abnormalities on CT can be determined. PET/CT increasingly is used to diagnose recurrent and/or metastatic colorectal cancer. However, the efficacy and use of this technology remains unproven.

ANGIOGRAPHY

Angiography occasionally is used for the detection of bleeding within the colon or small bowel. To visualize hemorrhage angiographically, bleeding must be relatively brisk (approximately 0.5 to 1.0 mL per minute). If extravasation of contrast is identified, infusion of vasopressin or angiographic embolization can be therapeutic.

CT and MR angiography also are useful for assessing patency of visceral vessels. This technique uses three dimensional reconstruction to detect vascular lesions. If an abnormality is found, more traditional techniques (angiography, surgery) may then be used to further define and/or correct the problem.

ENDORECTAL AND ENDOANAL ULTRASOUND

Endorectal ultrasound is primarily used to evaluate the depth of invasion of neoplastic lesions in the rectum. The normal rectal wall appears as a five-layer structure (Fig. 29-6). Ultrasound can reliably differentiate most benign polyps from invasive tumors based upon the integrity of the submucosal layer. Ultrasound also can differentiate superficial T1–T2 from deeper T3–T4 tumors. Overall, the accuracy of ultrasound in detecting depth of mural invasion ranges between 81 and 94%.⁵ This modality also can detect enlarged perirectal lymph nodes, which may suggest nodal metastases; accuracy of detection of pathologically positive lymph nodes is 58 to 83%. Ultrasound may also prove useful for early detection of local recurrence after surgery.

A. Schematic of the layers of the rectal wall observed on endorectal ultrasonography. **B.** Normal endorectal ultrasonography.

(**A.** Courtesy of Charles O. Finne III, MD, Minneapolis, MN.)

Endoanal ultrasound is used to evaluate the layers of the anal canal. Internal anal sphincter, external anal sphincter, and puborectalis muscle can be differentiated. Endoanal ultrasound is particularly useful for detecting sphincter defects and for outlining complex anal fistulas.

Physiologic and Pelvic Floor Investigations

Anorectal physiologic testing uses a variety of techniques to investigate the function of the pelvic floor. These techniques are useful in the evaluation of patients with incontinence, constipation, rectal prolapse, obstructed defecation, and other disorders of the pelvic floor.

MANOMETRY

Anorectal manometry is performed by placing a pressure-sensitive catheter in the lower rectum. The catheter is then withdrawn through the anal canal and pressures recorded. A balloon attached to the tip of the catheter also can be used to test anorectal sensation. The *resting pressure* in the anal canal reflects the function of the internal anal sphincter (normal: 40 to 80 mmHg), while the *squeeze pressure*, defined as the maximum voluntary contraction pressure minus the resting pressure, reflects function of the external anal sphincter (normal: 40 to 80 mmHg above resting pressure). The *high-pressure zone* estimates the length of the anal canal (normal: 2.0 to 4.0 cm). The *rectoanal inhibitory reflex* can be detected by inflating a balloon in the distal rectum; absence of this reflex is characteristic of Hirschsprung's disease.

NEUROPHYSIOLOGY

Neurophysiologic testing assesses function of the pudendal nerves and recruitment of puborectalis muscle fibers. Pudendal nerve terminal motor latency measures the speed of transmission of a nerve impulse through the distal pudendal nerve fibers (normal: 1.8 to 2.2 milliseconds); prolonged latency suggests the presence of neuropathy. Electromyography (EMG) recruitment assesses the contraction and relaxation of the puborectalis muscle during attempted defecation. Normally, recruitment increases when a patient is instructed to "squeeze," and decreases when a patient is instructed to "push." Inappropriate recruitment is an indication of paradoxical contraction (nonrelaxation of the puborectalis). Needle EMG has been used to map both the pudendal nerves and the anatomy of the internal and external sphincters. However, this examination is painful and poorly tolerated by most patients. Needle EMG has largely been replaced by pudendal nerve motor-latency testing to assess pudendal nerve function and endoanal ultrasound to map the sphincters.

RECTAL EVACUATION STUDIES

Rectal evacuation studies include the balloon expulsion test and video defecography. Balloon expulsion assesses a patient's ability to expel an intrarectal balloon. Video defecography provides a more detailed assessment of defecation. In this test, barium paste is placed in the rectum and defecation is then recorded fluoroscopically. Defecography is used to differentiate nonrelaxation of the puborectalis, obstructed defecation, increased perineal descent, rectal prolapse and intussusception, rectocele, and enterocele. The addition of vaginal contrast and intraperitoneal contrast is useful in delineating complex disorders of the pelvic floor.

Laboratory Studies

FECAL OCCULT BLOOD TESTING

Fecal occult blood testing (FOBT) is used as a screening test for colonic neoplasms in asymptomatic, average-risk individuals. The efficacy of this test is based upon serial testing because the majority of colorectal malignancies will bleed intermittently. FOBT has been a nonspecific test for peroxidase contained in hemoglobin; consequently, occult bleeding from any GI source will produce a positive result. Similarly, many foods (red meat, some fruits and vegetables, and vitamin C) will produce a false-positive result. Patients were counseled to eat a restricted diet for 2 to 3 days before the test. Increased specificity is now possible by using immunochemical FOBT. These tests rely on monoclonal or polyclonal antibodies to react with the intact globin portion of human hemoglobin. Because globin does not survive in the upper GI tract, the immunochemical tests are more specific for identifying occult bleeding from the colon or rectum. Dietary restrictions are not necessary. Any positive FOBT mandates further investigation, usually by colonoscopy.

STOOL STUDIES

Stool studies often are helpful in evaluating the etiology of diarrhea. Wet-mount examination reveals the presence of fecal leukocytes, which may suggest colonic inflammation or the presence of an invasive organism such as invasive *E. coli* or *Shigella*. Stool cultures can detect pathogenic bacteria, ova, and parasites. *C. difficile* colitis is diagnosed by detecting bacterial toxin in the stool.⁶ Steatorrhea may be diagnosed by adding Sudan red stain to a stool sample.

SERUM TESTS

Specific laboratory tests that should be performed will be dictated by the clinical scenario. Preoperative studies generally include a complete blood count and electrolyte panel. The addition of coagulation studies, liver function tests, and blood typing/cross-matching depends upon the patient's medical condition and the proposed surgical procedure.

TUMOR MARKERS

Carcinoembryonic antigen (CEA) may be elevated in 60 to 90% of patients with colorectal cancer. Despite this, CEA is not an effective screening tool for this malignancy. Many practitioners follow serial CEA levels after curative-intent surgery to detect early recurrence of colorectal cancer. However, this tumor marker is nonspecific, and no survival benefit has yet been proven. Other biochemical markers (ornithine decarboxylase, urokinase) have been proposed, but none has yet proven sensitive or specific for detection, staging, or predicting prognosis of colorectal carcinoma.⁷

GENETIC TESTING

Although familial colorectal cancer syndromes, such as familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are rare, information about the specific genetic abnormalities underlying these disorders has led to significant interest in the role of genetic testing for colorectal cancer.⁸ Tests for mutations in the adenomatous polyposis coli (APC) gene responsible for FAP, and in mismatch repair genes responsible for HNPCC, are commercially available and extremely accurate in families with known mutations. However, in the absence of an identified mutation, a negative result is uninformative. For individuals from high-risk families without an identified mutation, increased surveillance is recommended.⁹ Although many of these mutations also are present in sporadic colorectal cancer, the accuracy of genetic testing in average-risk individuals is considerably lower and these tests are not recommended for screening. Because of the potential psychosocial implications of genetic testing, it is strongly recommended that professional genetic counselors be involved in the care of any patient considering these tests.

Evaluation of Common Symptoms

PAIN

Abdominal pain is a nonspecific symptom with a myriad of causes. Abdominal pain related to the colon and rectum can result from obstruction (either inflammatory or neoplastic), inflammation, perforation, or ischemia. Plain x-rays and judicious use of contrast studies and/or a CT scan often can confirm the diagnosis. Gentle retrograde contrast studies (barium or Gastrografin enema) may be useful in delineating the degree of colonic obstruction. Sigmoidoscopy and/or colonoscopy performed by an experienced endoscopist can assist in the diagnosis of ischemic colitis, infectious colitis, and inflammatory bowel disease. However, if perforation is suspected, colonoscopy and/or sigmoidoscopy generally are contraindicated. Evaluation and treatment of abdominal pain from a colorectal source should follow the usual surgical principles of a thorough history and physical examination, appropriate diagnostic tests, resuscitation, and appropriately timed surgical intervention.

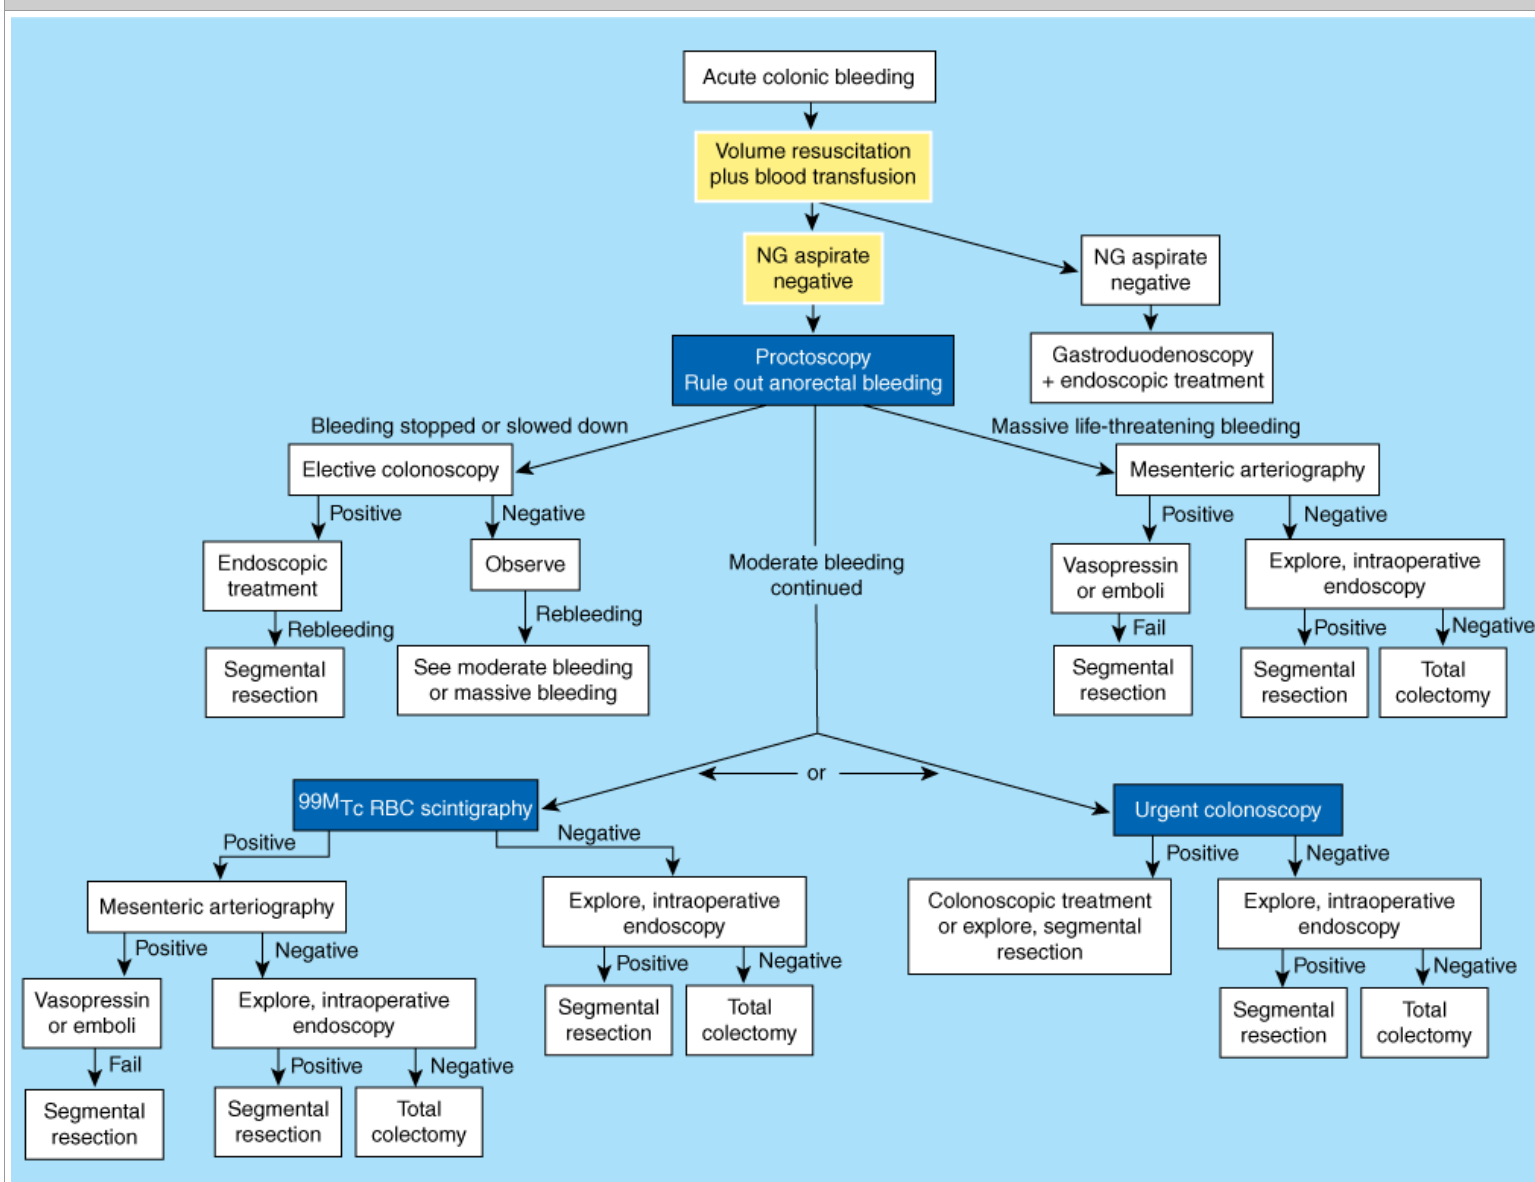

Pelvic pain can originate from the distal colon and rectum or from adjacent urogenital structures. Tenesmus may result from proctitis or from a rectal or retrorectal mass. Cyclical pain associated with menses, especially when accompanied by rectal bleeding, suggests a diagnosis of endometriosis. Pelvic inflammatory disease also can produce significant abdominal and pelvic pain. The extension of a peridiverticular abscess or periappendiceal abscess into the pelvis may also cause pain. CT scan and/or MRI may be useful in differentiating these diseases. Proctoscopy (if tolerated) also can be helpful. Occasionally, laparoscopy will yield a diagnosis.

Anorectal pain is most often secondary to an anal fissure, perirectal abscess and/or fistula, or a thrombosed hemorrhoid. Physical examination usually can differentiate these conditions. Other, less common causes of anorectal pain include anal canal neoplasms, perianal skin infection, and dermatologic conditions. Proctalgia fugax results from levator spasm and may present without any other anorectal findings. Physical examination is critical in evaluating patients with anorectal pain. If a patient is too tender to examine in the office, an examination under anesthesia is necessary. MRI or other imaging studies may be helpful in select cases where the etiology of pain is elusive.

LOWER GASTROINTESTINAL BLEEDING

The first goal in evaluating and treating a patient with GI hemorrhage is adequate resuscitation. The principles of ensuring a patent airway, supporting ventilation, and optimizing hemodynamic parameters apply and coagulopathy and/or thrombocytopenia should be corrected. The second goal is to identify the source of hemorrhage. Because the most common source of GI hemorrhage is esophageal, gastric, or duodenal, nasogastric aspiration should always be performed; return of bile suggests that the source of bleeding is distal to the ligament of Treitz. If aspiration reveals blood or nonbile secretions, or if symptoms suggest an upper intestinal source, esophagogastroduodenoscopy is performed. Anoscopy and/or limited proctoscopy can identify hemorrhoidal bleeding. A technetium-99–tagged red blood cell scan is extremely sensitive and is able to detect as little as 0.1 mL/h of bleeding; however, localization is imprecise. If the technetium-99–tagged red blood cell scan is positive, angiography can then be used to localize bleeding. Infusion of vasopressin or angioembolization may be therapeutic. Alternatively, a catheter can be left in the bleeding vessel to allow localization at the time of laparotomy. If the patient is hemodynamically stable, a rapid bowel preparation (over 4 to 6 hours) can be performed to allow colonoscopy. Colonoscopy may identify the cause of the bleeding, and cautery or injection of epinephrine into the bleeding site may be used to control hemorrhage. Colectomy may be required if bleeding persists despite these interventions. Intraoperative colonoscopy and/or enteroscopy may assist in localizing bleeding. If colectomy is required, a segmental resection is preferred if the bleeding source can be localized. "Blind" subtotal colectomy may very rarely be required in a patient who is hemodynamically unstable with ongoing colonic hemorrhage of an unknown source. In this setting, it is crucial to irrigate the rectum and examine the mucosa by proctoscopy to ensure that the source of bleeding is not distal to the resection margin (Fig. 29-7).

Occult blood loss from the GI tract may manifest as iron-deficiency anemia or may be detected with FOBT. Because colon neoplasms bleed intermittently and rarely present with rapid hemorrhage, the presence of occult fecal blood should always prompt a colonoscopy. Unexplained iron-deficiency anemia is also an indication for colonoscopy.

Hematochezia commonly is caused by hemorrhoids or fissure. Sharp, knife-like pain and bright-red rectal bleeding with bowel movements suggest the diagnosis of fissure. Painless, bright-red rectal bleeding with bowel movements often is secondary to a friable internal hemorrhoid that is easily detected by anoscopy. In the absence of a painful, obvious fissure, any patient with rectal bleeding should undergo a careful digital rectal examination, anoscopy, and proctosigmoidoscopy. Failure to diagnose a source in the distal anorectum should prompt colonoscopy.

CONSTIPATION AND OBSTRUCTED DEFECATION

Constipation is an extremely common complaint, affecting more than 4 million people in the United States. Despite the prevalence of this problem, there is lack of agreement about an appropriate definition of constipation. Patients may describe infrequent bowel movements, hard stools, or excessive straining. A careful history of these symptoms often clarifies the nature of the problem.

Constipation has a myriad of causes. Underlying metabolic, pharmacologic, endocrine, psychological, and neurologic causes often contribute to the problem. A stricture or mass lesion should be excluded by colonoscopy or barium enema. After these causes have been excluded, evaluation focuses on differentiating *slow-transit constipation* from *outlet obstruction*. Transit studies, in which radiopaque markers are swallowed and then followed radiographically, are useful for diagnosing slow-transit constipation. Anorectal manometry and EMG can detect nonrelaxation of the puborectalis, which contributes to outlet obstruction. The absence of an anorectal inhibitory reflex suggests Hirschsprung's disease and may prompt a rectal mucosal biopsy. Defecography can identify rectal prolapse, intussusception, rectocele, or enterocele.

Medical management is the mainstay of therapy for constipation and includes fiber, increased fluid intake, and laxatives. Outlet obstruction from nonrelaxation of the puborectalis often responds to biofeedback.¹⁰ Surgery to correct rectocele and rectal prolapse has a variable effect on symptoms of constipation, but can be successful in selected patients. Subtotal colectomy is considered only for patients with severe slow-transit constipation (colonic inertia) refractory to maximal medical interventions. Although this operation almost always increases bowel movement frequency, complaints of diarrhea, incontinence, and abdominal pain are not infrequent, and patients should be carefully selected.¹¹

DIARRHEA AND IRRITABLE BOWEL SYNDROME

Diarrhea is also a common complaint and is usually a self-limited symptom of infectious gastroenteritis. If diarrhea is chronic or is accompanied by bleeding or abdominal pain, further investigation is warranted. Bloody diarrhea and pain are characteristic of colitis; etiology can be an infection (invasive *E. coli*, *Shigella*, *Salmonella*, *Campylobacter*, *Entamoeba histolytica*, or *C. difficile*), inflammatory bowel disease (ulcerative colitis or Crohn's colitis), or ischemia. Stool wet-mount and culture often can diagnose infection. Sigmoidoscopy or colonoscopy can be helpful in diagnosing inflammatory bowel disease or ischemia. However, if the patient has abdominal tenderness, particularly with peritoneal signs, or any other evidence of perforation, endoscopy is contraindicated.

Chronic diarrhea may present a more difficult diagnostic dilemma. Chronic ulcerative colitis, Crohn's colitis, infection, malabsorption, and short-gut syndrome can cause chronic diarrhea. Rarely, carcinoid syndrome and islet cell tumors (vasoactive intestinal peptide-secreting tumor, somatostatinoma, gastrinoma) present with this symptom. Large villous lesions may cause secretory diarrhea. Collagenous colitis can cause diarrhea without any obvious mucosal abnormality. Along with stool cultures, tests for malabsorption, and metabolic investigations, colonoscopy can be invaluable in differentiating these causes. Biopsies should be taken even if the colonic mucosa appears grossly normal.

Irritable bowel syndrome is a particularly troubling constellation of symptoms consisting of crampy abdominal pain, bloating, constipation, and urgent diarrhea. Work-up reveals no underlying anatomic or physiologic abnormality. Once other disorders have been excluded, dietary restrictions and avoidance of caffeine, alcohol, and tobacco may help to alleviate symptoms. Antispasmodics and bulking agents may be helpful.

INCONTINENCE

The incidence of fecal incontinence has been estimated to occur in 10 to 13 individuals per 1000 people older than age 65 years. Incontinence ranges in severity from occasional leakage of gas and liquid stool to daily loss of solid stool. The underlying cause of incontinence is often multifactorial and diarrhea often is contributory. In general, causes of incontinence can be classified as *neurogenic* or *anatomic*. Neurogenic causes include diseases of the central nervous system and spinal cord along with pudendal nerve injury. Anatomic causes include congenital abnormalities, procidentia, overflow incontinence secondary to impaction or neoplasm, and trauma. The most common traumatic cause of incontinence is injury to the anal sphincter during vaginal delivery. Other causes include anorectal surgery, impalement, and pelvic fracture.

After a thorough medical evaluation to detect underlying conditions that might contribute to incontinence, evaluation focuses on assessment of the anal sphincter and pudendal nerves. Pudendal nerve terminal motor latency testing may detect neuropathy. Anal manometry can detect low resting and squeeze pressures.

Defecography can detect rectal prolapse. Endoanal ultrasound is invaluable in diagnosing sphincter defects (Fig. 29-8).

Therapy depends upon the underlying abnormality. Diarrhea should be treated medically (fiber, antidiarrheal agents). Even in the absence of frank diarrhea, the addition of dietary fiber may improve continence. Some patients may respond to biofeedback. Many patients with a sphincter defect are candidates for an overlapping sphincteroplasty. Innovative technologies that focus on stimulating the sacral nerve roots via an implantable nerve stimulator or replacing a damaged or poorly functioning sphincter with an artificial sphincter are proving useful in patients who fail other interventions.^{12,13} The delivery of radiofrequency energy to the anal canal (the Secca procedure) also has been proposed.¹⁴ Finally, a stoma can provide relief for severely incontinent patients who have failed or are not candidates for other interventions.¹⁵

GENERAL SURGICAL CONSIDERATIONS

Colorectal resections are performed for a wide variety of conditions, including neoplasms (benign and malignant), inflammatory bowel diseases, and other benign conditions. Although the indication and urgency for surgery will alter some of the technical details, the operative principles of colorectal resections, anastomoses, and use of ostomies are well established. These principles and general considerations for anesthesia and other operative preliminaries are outlined here.

Resections

The mesenteric clearance technique dictates the extent of colonic resection and is determined by the nature of the primary pathology (malignant or benign), the

intent of the resection (curative or palliative), the precise location(s) of the primary pathology, and the condition of the mesentery (thin and soft or thickened and indurated). In general, a proximal mesenteric ligation will eliminate the blood supply to a greater length of colon and require a more extensive "colectomy." Curative resection of a colorectal cancer usually is accomplished best by performing a proximal mesenteric vessel ligation and radical mesenteric clearance of the lymphatic drainage basin of the tumor site with concomitant resection of the overlying omentum (Fig. 29-9). Resection of a benign process does not require wide mesenteric resection and the omentum can be preserved, if desired.

EMERGENCY RESECTION

Emergency resection may be required because of obstruction, perforation, or hemorrhage. In this setting, the bowel is almost always unprepared and the patient may be unstable. The surgical principles described above in Resections apply and an attempt should be made to resect the involved segment along with its lymphovascular supply. If the resection involves the right colon or proximal transverse colon (right or extended right colectomy), a primary ileocolonic anastomosis usually can be performed safely as long as the remaining bowel appears healthy and the patient is stable. For left-sided tumors, the traditional approach has involved resection of the involved bowel and end colostomy, with or without a mucus fistula. However, there is an increasing body of data to suggest that a primary anastomosis without a bowel preparation or with an on-table lavage, with or without a diverting ileostomy, may be equally safe in this setting. If the proximal colon looks unhealthy (vascular compromise, serosal tears, perforation), a subtotal colectomy can be performed with a small bowel to rectosigmoid anastomosis. Resection and diversion (ileostomy or colostomy) remains safe and appropriate if the bowel looks compromised or if the patient is unstable, malnourished, or immunosuppressed.

MINIMALLY INVASIVE TECHNIQUES OF RESECTION

With advances in minimally invasive technology, many procedures that previously have required laparotomy can now be performed *laparoscopically* or *with hand-assisted laparoscopy*. Potential advantages of laparoscopy include improved cosmetic result, decreased postoperative pain, and earlier return of bowel function. Moreover, some experimental data suggest that minimally invasive operations have less immunosuppressive impact on the patient and thus might improve postoperative outcome and even long-term survival. To date, most studies have demonstrated equivalence between laparoscopic and open resection in terms of extent of resection. However, laparoscopic colon resections are technically demanding and consistently require longer operative time than do open procedures. Return of bowel function and length of hospital stay are highly variable. Long-term outcome has yet to be determined; however, short-term quality of life appears to be improved by laparoscopy.¹⁶ As training in minimally invasive techniques improves, laparoscopic colon resection increasingly is gaining popularity.

The most recent advances in minimally invasive surgery involves use of robotics and telemanipulation in which the surgeon operates from a console remote from the patient. Robotic colectomy has been performed and appears to be technically feasible.¹⁷ However, to date there has been no demonstrated advantage for robotic resection over laparoscopic resection.

COLECTOMY

A variety of terms are used to describe different types of colectomy (Fig. 29-10).

Fig. 29-10.

Ileocolic Resection

An ileocolic resection describes a limited resection of the terminal ileum, cecum, and appendix. It is used to remove disease involving these segments of the intestine

(e.g., ileocecal Crohn's disease) and benign lesions or incurable cancers arising in the terminal ileum, cecum, and, occasionally, the appendix. If curable malignancy is suspected, more radical resections, such as a right hemicolectomy, generally are indicated. The ileocolic vessels are ligated and divided. A variable length of small intestine may be resected, depending upon the disease process. A primary anastomosis is created between the distal small bowel and the ascending colon. It is technically difficult to perform an anastomosis at or just proximal to the ileocecal valve; therefore, if the most distal ileum needs to be resected, the cecum generally also is removed.

Right Colectomy

A right colectomy is used to remove lesions or disease in the right colon and is oncologically the most appropriate operation for curative intent resection of proximal colon carcinoma. The ileocolic vessels, right colic vessels, and right branches of the middle colic vessels are ligated and divided. Approximately 10 cm of terminal ileum usually are included in the resection. A primary ileal-transverse colon anastomosis is almost always possible.

Extended Right Colectomy

An extended right colectomy may be used for curative intent resection of lesions located at the hepatic flexure or proximal transverse colon. A standard right colectomy is extended to include ligation of the middle colic vessels at their base. The right colon and proximal transverse colon are resected, and a primary anastomosis is created between the distal ileum and distal transverse colon. Such an anastomosis relies on the marginal artery of Drummond. If the blood supply is questionable, the resection is extended to include the splenic flexure and the anastomosis of ileum is to the descending colon.

Transverse Colectomy

Lesions in the mid and distal transverse colon may be resected by ligating the middle colic vessels and resecting the transverse colon, followed by a colocolonic anastomosis. However, an extended right colectomy with an anastomosis between the terminal ileum and descending colon may be a safer anastomosis with an equivalent functional result.

Left Colectomy

For lesions or disease states confined to the distal transverse colon, splenic flexure, or descending colon, a left colectomy is performed. The left branches of the middle colic vessels, the left colic vessels, and the first branches of the sigmoid vessels are ligated. A colocolonic anastomosis usually can be performed.

Extended Left Colectomy

An extended left colectomy is an option for removing lesions in the distal transverse colon. In this operation, the left colectomy is extended proximally to include the right branches of the middle colic vessels.

Sigmoid Colectomy

Lesions in the sigmoid colon require ligation and division of the sigmoid branches of the inferior mesenteric artery. In general, the entire sigmoid colon should be resected to the level of the peritoneal reflection and an anastomosis created between the descending colon and upper rectum. Full mobilization of the splenic flexure often is required to create a tension-free anastomosis.

Total and Subtotal Colectomy

Total or subtotal colectomy occasionally is required for patients with fulminant colitis, attenuated FAP (AFAP), or synchronous colon carcinomas. In this procedure, the ileocolic vessels, right colic vessels, middle colic vessels, and left colic vessels are ligated and divided. The superior rectal vessels are preserved. If it is desired to preserve the sigmoid, the distal sigmoid vessels are left intact and an anastomosis is created between the ileum and distal sigmoid colon (subtotal colectomy with ileosigmoid anastomosis). If the sigmoid is to be resected, the sigmoidal vessels are ligated and divided, and the ileum is anastomosed to the upper rectum (total abdominal colectomy with ileorectal anastomosis). If an anastomosis is contraindicated, an end-ileostomy is created and the remaining sigmoid or rectum is managed either as a mucus fistula or a Hartmann pouch.

PROCTOCOLECTOMY

Total Proctocolectomy

In this procedure, the entire colon, rectum, and anus are removed and the ileum is brought to the skin as a Brooke ileostomy.

Restorative Proctocolectomy (Ileal Pouch Anal Anastomosis)

The entire colon and rectum are resected, but the anal sphincter muscles and a variable portion of the distal anal canal are preserved. Bowel continuity is restored by anastomosis of an ileal reservoir to the anal canal. The original technique included a transanal mucosectomy and handsewn ileoanal anastomosis. Proponents of this technique argue that mucosectomy guarantees removal of all of the diseased mucosa, including the anal transition zone, and therefore decreases the risk of ongoing disease, dysplasia, and carcinoma.¹⁸ Opponents cite the increased risk of incontinence after mucosectomy and argue that even meticulous technique invariably leaves behind mucosal "islands" that are subsequently hidden under the anastomosis. Moreover, the "double-staple" technique using the circular stapling devices is considerably simpler than mucosectomy and a handsewn anastomosis (Fig. 29-11).¹⁹ Regardless of the anastomotic technique, many surgeons recommend that patients undergo annual surveillance of the anastomosis and/or anal transition zone by digital rectal exam and anoscopy or proctoscopy.

After a total colectomy and resection of the rectum (A), the anal canal with a short cuff of transitional mucosa and sphincter muscles is preserved (B). An ileal J-pouch has been constructed and is anastomosed to the anal canal using a double-staple technique (C).

[Reproduced with permission from Bell RH, Rikkers LF, Mulholland M (eds): *Digestive Tract Surgery: A Text and Atlas*. Philadelphia: Lippincott Williams & Wilkins, 1996, p 1527.]

The neorectum is made by anastomosis of the terminal ileum aligned in a "J," "S," or "W" configuration. Because functional outcomes are similar and because the J-pouch is the simplest to construct, it has become the most used configuration. With increasing experience in laparoscopic colectomy, some centers have begun performing total proctocolectomy with ileal pouch anal reconstruction using minimally invasive surgical techniques. Most surgeons perform a proximal ileostomy to divert succus from the newly created pouch in an attempt to minimize the consequences of leak and sepsis, especially in patients who are malnourished or immunosuppressed (Fig. 29-12). The ileostomy is then closed 6 to 12 weeks later, after a contrast study confirms the integrity of the pouch. In low-risk patients, however, there are reports of successful creation of an ileoanal pouch without diverting stoma.²⁰

ANTERIOR RESECTION

Anterior resection is the general term used to describe resection of the rectum from an abdominal approach to the pelvis with no need for a perineal, sacral, or other incision. Three types of anterior resection have been described.

High Anterior Resection

A high anterior resection is the term used to describe resection of the distal sigmoid colon and upper rectum and is the appropriate operation for benign lesions and disease at the rectosigmoid junction such as diverticulitis. The upper rectum is mobilized but the pelvic peritoneum is not divided and the rectum is not mobilized fully from the concavity of the sacrum. The inferior mesenteric artery is ligated at its base and the inferior mesenteric vein, which follows a different course than the artery, is ligated separately. A primary anastomosis (usually end-to-end) between the colon and rectal stump with a short cuff of peritoneum surrounding its anterior two thirds generally can be performed.

Low Anterior Resection

A *low anterior resection* is used to remove lesions in the upper and midrectum. The rectosigmoid is mobilized, the pelvic peritoneum is opened, and the inferior mesenteric artery is ligated and divided either at its origin from the aorta or just distal to the takeoff of the left colic artery. The rectum is mobilized from the sacrum by sharp dissection under direct view within the endopelvic fascial plane. The dissection may be performed distally to the anorectal ring, extending posteriorly through the rectosacral fascia to the coccyx and anteriorly through Denonvilliers' fascia to the vagina in women or the seminal vesicles and prostate in men. The rectum and accompanying mesorectum are divided at the appropriate level, depending upon the nature of the lesion. A low rectal anastomosis usually requires mobilization of the splenic flexure and ligation and division of the inferior mesenteric vein just inferior to the pancreas. Circular stapling devices have greatly facilitated the conduct and improved the safety of the colon to extraperitoneal rectal anastomosis.

Extended Low Anterior Resection

An *extended low anterior resection* is necessary to remove lesions located in the distal rectum, but several centimeters above the sphincter. The rectum is fully mobilized to the level of the levator ani muscle just as for a low anterior resection, but the anterior dissection is extended along the rectovaginal septum in women and distal to the seminal vesicles and prostate in men. After resection at this level, a *coloanal anastomosis* can be created using one of a variety of techniques described below in Anastomoses. Because the risk of an anastomotic leak and subsequent sepsis is higher when an anastomosis is created in the distal rectum or anal canal, creation of a temporary ileostomy should be considered in this setting.

Although an anastomosis may be technically feasible very low in the rectum or anal canal, it is important to note that postoperative function may be poor. Because the descending colon lacks the distensibility of the rectum, the reservoir function may be compromised. Pelvic radiation, prior anorectal surgery, and obstetric trauma may cause unsuspected sphincter damage. Finally, a very low anastomosis may involve and compromise the upper sphincter. Creation of a *colon J-pouch* improves

function during the first postoperative year.²¹ A history of sphincter damage or any degree of incontinence is a relative contraindication for a coloanal anastomosis. In such patients, an end colostomy may be a more satisfactory option.

HARTMANN'S PROCEDURE AND MUCUS FISTULA

Hartmann's procedure refers to a colon or rectal resection without an anastomosis in which a colostomy or ileostomy is created and the distal colon or rectum is left as a blind pouch. The term typically is used when the left or sigmoid colon is resected and the closed off rectum is left in the pelvis. If the distal colon is long enough to reach the abdominal wall, a *mucus fistula* can be created by opening the defunctioned bowel and suturing it to the skin.

ABDOMINOPERINEAL RESECTION

An abdominoperineal resection (APR) involves removal of the entire rectum, anal canal, and anus with construction of a permanent colostomy from the descending or sigmoid colon. The abdominal-pelvic portion of this operation proceeds in the same fashion as described for an extended low anterior resection. The perineal dissection can be performed with the patient in lithotomy position (often by a second surgeon) or in the prone position after closure of the abdomen and creation of the colostomy. For cancer, the perineal dissection is designed to excise the anal canal with a wide circumferential margin. Primary wound closure usually is successful but the large perineal defect, especially if radiation has been used, may require a vascularized flap closure in some patients. For benign disease, proctectomy may be performed using an *intersphincteric dissection* between the internal and external sphincters. This approach minimizes the perineal wound making it easier to close because the levator muscle remains intact.

Anastomoses

Anastomoses may be created between two segments of bowel in a multitude of ways. The geometry of the anastomosis may be *end-to-end*, *end-to-side*, *side-to-end*, or *side-to-side*. The anastomotic technique may be *handsewn* (*single* or *double layer*) or *stapled* (Fig. 29-13). The submucosal layer of the intestine provides the strength of the bowel wall and must be incorporated in the anastomosis to assure healing. The choice of anastomosis depends upon the operative anatomy and surgeon preference. Although many surgeons advocate one method over another, none has been proven to be superior. Accurate approximation of two well-vascularized, healthy limbs of bowel without tension in a normotensive, well-nourished patient almost always results in a good outcome. Anastomoses at highest risk of leak or stricture are those that are in the distal rectal or anal canal, involve irradiated or diseased intestine, or are performed in malnourished, ill patients.

ANASTOMOTIC CONFIGURATION

End-to-End

An end-to-end anastomosis can be performed when two segments of bowel are roughly the same caliber. This technique most often is used in rectal resections, but may be used for colocolostomy or small bowel anastomoses.

End-to-Side

An end-to-side configuration is useful when one limb of bowel is larger than the other. This most commonly occurs in the setting of chronic obstruction.

Side-to-End

A side-to-end anastomosis is used when the proximal bowel is of smaller caliber than the distal bowel. Ileorectal anastomoses commonly make use of this configuration. A side-to-end anastomosis may have a less tenuous blood supply than an end-to-end anastomosis.

Side-to-Side

A side-to-side anastomosis allows a large, well-vascularized connection to be created on the antimesenteric side of two segments of intestine. This technique is commonly used in ileocolic and small bowel anastomoses.

ANASTOMOTIC TECHNIQUE

Hand-Sutured Technique

Any of the configurations described above under Anastomotic Configuration may be created using a hand-sutured or stapled technique. Hand-sutured anastomoses may be *single layer*, using either running or interrupted stitches, or *double layer*. A double-layer anastomosis usually consists of a continuous inner layer and an interrupted outer layer. Suture material may be either permanent or absorbable. After distal rectal or anal canal resection, a transanal, handsewn coloanal anastomosis may be necessary to restore bowel continuity. This can be done in conjunction with an anal canal mucosectomy to allow the anastomosis to be at the dentate line.

Stapled Techniques

Linear cutter stapling devices are used to divide the bowel and to create side-to-side anastomoses. The anastomosis may be reinforced with interrupted sutures if desired. Circular stapling devices can create end-to-end, end-to-side, or side-to-end anastomoses. These instruments are particularly useful for creating low rectal or anal canal anastomoses where the anatomy of the pelvis makes a handsewn anastomosis technically difficult or impossible.

Following resection of the colorectum, a stapled end-to-end colorectal, coloanal canal, or ileal pouch anal canal anastomosis may be created by one of two techniques. With the open purse-string technique, the distal rectal stump pursestring is placed by hand and the assembled circular stapler is inserted into the anus and guided up to the rectal pursestring. The stapler is opened and the distal pursestring is tied. A pursestring is placed in the distal end of the proximal colon; the proximal colon is placed over the anvil and the pursestring tightened. The stapler is closed and fired (Fig. 29-14). With the *alternative double-staple technique*, the distal rectum or anal canal is closed with a transverse staple line. The circular stapler is inserted through the anus without its anvil until the cartridge effaces the transverse staple line. The stapler is opened, causing the trocar to perforate through the rectal stump adjacent to the transverse staple line. A pursestring is placed in the distal end of the proximal colon or the end of the ileal pouch. The stapler anvil is inserted into the proximal colon or ileal pouch and the pursestring is tightened around the anvil. The anvil is mated to the trocar and the stapler closed and fired (see Fig. 29-11). After firing and removing the stapler, the resulting anastomotic rings should be inspected to ensure that they are intact. A gap in an anastomotic ring suggests that the circular staple line is incomplete and the anastomosis should be reinforced with suture circumferentially, if technically feasible. A temporary proximal ileostomy may be indicated as well.

Technique of end-to-end colorectal anastomosis using a circular stapler. **A.** The patient is in modified lithotomy position. **B.** After resection of the rectosigmoid and placement of purse-string sutures proximally and distally, the stapler is inserted into the anal canal and opened. **C.** Rectal purse-string suture is tied to secure the rectal stump to the rod of the stapler, and the colonic pursestring is tied to secure the colon to the anvil of the stapler. **D.** The stapler is closed and fired. **E.** The stapler is removed, leaving a circular stapled end-to-end anastomosis.

Ostomies

Depending upon the clinical situation, a stoma may be temporary or permanent. It may be end-on or a loop. However, regardless of the indication for a stoma, placement and construction are crucial for function. A stoma should be located within the rectus muscle to minimize the risk of a postoperative parastomal hernia. It also should be placed where the patient can see it and easily manipulate the appliance. The surrounding abdominal soft tissue should be as flat as possible to ensure a tight seal and prevent leakage. Preoperative evaluation by an enterostomal therapy (ET) nurse to identify the ideal stoma site and to counsel and educate the patient is invaluable (Fig. 29-15).

Fig. 29-15.

Marking of an ideal site for ileostomy.

[Reproduced with permission from Bell RH, Rikkers LF, Mulholland M (eds): *Digestive Tract Surgery: A Text and Atlas*. Philadelphia: Lippincott Williams & Wilkins, 1996, p 1273.]

For all stomas, a circular skin incision is created and the subcutaneous tissue dissected to the level of the anterior rectus sheath. The anterior rectus sheath is incised in a cruciate fashion, the muscle fibers separated bluntly, and the posterior sheath identified and incised. The size of the defect depends upon the size of the bowel used to create the stoma, but should be as small as possible without compromising the intestinal blood supply (usually the width of two to three fingers). The bowel is then brought through the defect and secured. The abdominal incision is usually closed and dressed before maturing the stoma to avoid contaminating the wound. To make appliance use easier, a protruding nipple is fashioned by everting the bowel. Three or four interrupted absorbable sutures are placed through the edge of the bowel, then through the serosa, approximately 2 cm proximal to the edge, and then through the dermis (Brooke technique). After the stoma is everted, the mucocutaneous junction is sutured circumferentially with interrupted absorbable suture (Fig. 29-16).

ILEOSTOMY

Temporary Ileostomy

A temporary ileostomy often is used to "protect" an anastomosis that is at risk for leakage (low in the rectum, in an irradiated field, in an immunocompromised or malnourished patient, and in some emergency operations). In this setting, the stoma often is constructed as a *loop ileostomy* (see Fig. 29-12). A segment of distal ileum is brought through the defect in the abdominal wall as a loop. An enterotomy is created and the stoma matured as described above in Ostomies. The loop may be secured with or without an underlying rod. A *divided loop* may also be created by firing a linear cutter stapler across the distal limb of the loop flush with the skin followed by maturation of the proximal limb of the loop. This technique prevents incomplete diversion that occasionally occurs with a loop ileostomy.

The advantage of a loop or divided loop ileostomy is that subsequent closure often can be accomplished without a formal laparotomy. An elliptical incision is created around the stoma and the bowel gently dissected free of the subcutaneous tissues and fascia. A handsewn or stapled anastomosis can then be created and the intestine returned to the peritoneal cavity. This avoids a long laparotomy incision and generally is well tolerated. Timing of ileostomy closure should take into account anastomotic healing as well as the patient's overall condition. A flexible endoscopy exam and a contrast enema (Gastrografin) are recommended before closure to ensure that the anastomosis has not leaked and is patent. A patient's nutritional status should be optimized. In cancer patients receiving adjuvant chemotherapy, ileostomy closure should be delayed until chemotherapy is completed.

Permanent Ileostomy

A permanent ileostomy sometimes is required after total proctocolectomy or in patients with obstruction. An *end ileostomy* is the preferred configuration for a permanent ileostomy because a symmetric protruding nipple can be fashioned more easily than with a loop ileostomy (see Fig. 29-16). The end of the small intestine is brought through the abdominal wall defect and matured. Stitches often are used to secure the bowel to the posterior fascia.

Complications of Ileostomy

Stoma necrosis may occur in the early postoperative period and usually is caused by skeletonizing the distal small bowel and/or creating an overly tight fascial defect. Limited mucosal necrosis above the fascia may be treated expectantly, but necrosis below the level of the fascia requires surgical revision. Stoma retraction may occur early or late, and may be exacerbated by obesity. Local revision may be necessary. The creation of an ileostomy bypasses the fluid absorbing capability of the colon, and dehydration with fluid and electrolyte abnormalities is not uncommon. Ideally, ileostomy output should be maintained at less than 1500 mL/d to avoid this problem. Bulk agents and opioids (Lomotil, Imodium, tincture of opium) are useful. The somatostatin analogue, Octreotide, has been used with variable success in this setting. Skin irritation also can occur, especially if the stoma appliance fits poorly. Skin protecting agents and custom pouches can help to solve this problem. Obstruction may occur intra-abdominally or at the site where the stoma exits the fascia. Parastomal hernia is less common after an ileostomy than after a colostomy,

but can cause poor appliance fitting, pain, obstruction, or strangulation. In general, symptomatic parastomal hernias should be repaired. Repair usually requires re-siting the stoma to the contralateral side of the abdomen. Prolapse is a rare, late complication and often is associated with a parastomal hernia. Valve slippage resulting in either leakage or obstruction is a common complication of a continent Kock pouch ileostomy.

COLOSTOMY

Most colostomies are created as *end colostomies* rather than *loop colostomies* (Fig. 29-17). The bulkiness of the colon makes a loop colostomy awkward for an appliance, and prolapse is more likely with this configuration. Most colostomies are created on the left side of the colon. An abdominal wall defect is created and the end of the colon mobilized through it. Because a protruding stoma is considerably easier to pouch, colostomies also should be matured in a Brooke fashion. The distal bowel may be brought through the abdominal wall as a *mucus fistula* or left intra-abdominally as a *Hartmann's pouch*. Tacking the distal end of the colon to the abdominal wall or tagging it with permanent suture can make identification of the stump easier if the colostomy is closed at a later date. Closure of a colostomy usually requires laparotomy. The stoma is dissected free of the abdominal wall and the distal bowel identified. An end-to-end anastomosis is then created.

Intraperitoneal end colostomy.

Complications of Colostomy

Colostomy necrosis may occur in the early postoperative period and results from an impaired vascular supply (skeletonization of the distal colon or a tight fascial defect). Like ileostomy necrosis, limited suprafascial necrosis may be followed expectantly, but necrosis below the fascia requires surgery. *Retraction* may also occur, but is less problematic with a colostomy than with an ileostomy because the stool is less irritating to the skin than *succus entericus*. *Obstruction* is unusual, but may also occur. *Parastomal hernia* is the most common late complication of a colostomy and requires repair if it is symptomatic. *Prolapse* occurs rarely. Dehydration is rare after colostomy and skin irritation is less common than with ileostomy.

Functional Results

Function following segmental colonic resection and primary anastomosis generally is excellent. A small percentage of patients following subtotal or total colectomy and ileosigmoid or ileorectal anastomosis may experience diarrhea and bowel frequency. This is especially true if the patient is elderly, if significant length of small bowel has been resected, and if residual proctocolitis is poorly controlled. In general, the more distal the anastomosis, the more the risk of troublesome diarrhea and frequency.

Function following anterior resection is highly dependent on the level of anastomosis, the use of pre- or postoperative pelvic radiation, and underlying sphincter function. Following low anterior or extended low anterior resection, some surgeons prefer to construct a short (8 to 10 cm) colon-J-pouch to anastomose to the distal rectum or anal canal. The reservoir lessens urgency, frequency, and incontinence, but some patients have difficulty initiating defecation after construction of a colon-J-pouch.²¹

The physical and psychological problems associated with a permanent Brooke ileostomy led to development of the continent Kock pouch ileostomy. Unfortunately, complications, especially complications related to valve slippage, are common. Despite variations of technique designed to improve the function of the continent ileostomy, most surgeons have abandoned this operation and instead perform restorative proctocolectomy with ileal pouch anal anastomosis.

Although ileal pouch anal reconstruction is anatomically appealing, functional outcome is far from perfect.^{22,23} Patients should be counseled to expect eight to 10 bowel movements per day. Up to 50% have some degree of nocturnal incontinence. Pouchitis occurs in nearly 50% of patients, and small bowel obstruction is not uncommon. Other less common complications include difficulties with pouch evacuation, pouch–anal and/or pouch–vaginal fistula, and anal stricture. Pouch failure rate averages 5 to 10%. Patients who are subsequently diagnosed with Crohn's disease have a considerably higher pouch failure rate (approximately 50%), while patients with indeterminate colitis have an intermediate pouch failure rate (15 to 20%). Despite these drawbacks, the vast majority of patients are satisfied and prefer ileal pouch–anal reconstruction to permanent ileostomy.

Pouchitis is an inflammatory condition that affects both ileoanal pouches and continent ileostomy reservoirs. Incidence of pouchitis ranges from 30 to 55%. Symptoms include increased diarrhea, hematochezia, abdominal pain, fever, and malaise. Diagnosis is made endoscopically with biopsies. Differential diagnosis includes infection and undiagnosed Crohn's disease. The etiology of pouchitis is unknown. Some believe pouchitis results from fecal stasis within the pouch but emptying studies are not confirmatory. Antibiotics (metronidazole ± ciprofloxacin) are the mainstays of therapy and most patients will respond rapidly to either oral preparations or enemas.^{24,25} Some patients develop chronic pouchitis that necessitates ongoing suppressive antibiotic therapy. Salicylate and corticosteroid enemas also have been used with some success. Reintroduction of normal flora by ingestion of *probiotics* has been suggested as a possible treatment in refractory cases. Occasionally, pouch excision is necessary to control the symptoms of chronic pouchitis.

Anesthesia Considerations

LOCAL ANESTHESIA

Many anorectal procedures can be performed with local anesthetic alone. IV sedation often is provided to calm the patient. Injection of 0.5% lidocaine (short acting) and 0.25% bupivacaine (long acting) into the perianal skin, sphincter, and area around the pudendal nerves usually provides an adequate block. The addition of dilute epinephrine decreases bleeding and prolongs the anesthetic effect.

REGIONAL ANESTHESIA

Epidural, spinal, and caudal anesthetics can be used for anorectal procedures and transanal resections. In patients with severe medical comorbidity, regional anesthesia occasionally may be used for laparotomy and colectomy. Postoperative epidural anesthesia provides excellent pain relief and improves pulmonary function.

GENERAL ANESTHESIA

General anesthesia is required for the vast majority of intra-abdominal procedures. Patients should undergo a thorough preoperative cardiovascular evaluation. In patients with significant comorbid disease, preadmission and an anesthesia consultation may be appropriate.

POSITIONING

Most abdominal colectomies can be performed in the supine position. Anterior and APRs require lithotomy positioning. Adequate padding should be provided for the patient's sacrum and care should be taken to avoid stirrup pressure on the peroneal nerves.

Anorectal procedures may be performed in lithotomy but the prone jackknife position is preferred for most procedures, especially if the anterior quadrant needs to be seen well. Distal posterior lesions usually can be accessed from either position, but more proximal posterior lesions are better accessed in prone position.

Operative Preliminaries

BOWEL PREPARATION

The rationale for bowel preparation is that decreasing the bacterial load in the colon and rectum will decrease the incidence of postoperative infection. *Mechanical bowel preparation* uses cathartics to rid the colon of solid stool the night before surgery.²⁶ The most commonly used regimens include polyethylene glycol (PEG) solutions or sodium phosphate. PEG solutions require patients to drink a large volume and may cause bloating and nausea. Sodium phosphate solutions generally are better tolerated, but are more likely to cause fluid and electrolyte abnormalities. PEG and sodium phosphate are equally efficacious in bowel cleansing. The preparatory formulations recently have been introduced in tablet form in an attempt to improve tolerance. However, these methods of bowel cleansing require ingestion of 40 or more tablets with water over several hours. To date, this has not proven superior to the more traditional products.²⁷ *Antibiotic prophylaxis* also is recommended. The addition of oral antibiotics to the preoperative mechanical bowel preparation is thought to decrease postoperative infection by further decreasing the bacterial load of the colon. A combination of three doses of neomycin (1 g) and erythromycin base (1 g) is most commonly used. Some surgeons substitute metronidazole (500 mg) for erythromycin to avoid GI upset. Ciprofloxacin also has been used in this setting. It is important to note, however, that although the majority of surgeons use oral antibiotic prophylaxis, this practice has never been proven to decrease postoperative infectious complications.^{28,29} A broad-spectrum parenteral antibiotic(s) should be administered just before the skin incision. There is no proven benefit to using antibiotics postoperatively after an uncomplicated colectomy.

Despite widespread use of mechanical bowel preparation, the necessity of bowel cleansing before colectomy has been questioned. European surgeons in particular have advocated abandoning this practice. Several small studies suggest that a mechanical bowel preparation does not decrease the risk of postoperative wound infection or anastomotic dehiscence.^{30–32} Larger prospective trials are needed to determine whether mechanical bowel preparation before colectomy is a necessity or a source of added morbidity that can be avoided.

STOMA PLANNING

The preoperative preparation of a patient who is expected to require a stoma should include a consultation with an *enterostomal therapy* nurse. ET nurses are specially trained and credentialed by the Wound, Ostomy and Continence Nurses Society. Preoperative planning includes counseling, education, and stoma siting. Postoperatively, the ET nurse assists with local skin care and pouching. Other considerations in stoma planning include evaluation of other medical conditions that may impact a patient's ability to manage a stoma (e.g., eyesight, manual dexterity).

Preoperative stoma siting is crucial for a patient's postoperative function and quality of life. A poorly placed stoma can result in leakage and skin breakdown. Ideally, a stoma should be placed in a location that the patient can easily see and manipulate, within the rectus muscle, and below the belt line (see Fig. 29-15). Because the abdominal landmarks in a supine, anesthetized patient may be dramatically different from those in an awake, standing, or sitting patient, the stoma site should always be marked with a tattoo, skin scratch, or permanent marker preoperatively, if possible. In an emergency operation where the stoma site has not been marked, an attempt should be made to place a stoma within the rectus muscle and away from both the costal margin and iliac crest. In emergencies, placement high on the abdominal wall is preferred to a low-lying site.

URETERAL STENTS

Ureteral stents may be useful for identifying the ureters intraoperatively and are placed via cystoscopy after the induction of general anesthesia and removed at the end of the operation. Stents can be invaluable in reoperative pelvic surgery or when there is significant retroperitoneal inflammation (such as complicated diverticulitis). Lighted stents may be helpful in laparoscopic resections. Patients often have transient hematuria postoperatively but major complications are rare.

MULTIDISCIPLINARY TEAMS

Patients with complex colorectal disease often benefit from a multidisciplinary approach. Patients with pelvic floor disorders (especially incontinence) often require evaluation by both a colorectal surgeon and a urologist or urogynecologist. Preoperative evaluation of cancer patients by a medical oncologist and/or radiation oncologist is crucial for planning either neoadjuvant or adjuvant therapy. Intraoperatively, complex pelvic resections often require the involvement of not only a colorectal surgeon but also a urologist, gynecologic oncologist, neurosurgeon, and/or plastic surgeon. Radiation oncologists should be involved in the operation if brachytherapy catheters are to be placed for intracavitary radiation or if intraoperative radiation therapy is planned. Rarely, psychiatric disorders may manifest as colorectal problems (especially functional disorders and chronic pain) and involvement of a psychiatrist or psychologist may be beneficial.

INFLAMMATORY BOWEL DISEASE

General Considerations

EPIDEMIOLOGY

Inflammatory bowel disease includes *ulcerative colitis*, *Crohn's disease*, and *indeterminate colitis*. *Ulcerative colitis* occurs in eight to 15 people per 100,000 in the United States and Northern Europe. The incidence is considerably lower in Asia, Africa, and South America, and among the nonwhite population in the United States. Ulcerative colitis incidence peaks during the third decade of life and again in the seventh decade of life. The incidence of Crohn's disease is slightly lower, one to five people per 100,000 population. Crohn's disease also affects Northern European and white populations disproportionately. Crohn's disease has a similar bimodal incidence, with most cases occurring between ages 15 to 30 years and ages 55 to 60 years. In 15% of patients with inflammatory bowel disease, differentiation between ulcerative colitis and Crohn's colitis is impossible; these patients are classified as having *indeterminate colitis*.

ETIOLOGY
